MELVILLE, JAMES (1556–1614), Scottish reformer, nephew of Andrew Melville (*q.v.*), was born on July 26, 1556. He was educated at Montrose and St. Leonard's college, St. Andrews. He was one of the regents of Glasgow university, and then professor of oriental languages at St. Andrews. In 1584 he joined some of the leaders of the Scottish Presbyterian party in London for a short time. From 1586 to his death he took an active part in Church controversy. In 1589 he was moderator of the General Assembly and on several occasions represented his party in conferences with the court. Despite his antagonism to James's episcopal schemes, he appears to have won the king's respect. He answered, with his uncle, a royal summons to London in 1606 for the discussion of Church policy. Andrew Mel-

ville was sent to the Tower, and James was placed in easy detention within ten miles of Newcastle-on-Tyne. In 1613 negotiations were begun for his return to Scotland, but his health was broken, and he died at Berwick in Jan. 1614.

Melville has left ample materials for the history of his time from the Presbyterian standpoint, in (*a*) correspondence with his uncle Andrew Melville (ms. in the library of the university of Edinburgh), and (*b*) a diary (ms. in the Advocates' Library, Edinburgh). His sketch of John Knox at St. Andrews is one of his best passages.

The *Diary* was printed by the Bannatyne club in 1829, and by the Wodrow society in 1842. Large portions of it are incorporated in David Calderwood's (1575–1650) *History of the Kirk of Scotland* (first printed in 1678). For the life and times, *see* Thomas M'Crie's *Life of Andrew Melville.*

MEMBRANELLE, in some ciliate infusoria (*q.v.*) a flattened or compressed organ appearing near the mouth, and regarded as a short row of fused cilia, as shown in the plates of *Ctenophora* (*q.v.*).

MEMEL, a town of Lithuania, 91 m. by rail N.N.E. of Königsberg on the bank of the sound through which the Kurische Haff and the river Nemunas or Niemen (called Memel in its lower reaches) connect with the Baltic. Pop. 36,000, mainly German. The entrance to the harbour is protected by a lighthouse; the depth on the bar is about 20 ft., and icebreakers are needed to keep the port open between December and March. The town possesses iron foundries, shipbuilding yards, breweries, distilleries and manufactories of chemicals, soap and amber wares. The chief interest of the town, however, is its transit trade in timber, grain, other agricultural produce and fish. Its economic hinterland extends across Lithuania into Poland and Russia and much of the goods is brought down by the river.

History.—Memel was founded in 1252 by Poppo von Osterna, grand master of the Teutonic order, and was at first called New Dortmund and afterwards Memelburg. It soon acquired a considerable trade, and joined the Hanseatic League. During the 13th, 14th and 15th centuries it was repeatedly burned by its hostile neighbours, the Lithuanians and Poles. In the 17th century it remained for some time in the possession of Sweden. In 1757, and again in 1813, it was occupied by Russian troops. After the battle of Jena, King Frederick William III. retired to Memel; and here, in 1807, a treaty was concluded between England and Prussia. The poet Simon Dach was a native of Memel.

Before the World War the town of Memel, with a strip of territory east of the river, belonged to Germany, while the hinterland belonged to the Russian empire. Under the Versailles treaty (Article 99), Germany ceded all her territory east of the river to the Allied and Associated Powers and undertook to accept whatever disposal they made of it. Upon the ratification of the treaty the Allies occupied and administered the territory for three years. The conference of ambassadors did not take up the question of Memel till the autumn of 1922, and meanwhile it had been suggested that Memel might be given a status in regard to Lithuania like that which had been given to Danzig in regard to Poland. This was unacceptable to the Lithuanians, since the population of the country districts of Memel territory was Lithuanian in nationality, while the port was almost the only possible maritime outlet and inlet for Lithuania herself. Accordingly the Lithuanians seized Memel by a surprise attack on Jan. 15, 1923, and forced the French garrison to surrender and evacuate.

On Feb. 16 the conference of ambassadors proposed that Memel should be handed over to Lithuania, subject to local autonomy and to freedom of transit for Poland. Later, in Sept. 1923, the case was referred to the League of Nations. A commission of enquiry was appointed and in March 1924 presented a draft convention to the Council. This convention constituted the Memel territory as a unit within the sovereignty of Lithuania with a clearly defined measure of administrative and financial autonomy and with a governor to be appointed by the president of the Lithuanian republic. The port was defined as a port of international concern to which the provisions of the League's Barcelona transit conference apply, and was placed under a harbour board including a technical expert of neutral nationality appointed by the League. The convention was accepted and signed by all parties in May 1924.

MEMLINC, HANS (*c.* 1430–1494), Flemish painter, whose art gave lustre to Bruges in the period of its political and commercial decline. Memlinc was a skilled artist before he settled at Bruges. Hans Memlinc probably served his apprenticeship at Cologne, and later worked under Roger van der Weyden. The inventories of Margaret of Austria, made in 1524, describe a triptych of which the central panel was by Roger, the wings by "Master Hans." Another clear proof of the connection of the two masters is afforded by an altarpiece ordered for a patron of the house of Sforza. It is now in the Brussels gallery. The date of it is fixed at about 1460–62 by the apparent ages of Francesco Maria Sforza, Bianca Visconti, and their son Galeazzo, whose portraits appear upon it. The central portion of the tryptych was obviously done in the studio of Roger; the wings appear to be by Memlinc, and were probably done by him in Roger's workshop. Moreover in Memlinc's later work certain figures seem borrowed directly from pictures of Roger. Memlinc, therefore, may have stayed in Brussels working under Roger before going to Bruges. He resided at Bruges from about 1465 until his death on Aug. 11, 1494.

The earliest work, which can be dated, is the triptych in the collection of the duke of Devonshire at Chatsworth. It was painted for Sir John Donne of Kidwelly, whose portrait with that of his wife and daughter appears in the foreground as donors, kneeling before the Virgin Enthroned. On the wings are two saints. Sir John was one of the English courtiers who attended the wedding of Margaret of York with Charles the Bold which took place in Bruges in 1468. The picture was commissioned on that occasion. In the background of the left wing the artist painted himself peering behind a column. He is a man about 35 years of age and we may conclude that he was born about 1430–35. This picture is typical of Memlinc's art. His later works are painted in the same style.

The great "Last Judgment" altarpiece in St. Mary's church at Danzig is generally ascribed to Memlinc. It was ordered by Angelo Tani, the representative of the Medici in Bruges, and was finished in 1472. Destined for Florence, the ship that carried it was made prize of war by Danzig vessels in 1473. It is a picture measuring some 72 sq.ft. with upwards of 150 figures.

In 1477 he was under contract to furnish an altarpiece for the guild-chapel of the booksellers of Bruges; and this altarpiece is now preserved, under the name of the "Seven Griefs of Mary," in the gallery of Turin. The effect of the whole is chaotic. That did not prevent Peter Bultync from ordering a similar type of picture with the "Seven Joys of Mary," for presentation to the guild of the tanners in 1480. This panel is now in the Munich Pinakothek. All of Memlinc's pictures which have survived in Bruges, except one, are in the chapter house of the Hospital of St. John. He painted more than one masterpiece for his patrons of St. John. Of these the first in order of date is the great triptych of 1479. The subject of the central panel is "The Mystic Marriage of St. Catherine." On the wings are "The Martyrdom of St. John the Baptist," and "The Vision at Patmos." In the background is a view of Bruges.

In the same year he painted another triptych on a smaller scale and finely finished. An inscription on the frame informs us that it was painted for John Floreins. The central panel represents the "Adoration of the Magi," that on the right "The Nativity" and the other panel "The Presentation in the Temple." The triptych when closed shows the figures of St. John the Baptist and St. Veronica. In 1484 he painted the triptych in honour of St. Christopher in the municipal gallery at Bruges.

A beautiful diptych painted in 1487 for Martin van Nieuwenhove is now in the hospital of St. John. The left panel shows "The Virgin and the Child," the right has a portrait of the donor

with his hands clasped in prayer and an open breviary before him. This is one of Memlinc's finest portraits. The portraits of the donors on Memlinc's pictures were distinguished and lifelike. So are the groups of the family of James Floreins, father, mother and children, which fill the noble altarpiece of the Louvre. As single portraits the busts of Burgomaster Moreel and his wife in the museum of Brussels, and their daughter the "Sibyl Zambetha" (according to the added description) (1480) in the hospital at Bruges, are the finest.

Memlinc was favoured as a portraitist by Italians. The Antwerp museum has the portrait of the medallist, Niccolo Spinelli, who was engaged as a seal engraver by Charles the Bold from 1467–68. He is depicted holding a medal against a landscape background. In the Altman collection, Metropolitan Museum of Art, New York, a pair of portraits represent Thomas Portinari and his wife; in the J. P. Morgan collection is the Machiavellian "Man with a Pink," formerly in the possession of R. Kann. These four are early pictures. The portraits of a married pair of mature age, formerly at Milan, are now divided between the Berlin and the Louvre galleries. They are full of character and expression; and so is the portrait of an old man in the Altman collection, New York. Three panels of equal size, one dated 1487, are in the Uffizi and at Berlin. The last is a Madonna; the other two represent St. Benedict and a praying donor. It has been suggested that they may have been framed together. The pair in the Uffizi came from the hospital of Santa Maria Nuova in Florence. If they belong together the young donor was doubtless named Benedict, and he may be Benedetto Portinari, whose family were closely associated with Bruges and the said hospital. The portrait of a young man, probably again an Italian, in the Dun collection, has a distinct personality and a determined expression. Memlinc's Madonna pictures possess unusual charm. One of the earliest is the full length standing Virgin of 1472 in the Lischtenstein collection. The Madonna in the Radziwill collection, Berlin, is one of the finest.

The masterpiece of Memlinc's later years, a shrine containing relics of St. Ursula in the museum of the hospital of Bruges, is fairly supposed to have been ordered and finished in 1489. The delicacy of finish in its miniature figures, the variety of its landscapes and costume, the marvellous patience with which its details are given, are all matters of enjoyment to the spectator. There is a later work of the master, a large "Crucifixion," with scenes from the Passion, of 1491, in the cathedral of Lübeck. But as we near the close of Memlinc's career we observe that his practice has become larger than he can compass alone; and, as usual in such cases, the labour of disciples is substituted for his own. Moreover it is hard to distinguish between the work which may be attributed to his studio or to his followers. Memlinc's influence is felt in the work of his contemporaries and in that of the next generation.

The trustees of his will appeared before the court of wards at Bruges on Dec. 10, 1495, and we gather from records of that date and place that Memlinc left behind several children and a considerable property.

MEMMINGEN, a town of Germany, in the republic of Bavaria, on the Ach, a tributary of the Iller, 35 m. S.W. of Augsburg on the railway to Ulm-Kempten. Pop. (1925) 14,049. Memmingen, first mentioned in a document of 1010, belonged originally to the Guelf family, and later to the Hohenstaufens. In 1286 it became a free city of the empire, a position which it maintained down to 1802, when it was allotted to Bavaria. It is partly surrounded with walls, and has some old gates and houses. It contains the Gothic church of St. Martin, which contains beautifully carved choir-stalls, and a town hall dating from about 1580. Its industries include linen spinning and weaving, and the manufacture of woollen goods, soap, ropes, emery cloth and machinery. Trade is carried on in cattle, timber, cloth and wine.

MEMNON, in Greek mythology, son of Tithonus (q.v.) and Eos (Dawn), king of the Aethiopians. Although mentioned in Hesiod and the *Odyssey,* he is rather a post-Homeric hero. After the death of Hector he went to assist his uncle Priam against the Greeks. He performed prodigies of valour, but was slain by Achilles, after he had himself killed Antilochus, the son of Nestor and the friend of Achilles. His mother, Eos, removed his body from the field of battle, and it was said that Zeus, moved by her tears, bestowed immortality upon him. His mother wept for him every morning, and the early dewdrops were said to be her tears. His companions were changed into birds, called *Memnonides,* which came every year to fight and lament over his grave, which was variously located (Ovid, *Metam.,* XIII. 576–622; Pausanias x. 31). The story of Memnon was the subject of the lost *Aethiopis* of Arctinus of Miletus; the chief source from which our knowledge of him is derived is the second book of the *Posthomerica* of Quintus Smyrnaeus (itself probably an adaptation of the works of Arctinus and Lesches). As an Aethiopian, Memnon was described as black, but was noted for his beauty. The fight between Achilles and Memnon was often represented by Greek artists. Later, the story was rationalized (Diod. Sic. II. 22). In Egypt, the name of Memnon was connected with the colossal statues of Amenhotep III. near Thebes, two of which still remain. The more northerly of these was partly destroyed by an earthquake (27 B.C.) and the upper part thrown down. A curious phenomenon then occurred. Every morning, when the rays of the rising sun touched the statue, it gave forth musical sounds, like the twang of a harp-string. This was supposed to be the voice of Memnon responding to the greeting of his mother Eos. After the restoration of the statue by Septimius Severus (A.D. 170) the sounds ceased. The sound, which has been heard by modern travellers, is generally attributed to the passage of the air through the pores of the stone, chiefly due to the change of temperature at sunrise. (Juvenal XV. 5, with Mayor's note; Tacitus, *Annals,* ii. 61).

See R. Holland in Roscher's *Lexikon der mythologie,* art. "Memnon."

MEMNON OF RHODES, brother of Mentor (*q.v.*), with whom he entered the services of the rebellious satrap Artabazus of Phrygia (363). In 344 Mentor, who had deserted to the Persians again, obtained Memnon's recall and pardon. Both Mentor and he rose high in the service of the king after the conquest of Egypt; Memnon assisted Mentor in quelling revolt in Asia Minor, and succeeded him as general of the Persian troops. He owned a large territory in eastern Troas (Arrian i. 17, 8; Strabo xiii. 587). He gained some successes against Philip II. of Macedon in 336 (Diod. xvii. 6; Polyaen. v. 44, 4, 5) and commanded the Persian army against Alexander's invasion. His plan was to avoid a decisive action, to lay waste the country and retire into the interior, meanwhile organizing resistance on sea (where the Persians were far superior to the Macedonians) and carrying the war into Greece. But his advice was overridden by the Persian satraps, who forced him to fight at the Granicus. After his defeat he tried to organize the maritime war and occupied the Greek islands, but in the beginning of 333 he died (Arrian ii. 1, 1).

MEMORIAL DAY: *see* DECORATION DAY.

MEMORY. The term "Memory" denotes the mental processes whereby past experience is recalled to present consciousness. Used strictly it denotes an individual's recall of his own life story. His memory knowledge is what he can recall of events which happened to him in the past. The knowledge is *personal and is referred to the past.* It is recalled with some setting or background. "I remember the first time I rode in a motor car." "I remember posting the letter myself on Monday." All personal reminiscence is memory in this strict sense. In a looser use of the term memory denotes the recall of any knowledge which an individual has acquired through his past experience. Such knowledge is not recalled as part of the individual's life

story. It is ***not referred to his past*** and it is ***impersonal***. The knowledge has been acquired in the past and may even be about past events but it is remembered as an item of knowledge without a setting in personal experience. For example one remembers how to put up a given electric circuit but one need not recall when and how one acquired this knowledge nor recall the previous occasions on which one had set up this circuit. An individual's memory knowledge of Henry VIII.'s matrimonial adventures is knowledge about these past events, but not of the individual's own past and it is not necessarily more past for him than his knowledge of the fate of Charles I. The time order of these items of memory knowledge is determined by their place in his knowledge of English History and not by any personal reminiscences of when or how he learnt these facts.

Retentiveness.—From memory as the conscious recall of past experience must be distinguished retentiveness. Retentiveness is the basal fact of all life. All growth and development in an organism demands continuity. Each new stage of life arises out of, and continues the preceding stages. What will be is dependent upon what is, and what is rests upon what has been. By reason of its influence on the present the past is said to be retained in the present. Flaws in the leaf testify to (or retain) the bruises inflicted on the leaf bud. The stunted growth of a man testifies to the privations of childhood, the muscles of an athlete to years of training. Both the immediate and the remote past of an organism are retained in its habits, its present abilities and disabilities. What is true of bodily life is true of mental life. Ability to pick out the overtones in a chord testifies to past musical training, skill in typewriting to months of practice, dislike of cats to an episode in childhood of which there may be no remembrance. This last example will serve to bring out the difference between retentiveness and memory. The events of a life story would form no story, could have no continuity one with another, unless at every moment the past lived on into the present. But such continuity does not necessarily involve knowledge of the past. If there were memory in the strict sense of the cat episode, there would be a recognized continuity between the present dislike of cats and the episode in question. But there may be no recall of this far away episode of childhood. The individual may only know of it through the testimony of others. Although there may be no memory of this event, there is, none the less, continuity; the cat episode is retained and the present dislike of cats is evidence thereof. Memory is based on retentiveness, but is a more specialized characteristic of mental life. We may specify it thus: in retentiveness the past is continued on into the present and loses itself in making the present what it is; in memory the past is known *directly* for what it was in its own passing or *indirectly* by the contribution it has made to the sum of knowledge. All organisms show retentiveness but only the higher animals give evidence of memory. It is doubtful whether any animal other than man evinces memory in the more restricted sense, ability to recall incidents with a consciousness of their setting in the past life story. This reproduction of past experience may only be possible where there is the highly organized nervous system found in man.

Imagery.—Just as knowledge of the present physical environment and response to its demands involves the mental events named "sensations," so knowledge of the past or use of knowledge acquired in the past is bound up with events termed "images." For every variety of sensation, sight, sound, etc., there is a corresponding variety of imagery. When to-day we recall the sight of the fishing boats returning to harbour, we have visual imagery of what we saw last evening; similarly we may recall the cry of the gulls by auditory imagery. We may recall in verbal imagery the comments made when the scene was presented. The difference between sensation and imagery is not one which can be well expressed in words. Everyone knows it from his own experience. We call images "dead" as compared with actual sense data. They not only lack "liveliness" but seem fragmentary and fluctuating; now this is present, now that, and as we attempt to fixate them they are apt to die out. Imagery, again, does not stand in as close relation to movement as sense experience. A sensation produces a motor response. There is adjustment of sense organ and impulsive action. With imagery there may be some adjustment of sense organ as in the fixed look when trying to see a visual image clearly, but there is no attempt to stretch out a hand to take the imaged object nor to step aside to avoid it. Imagery is not normally accompanied by the wealth of organic sensations which form a background to sense experience of the special senses.

Conditions of Memory and Obliviscence.—Accepting retentiveness as the fundamental vital fact lying behind all memory, we may ask what are the special conditions which determine memory. They are: depth of impression and strength of association. The rationale of all memory training is based on these two conditions. To be recalled the original incident or acquirement must have made a sufficiently deep impression upon us. Physical circumstances may secure this; strength of stimulation or repeated stimulation. Important also is the physical fitness of the organism to receive impressions. Depth of impression also depends upon the individual's interest in the situation, its appeal to his emotions, its connection with some purpose he has in view. To be remembered or recalled the past experience must be suggested by the present. Suggestion depends upon continuity between the past and the present, a continuity of interest, direct or indirect. There is an association between the suggest*ing* present and the suggest*ed* past experience or acquirement. The conditions of suggestion are known as the "laws of association" (*see* ASSOCIATION OF IDEAS). If depth of impression and strength of association ensure memory, feebleness of impression and failure of association entail obliviscence or forgetting. If association links fail there can be no suggestion, and where there is no suggestion there can be no recall of past experience by the present. The breaking down of association links gives rise to a condition known as "dissociation." This may occur for a given group of ideas or for incidents connected with a given period in a man's life (*see* AMNESIA). Some psychologists attribute all failure of association to "repression." They assert that all experiences which are painful or in conflict with accepted standards of life are repressed into the unconscious and thereby cut off from the associations of conscious memory. They regard repression as the explanation of all forgetting. But this view is unwarrantably narrow. It not only overlooks natural decay which is the complement of growth in all living processes, but it confuses conditions which ought to be distinguished: the repression of an associated idea by reason of its pain value and the temporary inhibition of one line of association through interest in another. It is, surely, perverted pedantry to seek some painful association in a forgotten engagement when such obliviscence is due to the inhibition of all ideas unconnected with an absorbing occupation.

Characteristics of a Good Memory.—These may be summarized as *readiness* in forming deep impressions and strong associations, the *durability* of these and the *ease of recall*, their *faithfulness* to the originals of experience. The characteristic that renders memory serviceable in practical life is *relevancy*. In relevant recall only those associations are followed which have bearing on the purpose in hand. A rambling memory may be full and faithful but in the service of thought a controlled selective recall of important points is more fruitful.

BIBLIOGRAPHY.—M. Bergson, *Matter and Memory* (Eng. trans. 1912); J. Ward, *Heredity and Memory* (1913); Colvin, *The Learning Process* (1915); T. H. Pear, *Remembering and Forgetting* (1922); B. Edgell, *Theories of Memory* (1924).

Physiology of Memory.—The bodily structures involved in the memory process and the common order of events are as follows: (1) A stimulus affects a sense organ. (2) Nervous impulses pass from this structure to the centres in the brain. (3) Nervous connections are made by the association neurones in the brain. The function of the association neurones is similar to the connecting process in the central office of an automatic telephone system. (4) Nervous impulses pass outward from the brain and (5) cause a response in a muscle or gland. Learning or association consists in the formation of a functional connection in the central nervous system between a stimulus and a response

The important phase of memory called retention is the passive condition of the central nervous system in which this connection between a stimulus and a response persists for a period of time. The memory process is known as recall when the stimulus is given and the learned response occurs. Memory is never entirely conscious because we are never completely aware of the physiological activities in our own nervous systems. We learn and remember affective and motor activities, as well as intellectual material.

The mechanism of learning or association is a function of and is dependent upon the activity in the nervous system, muscles, glands, and also sense organs. The ways in which learning, retention and recall can be influenced by bodily fatigue, drugs, severe illness, lesion of the brain, and fracture of the skull have been studied experimentally. When learning and memory are seriously impaired, as in idiocy, the scientific studies have shown that (1) the brain has fewer nerve cells, (2) the neurones are more irregularly arranged, and (3) the functional efficiency is low. These facts are of great theoretical importance, because they have shown that memory is at the same time both a physiological and a psychological process.

MEMPHIS, the capital of Egypt through most of its early history, now represented by the rubbish mounds at Bedreshēn on the W. bank of the Nile 14 m. S. of Cairo. As the chief seat of the worship of Ptah, the artisan god (Hephaestus), Memphis must have existed from a very remote time. But its greatness probably began with Menes (*q.v.*), who united the kingdoms of Upper and Lower Egypt, and is said to have secured the site for his capital near the border of the two lands by diverting the course of the river eastward. The residence here of Pepi I. of the VIth Dynasty, as well as his pyramid in the necropolis, was named *Men-nefer,* and this gradually became the usual designation of the whole city, becoming Menfi, Membi in late Egyptian, *i.e.,* Memphis. It was also called Hakeptah, "Residence of the *ka* of Ptah," and this name furnishes a possible origin for that of Egypt (Αἴγυπτος). Memphis remained the centre of the government and the largest city in Egypt until the New Empire (Dyns. XVIII.–XX.), when Amen worship replaced that of Ptah and Thebes took the lead. After the conquest of Alexander the city quickly lost its supremacy to his new foundation, and although it remained the greatest native centre, its population was less than that of Alexandria. Its final fall was due to the rise of the Arabic city of Fostāt on the right bank of the Nile almost opposite the northern end of the old capital; and its ruins, so far as they still lay above ground, gradually disappeared, being used as a quarry for the new city, and afterwards for Cairo. Now the ruins of the city, the great temple of Ptah, the dwelling of Apis, and the palaces of the kings, are traceable only by a few stones among the palm trees and fields and heaps of rubbish. But the necropolis has been to a great extent protected by the accumulations of blown sand. Pyramids of the Old and Middle kingdoms form a chain 20 m. long upon the edge of the valley from Giza to Dahshur. At Saqqara, the step-pyramid of Zoser of the IIIrd Dynasty, several pyramids of the Vth and VIth Dynasties, and innumerable mastaba-tombs of the Old Kingdom, are crowded together in the cemetery. Later tombs are piled upon and cut through the old ones. One of the chief monuments is the Serapeum or sepulchre of the Apis bulls, discovered by Mariette in 1861. From 1905 J. E. Quibell was charged by the Service des Antiquités solely with the excavations in this vast necropolis. His principal discovery was the extensive remains of the Coptic monastery of St. Jeremias, with remarkable sculptures and frescoes. Flinders Petrie made a systematic exploration of the ruins of Bedreshēn; among his finds not the least interesting is a large series of terra-cotta heads representing the characteristic features of the foreigners who thronged the bazaars of Memphis. They date from the Persian rule down to the Ptolemaic period and are evidently modelled by Greek workmen. In the Old Testament Memphis is mentioned under the names of Moph (Hos. ix. 6) and Noph (Isa. xix. 13; Jer. ii. 16; Ezek. xxx. 13, 16).

MEMPHIS, the largest city of Tennessee, U.S.A., a port of entry and the county seat of Shelby county; on the Mississippi river, in the south-west corner of the State. It is on Federal highways 51, 61, 70, 72 and 78, and is served by the Frisco, the Illinois Central, the Louisville and Nashville, the Missouri Pacific, the Mobile and Ohio, the Nashville, Chattanooga and St. Louis, the Rock Island, the St. Louis Southwestern, the Southern, and the Union (an industrial belt line) railways, and by two barge lines and river packets. Pop. 162,351 in 1920 (38% negroes); and 253,143 in 1930.

The city is built on the Chickasaw bluffs, 50 ft. above the flood stage of the river, and has an area of 30·34 square miles. It is one of the country's chief centres of traffic, by rail, water and highway. Two cantilever railway bridges cross the Mississippi, one of which (the Harahan, completed 1917) carries also vehicular traffic, without toll charges, giving direct access to and from the fertile alluvial lands of Arkansas. Water and rail transportation facilities are co-ordinated by two municipal terminals, completed in 1913 at a cost of over $2,000,000. Natural gas was piped in from the Louisiana fields early in 1929, and hydro-electric power will be available from the Muscle Shoals district and from developments on the White river of Arkansas. The water-supply, from artesian wells, is ample for three or four times the present demand. The city operates under a commission form of government, established in 1910. Through a city-planning commission, created in 1921, a comprehensive plan for improvement and development has been prepared, and zoning ordinances have been adopted. The public parks cover 1,248 acres. The fine auditorium seats 12,500. Memphis is the see of a Protestant Episcopal bishopric. It is the seat of the colleges of medicine and dentistry and the schools of pharmacy and nursing of the University of Tennessee; the West Tennessee State Teachers college (1912) located at Normal, just outside the city limits; and Southwestern, a Presbyterian college, opened in Clarksville in 1875 and moved to Memphis in 1925. There are 84 schools and colleges in all.

Because of its geographical position and transport facilities, Memphis has long been a leading commercial city of the South, and since the World War and the revival of river traffic (beginning with the establishment of the Federal Barge Line in 1918) its trade area has greatly widened and the volume of its wholesale and distributing business has increased vastly. Manufacturing also has grown rapidly. In 1927 there were nearly 600 distributing houses, including the southern headquarters of many northern and eastern firms, and 286 widely diversified manufacturing establishments, with an output valued at $91,670,156. A branch of the Federal Reserve Bank is located here. Bank debits for the year totalled $1,906,725,500; postal receipts amounted to $2,371,720. Memphis is the largest inland cotton market (handling over 2,000,000 bales in a normal year) and the largest hardwood lumber market of the country. The Tri-State fair, in which Tennessee, Mississippi and Arkansas participate, is held here annually.

History.—From a high point in the park that bears his name, De Soto (according to tradition) first saw the Mississippi, in 1541, and there he met in consultation with Chisca, chief of the Chickasaw Indians. Late in the 17th century the French built a fort within the present limits of the city, and the site was held by the French and the Spanish alternately until the close of the French and Indian War, when it passed to Great Britain. In 1797 it came into the possession of the United States. By a treaty of Oct. 19, 1818, negotiated by General Andrew Jackson and General Isaac Shelby, the Chickasaws ceded all their claims east of the Mississippi, and early in 1819 Memphis was laid out in accordance with an agreement entered into by John Overton, Andrew Jackson and James Winchester, the proprietors of the land. Its name was suggested by the similarity of its location to that of the Egyptian city on the Nile. The town was incorporated in 1826, and in 1849 was chartered as a city. By 1830 the cultivation of cotton was general in the surrounding country. In 1834 Memphis established her first steamboat line (to New Orleans) and in 1836 began the construction of a railroad. About 1840 Congress established here an experimental inland navy yard, where one iron ship was launched. In 1857 through railway connection with the Atlantic (at Charleston) was completed. The

decade 1850–60 was one of rapid development, and by 1860 the city had a population of 22,623. On June 6, 1862, a Union fleet of 9 vessels and 68 guns defeated a Confederate fleet of 8 vessels and 28 guns just north of Memphis, and the city was then occupied by Federal troops until the end of the war, except for a few hours on Aug. 21, 1864, when General Nathan B. Forrest made a daring raid and took several hundred prisoners.

By 1870 the city was well on the way to recovery from the prostration left by the war: the railroads had been rebuilt, river commerce was re-established, building was active, and the population had increased to 40,226. Then, in 1873, 1878 and 1879, it was ravaged by epidemics of yellow fever, which resulted in over 8,000 deaths. Thousands fled the city and did not return. Business was suspended for three months both in 1878 and in 1879, and intercourse with the outside was practically cut off. The city was left almost bankrupt. As a means of relief the State legislature (on Jan. 29, 1879) repealed the city's charter, made it a "taxing district," and placed its affairs in the hands of a "legislative council." A complete sewer system was installed, at great cost, and artesian wells were dug to supply the city with water. In the next decade the population, which had fallen to 33,592 in 1880, almost doubled, reaching 64,495 in 1890. The first bridge across the Mississippi was completed in 1892.

MENA, JUAN DE (1411–1456), Spanish poet, was born at Cordova. His principal work is his allegorical poem, *El Laberinto de Fortuna* (1444?), dedicated to John II.; in the oldest mss. it consists of 297 stanzas, but three more stanzas were added to it later, whence the alternative, popular title of *Las Trezientas*. The *Laberinto* is modelled on Dante, and further contains reminiscences of the *Roman de la rose*, as well as episodes borrowed from Virgil and Lucan. It is marred by excessive emphasis and pedantic diction, and the *arte mayor* measure in which it is written is monotonous; but many octaves are of such excellence that the *arte mayor* metre (verses of 12 syllables) continued in fashion for nearly a century.

MENA, PEDRO DE (d. 1693), Spanish sculptor, was born in Adra. He was a pupil of his father and of Alonzo Cano. His first conspicuous success was achieved with the figures for the convent of El Angel at Granada. In 1658 he signed a contract for sculptural work on the choir stalls of the cathedral at Malaga. Other works are the statues of the Madonna and Child and of St. Joseph in Madrid, the polychromatic figures in the church of St. Isodoro, the Magdalena and the Gertrudis in the church of St. Martin (Madrid), the crucifixion in the Nuestra Señora de Gracia (Madrid), the statuette of St. Francis of Assisi in Toledo, and of St. Joseph in the St. Nicholas church in Murcia. Between 1673 and 1679 Mena worked at Cordova. About 1680 he was in Granada, where he executed a half-length Madonna and Child (seated) for St. Dominicos. He died in Malaga in 1693. Mena and Mora (*q.v.*) may be regarded as artistic descendants of Montañes and Alonzo Cano, but in technical skill and the expression of religious motive Mena's statues are unsurpassed in the sculpture of Spain. His feeling for the nude was remarkable, and he excelled in the portrayal of contemplative figures and scenes.

See B. Haendcke, *Studien zur Geschichte der spanischen Plastik* (Strasbourg, 1900).

MENADO, a government of the island of Celebes, Dutch East Indies, comprising the north-eastern peninsula and the coast of the Gulf of Tomini; area 63,761 sq.km.; pop. 967,520. (*See* CELEBES.)

MENAGE, GILLES (1613–1692), French scholar, son of Guillaume Ménage, king's advocate at Angers, was born in that city on Aug. 15, 1613. He became prior of Montdidier without taking holy orders, and lived for some years in the household of Cardinal de Retz (then coadjutor to the archbishop of Paris). Some time after 1648 he quarrelled with his patron and withdrew to a house in the cloister of Notre-Dame, where he gathered round him on Wednesday evenings those literary assemblies which he called "*Mercuriales*." Chapelain, Pellisson, Conrart, Sarrazin and Du Bos were among the *habitués*. Ménage was the original of the pedant Vadius in *Les Femmes savantes*. He died in Paris on July 23, 1692.

Of his works the following may be mentioned: *Poemata latina, gallica, graeca, et italica* (1656); *Origini della lingua italiana* (1669); *Dictionnaire étymologique* (1650 and 1670); *Observations sur la langue française* (1672–76,) and *Anti-Baillet* (1690).

MENAHEM, king of Israel, seized the throne *c.* 745 B.C., after the death of Zechariah, whose reign had lasted but six months. From his headquarters at Tirzah, the old royal city of Israel, he advanced against Shallum, a rival aspirant to the throne who maintained royal state in Samaria for a month, and slew him. He was not accepted by the district of which Tappuah (so read for Tiphsah in 2 Kings xv. 16) was the centre, and made his position good only by bitter fighting, after which he inflicted barbarous punishment on those who would have thwarted him. Towards the end of his reign, which lasted ten years, the peoples of Syria formed an anti-Assyrian coalition. Tiglath-Pileser III. advanced against the rebels, 738 B.C., and crushed them. The Assyrian king, in an inscription recording his successes, names among the kings who paid tribute Menahem of Samaria. The narrative 2 Kings xv. confirms this, and indeed suggests that Tiglath-Pileser advanced against Israel itself. The inscription is silent on this latter detail, and probably Menahem thought it wise to pay tribute before this pass was reached.

MENAI STRAIT, a channel of the Irish sea, separating Anglesey from Carnarvonshire, north Wales, extending 14 m. from Beaumaris to Abermenai, and varying in breadth from 200 yd. to 2 m. It is famous for the suspension and tubular bridges which cross it. The suspension bridge carries the Holyhead road from Bangor. It was designed by T. Telford, begun in 1819 and completed in 1826. The length of roadway between the piers is 550 ft., total length 1,000 ft. and height above the spring tide high-water level is 100 ft. The tubular bridge, which carries the L.M.S. railway, was finished in 1850. The bridge, 1,841 ft. 5 in. long, is supported by a central (Britannia) tower and two side towers. Here the channel is about 1,100 ft. wide, and divided in the middle by the Britannia rock, bare at low water. The tide generally rises 20 ft., with great velocity. There are 101 ft. between the sea at high tide and the bridge roadway bottom. The limestone used is from Penmon, 4 m. from Beaumaris. The engineer of the tubular bridge was Robert Stephenson, assisted by Sir William Fairbairn and Eaton Hodgkinson.

The origin of the Menai strait has been much discussed (*see* E. Greenly, "Geology of Anglesey," *Mem. Geol. Survey*, 1919). The channel consists of an eastern and a western reach, having a parallel direction from south-west to north-east, and being joined by a middle reach, 2 m. long, having a north to south direction. The two longer arms are typical valleys, belonging to a system of parallel valleys upon the Menaian platform. In pre-glacial times the strait did not exist, but its location was marked by three rivers, one flowing north-east, a small one flowing south and joining a larger one flowing south-west. In late glacial times the western and eastern reaches came into existence, but the water of the latter was dammed back by the Ogwen glacier from the mainland, thus forming a long glacial lake which overflowed into what is now the middle reach, following the line of the southward flowing river, the valley of which it quickly deepened and thus emptied the lake. Post-glacial subsidence and scouring by the tides have completed the work.

MENAM, the chief river highway of Siam, on whose yearly rise and fall depends the rice crop of Lower Siam. Rising in the state of Nan, upon the mountain mass of Doi Luang, it is known as the Nam Ngob, after a village of that name. As the Nam Nan, it flows southward between high forested ranges, and, notwithstanding the frequent rapids along its course, is used by the natives for the transport of hill produce. From Utaradit it flows through the plain of Lower Siam, is navigable for large flat-bottomed native craft and is known as the Menam Pichai. Below Pichai the river flows through forest and swamp, the latter providing vast overflow basins for the yearly floods. Thousands of tons of fish are caught and cured here during the fall of the river. Below Pitsunalok the waters of the Menam Yom, upon which two ancient capitals, Sawankalok and Sukotai, were situated, meander by tortuous clayey channels to the main river, and com-

bine to form the Nam Po. At Paknam Po the main western tributary comes in, the shallow Me Ping, the river of Raheng and Chieng Mai, bringing with it the waters of the Me Wang. As the chief duty-station for teak, and as a place of transshipment for boats, Paknam Po is an important and growing town. From this point the river winds by many channels through the richest and most densely populated portion of Siam. About Chainat the Tachin branches off, forming the main western branch of the Menam, and falling into the gulf about 24 m. west of the bar of the main river. At Ayuthia, the Nam Sak flows in from the north-east, affording communication with the tobacco district of Pechabun, and draining the western slopes of the Korat escarpment.

MENANDER (Μένανδρος) (*c.* 343/2–291/0 B.C.), the chief poet of the Greek New Comedy, was the son of a wealthy Athenian, Diopeithes, of the deme Cephisia, and his wife, Hegesistrate. Alexis, the distinguished poet of the Middle Comedy, was his uncle. Of his uneventful life almost nothing is known. He was a pupil of Theophrastus (Diog. L., v.36) as was also Demetrius of Phalerum (Diog. L., v. 39, v. 75), who in 317 B.C. had been appointed by Cassander to be governor of Athens, and with whom Menander was on friendly terms (Diog. L., v.79). Phaedrus, *Fab.* v. 1, tells how Demetrius was fawned upon not merely by prominent politicians but also by retired lovers of ease: "among whom Menander, famous for his comedies—whom Demetrius had not known personally though he had read him and admired his genius—came, perfumed and in flowing robe, with languid step and slow. Seeing him at the end of the line the tyrant asked "What effeminate is that who dares to enter my presence?" Those nearest replied "This is Menander, the writer!" He was no doubt acquainted also with his distinguished contemporary, Epicurus (Strabo, 638). He declined an invitation from the court of Macedon, as also one from Ptolemy Soter to Alexandria (Plin. N.H. vii. 111. Alciphr, *Ep.* iv.18) and remained in Athens till his death, which is said to have occurred through drowning in the Bay of Phalerum (schol. Ovid, *Ibis*). His tomb beside the cenotaph of Euripides between Athens and the Peiraeeus was seen by Pausanias. Of his personal appearance we are told that he had a squint (Suidas, *s.v.* Μένανδρος). His portrait is supposed to be represented by a head in the Vatican.

He appears to have produced his first play, the Ὀργή, in 324 and he won his first victory, according to the *Marmor Parium*, in 316/5. According to Apollodorus *ap.* Aul. Gell. xvii. 5 Menander "of Cephisia, son of Diopeithes, wrote 105 dramas and died at 52," but won the prize only eight times. In his own day Philemon was preferred to him. (Quintil. x.1.72.) "Yet other comic poets . . . and especially Philemon, who, if by the verdicts of his own time he was often wrongly preferred to Menander, is universally allowed to have deserved to be considered second to him" (*cf.* Aul. Gell. xvii. 4.1). Menander was often defeated by Philemon, by no means his equal as a writer, through canvassing and faction. Meeting him on one occasion "Excuse me, Philemon," he said, "when you defeat me, do you not blush?" (Martial v.10 *Rara coronato plausere theatra Menandro*). But after his death he came to be regarded not merely as the leading poet of the New Comedy, but as the chief representative of comedy in general.

At the beginning of the 19th century all that was extant of Menander was a number of fragments, some of uncertain source, quoted by grammarians or other writers, and a collection of single lines of a sententious character (Μενάνδρου γνῶμαι μονόστιχοι), 850 in all, and not all of them authentic. Considerable information as to the character of his plays was to be gathered at second-hand from the use made of them by Plautus, who based his *Bacchides* on the *Dis Exapaton*, his *Poenulus* probably on the *Karchedonios*, his *Stichus* on the *Adelphoi*, one of the two plays of that name written by Menander; and still more from Terence —who is saluted by Julius Caesar in the well known epigram (Sueton. *Vit. Ter.*) as "dimidiate Menander," "Menander in half" —of whose plays the *Andria* is a "contamination" of Menander's *Andria* and *Perinthia*, the *Eunuchus* a "contamination" of the *Eunouchos* and *Kolax*, the *Heautontimorumenos* a version of a play of the same name by Menander, while the *Adelphoi* is based on Menander's *Adelphoi* and the *Synapothneskontes* of Diphilus.

But since 1844 when C. Tischendorf found in the monastery of St. Catherine on Mt. Sinai three papyrus fragments containing 52 lines from the *Phasma*, 41 from the *Epitrepontes*, six from an uncertain play—all in a more or less mutilated condition—the Menander *corpus* has been greatly augmented by fresh papyrus discoveries. Incomparably the most important is the Cairo papyrus, discovered in 1905 by G. Lefebure at Aphroditopolis, containing 659 lines from the *Epitrepontes*, 83 from the *Heros*, 341 from the *Samia*, 324 from the *Perikeiromene*, and 61 from an uncertain play. In addition 87 lines of the *Georgos* were recovered in Egypt by I. Nicole in 1897. A series of Oxyrhynchus papyri published by Grenfell and Hunt restored to us, in 1899, 51 lines of the *Perikeiromene;* in 1903 and 1914, 115 (fragmentary) lines of the *Kolax;* in 1908, 23 lines of the *Perinthia;* in 1910 and 1920, some 80 (fragmentary) lines of the *Misoumenos*. A Berlin papyrus (pub. 1907) gives 93 (fragmentary) lines of the *Kitharistes,* while another (pub. 1918) contains 23 lines of the *Misoumenos*. Some mutilated lines of the *Georgos* are given in a Florence papyrus (pub. 1912) and 20 (mutilated) lines of the *Koneiazomenai* in a Dorpat papyrus.

In structure, in subject matter, and in general tone, the New Comedy, which is essentially a comedy of manners, presents a marked contrast to the Old Comedy as we know it in the plays of Aristophanes. The chorus as an organic element in the play has wholly vanished—although there seems to have been some sort of choric interlude between the acts, as indicated in our texts by the single word ΧΟΡΟΥ—and with it the Parabasis, and the agon, the central element in the Old Comedy, in the sense of a formal debate between two clearly defined antagonists, has also disappeared. The theme is no longer some high question of political or social or religious moment, but merely the presentation of some commonplace complication of ordinary Athenian life, in which common types of character—the wealthy father, the dissolute son, the cunning slave—play their part, the complication being most commonly due to love (Ovid, *Trist.* II. 369 *Fabula iucundi nulla est sine amore Menandri*) in its least lovely guise, and the disentanglement being usually effected, more or less plausibly, by recognition (Ἀναγνώρισις), *i.e.*, by the timely discovery that some supposed stranger is in reality a long lost son or daughter, who had disappeared, whether by exposure in infancy or by shipwreck in a foreign land or other similar misfortune. The humour, whether of situation or of character, is of a subdued type, and the general atmosphere is quiet and little charged with emotion. A glance at the titles of Menander's plays, such as Κόλαξ, *The Flatterer*, Δεισιδαίμων, *The Superstitious Man*, and the like, suggest the prominence of character study, while the long list of such titles as Ανδρία, *The Lady from Andros*, Κνιδία, *The Lady from Cnidus*, etc., emphasize the place of recognition as a mode of dénouement, the supposed foreigner being discovered to be a true-born Athenian.

"Truth to life," his scrupulous observation of "propriety" or what the Greeks called τὸ πρέπον, was the great merit which the ancients recognized in Menander. "Ὦ Μένανδρε καὶ βίε, πότερος ἄρ' ὑμῶν πότερον ἀπεμιμήσατο; O Menander and Life, which of you imitated the other?" so runs the highly flattering apostrophe to Menander attributed to Aristophanes of Byzantium. So Quintilian X. 1.69 writes of "Menander who, in my judgment, would alone, if carefully read, be sufficient to illustrate all my precepts: so well has he expressed the whole picture of life (*omnem vitae imaginem expressit*), such copiousness of invention has he, such a gift of speech, so appropriate is he in all his incidents, characters, emotions." *Cf.* Dio Chrysos. xviii. 7. Plutarch *comp. Menand. et Aristoph.* p. 853. A.P. vii. 370. ix. 187. The subtle presentation of character is perhaps a thing too delicate in its nature to exert its full appeal after the lapse of more than 2,000 years, but even the broken fragments of his work that remain enable us as assent to the judgment of antiquity.

Lastly it may be remarked that the sententious character, which he shared with Euripides (of whom he was a confessed admirer and imitator, Quintil. x. 1. 69) is not nearly so marked in the new fragments as one might have expected from the Μονόστιχοι, two of which—"Whom the gods love dies young" (ὃν οἱ θεοὶ

φιλοῦσιν ἀποθνήσκει νέος) and "Evil communications corrupt good manners" (*φθείρουσιν ἤθη χρήσθ' ὁμιλίαι κακαί*—*cf.* N. T. I Corinth. xv. 33)—are known to multitudes who never heard the name of Menander.

BIBLIOGRAPHY.—The old fragments are in *Comicorum Atticorum Fragmenta* ed. Kock (1880–88), iii. 3 *sqq.* Newly discovered fragments ed. Sudhaus (1909); *Menandrea*, A. Koerte, ed. major (Berlin, 1912); *Selections*, from Menander, ed. Waddell (Oxford, 1927).

(A. W. MA.)

MENANDER (MILINDA), a Graeco-Indian dynast. When the Graeco-Indian king Demetrius had been beaten by Eucratides of Bactria, about 160 B.C., and the kingdom of Eucratides (*q.v.*) dissolved after his assassination (*c.* 150 B.C.), a Greek dynasty maintained itself in the Kabul Valley and the Punjab. The only two kings of this dynasty mentioned by classical authors are Apollodotus and Menander, who conquered a great part of India. Trogus Pompeius described in his forty-first book (*see* the prologue) "the Indian history of these kings, Apollodotus and Menander," and Strabo, xi. 516, mentions from Apollodotus of Artemita, the historian of the Parthians, that Menander "conquered more tribes than Alexander, as he crossed the Hypanis to the east and advanced to the Osamus; he and other kings (especially Demetrius) occupied also Patalene (the district of Patala near Hyderabad on the head of the delta of the Indus) and the coast which is called the district of Saraostes (*i.e.*, Syrastene, in mod. Gujarat, Brahman *Saurashtra*) and the kingdom of Sigerdis (not otherwise known); and they extended their dominion to the Seres (*i.e.*, the Chinese) and Phryni (?)." The last statement is an exaggeration, probably based upon the fact that from the mouth of the Indus trade went as far as China. That the old coins of Apollodotus and Menander, with Greek legends, were still in currency in Barygaza (mod. Broach), the great port of Gujarat, about A.D. 70 we are told by the *Periplus maris Erythraei*, 48. Their reigns may be placed about 140–80 B.C. Menander appears in Indian traditions as Milinda; he is praised by the Buddhists, whose religion he is said to have adopted, and who in the *Milindapanha* or *Milinda Pañho* (*see* below), "the questions of Milinda" (Rhys Davids, *Sacred Books of the East*, xxxv., xxxvi.) relate his discourses with the wise Nāgasena. Plutarch (*Praec. reip. ger.* 28, 6) relates that "when Menander, one of the Bactrian kings, died on a campaign after a mild rule, all the subject towns disputed about the honour of his burial, till at last his ashes were divided between them in equal parts." (The Buddhist tradition relates a similar story of the relics of Buddha.) Besides Apollodotus and Menander, we know from the coins a great many other Greek kings of western India, among whom two with the name of Straton are most conspicuous. The last of them, with degenerate coins, seems to have been Hermaeus Soter. These Greek dynasts may have maintained themselves, with diminished realms, in some part of India till about 40 B.C. (*See* INDIA: *History*.)

The *Milinda Pañho* is preserved in Pali, in Ceylon, Burma and Siam, but was probably composed originally in the extreme northwest of India, and in a dialect spoken in that region. Neither date nor author is known; but the approximate date must have been about the 2nd century of our era. The work is entitled *Milinda Pañho*—that is, *The Questions of King Milinda.* The work is several times quoted as authority by Buddhaghosa, who wrote about A.D. 450, and it is the only work, not in the canon, which receives this honour.

MENANGKABAUS, the most civilized of all the true Malays of Sumatra, inhabiting the mountains above Padang. Their district is regarded as the cradle of the Malay race, and thence began, about 1160, the migrations of the Malays throughout the peninsula and the Malay Archipelago. The Menangkabaus are said to be the original conquerors of the island. Though converts to Islam, the ancient village communes and the matriarchal system still exist. The people are divided into clans, the chiefs together forming the district council. Early in the 19th century a religious sect was founded among the Menangkabaus, known as "Padris" from its zealous proselytism, or *Orang puti* (white men) from the converts being dressed in white. The tendency was towards asceticism, the chief tenet being the prohibition of opium, the use of which was made a capital offence. The sect brought a large portion of the interior of Sumatra under its rule, but the neighbouring tribes asked the Dutch to protect them, and this led to the Netherlands acquiring the Menangkabau territory.

MÉNANT, JOACHIM (1820–1899), French magistrate and Orientalist, was born at Cherbourg on April 16, 1820. He studied law and in 1881 became a member of the *cour d'appel* of Rouen. He is known by his studies on cuneiform inscriptions. He died in Paris on Aug. 30, 1899.

His publications include: *Recueil d'alphabets des écritures cunéiformes* (1860); *Exposé des éléments de la grammaire assyrienne* (1868); *Le Syllabaire assyrien* (2 vols., 1869–73); *Les Langues perdues de la Perse et de l'Assyrie* (2 vols., 1885–86); *Les Pierres gravées de la Haute-Asie* (2 vols., 1883–86).

MENARD, LOUIS NICOLAS (1822–1901), French man of letters, was born in Paris on Oct. 19, 1822. His versatile genius occupied itself in turn with chemistry, poetry, painting and history. He discovered collodion in 1846, but its value was not recognized; and its application later to surgery and photography brought him no advantage. Louis Ménard was a socialist, always in advance of the reform movements of his time. After 1848 he was condemned to imprisonment for his *Prologue d'une révolution.* He escaped to London, returning to Paris only in 1852. Until 1860 he occupied himself with classical studies, the fruits of which are to be seen in his *Poèmes* (1855), *Polythéisme hellénique* (1863), and two academic theses, *De sacra poesi graecorum* and *La Morale avant les philosophes* (1860). The next ten years Ménard spent chiefly among the Barbizon artists, and he exhibited several pictures. He was in London at the time of the Commune, and defended it with his pen. In 1887 he became professor at the Ecole des Arts décoratifs, and in 1895 professor of universal history at the Hôtel de Ville in Paris. His *Rêveries d'un païen mystique* (1876), which contained sonnets, philosophical dialogues and some stories, was followed in 1896 by *Poëmes et rêveries d'un païen mystique,* in which he resuscitated many ancient myths. He had views on spelling reform, and adopts his own orthography in some of his work. Ménard died in Paris on Feb. 12, 1901.

His works include: *Histoire des anciens peuples de l'Orient* (1882); *Histoire des Israélites d'après l'exégèse biblique* (1883), and *Histoire des Grecs* (1884–86).

MENASHA, a city of Winnebago county, Wisconsin, U.S.A., 85 m. N. by W. of Milwaukee, on Lake Winnebago at its outlet into the (canalized) Fox river. It is on Federal highway 41, and is served by the Chicago and North Western, the Chicago, Milwaukee, St. Paul and Pacific, and the Soo Line railways, and by lake and river steamers. Pop. (1920) 7,214 (82% native white); 9,062, Federal census, 1930. Menasha and Neenah, across the river, are practically one community in economic and social interests. There is abundant water-power, and the manufactures of Menasha are numerous and diversified, with an annual output valued at $25,000,000. It is an important publication centre, printing some 20 periodicals of learned societies and college fraternities. The city owns both the water and the electricity plants. In 1634–35 Jean Nicollet visited the region, finding here villages of the Fox and Winnebago Indians, and later French and English trading posts were established on the site of Menasha. Permanent settlement began in 1848, and the city was chartered in 1874.

MENASSEH BEN ISRAEL (*c.* 1604–1657), Jewish leader, was born in Lisbon about 1604, and was brought up in Amsterdam. His family had suffered under the Inquisition, but found an asylum first in La Rochelle and later in Holland. Here Menasseh rose to eminence as rabbi, author and printer. He established the first Hebrew press in Holland. One of his earliest works *El Conciliador* won immediate reputation. It was an attempt at reconciliation between apparent discrepancies in various parts of the Old Testament. Among his correspondents were Vossius, Grotius and Huet. In 1638 he decided to settle in Brazil, as he still found it difficult

to provide in Amsterdam for his wife and family, but this step was rendered unnecessary by his appointment to direct a college founded by the Pereiras.

In 1644 Menasseh met Antonio de Montesinos, who persuaded him that the North American Indians were the descendants of the lost ten tribes of Israel. This supposed discovery gave a new impulse to Menasseh's Messianic hopes. But he was convinced that the Messianic age needed as its certain precursor the settlement of Jews in all parts of the known world. Filled with this idea, he turned his attention to England, whence the Jews had been expelled since 1290. He found much Christian support in England. Messianic and other mystic hopes were current in England. In 1650 appeared an English version of the *Hope of Israel,* a tract which deeply impressed public opinion. Cromwell had been moved to sympathy with the Jewish cause, chiefly because he foresaw the importance for English commerce of the presence of the Jewish merchant princes, some of whom had already found their way to London. At this juncture Jews received full rights in the colony of Surinam, which had been English since 1650. In 1655 Menasseh arrived in London. It was during his absence that the Amsterdam Rabbis excommunicated Spinoza, a catastrophe which might have been avoided had Menasseh—Spinoza's teacher—been on the spot.

One of Menasseh's first acts on reaching London was the issue of his *Humble Addresses* to the Lord Protector, but its effect was weakened by the issue of Prynne's *Short Demurrer.* Cromwell summoned the Whitehall Conference in December of the same year. The chief practical result was the declaration of Judges Glynne and Steele that "there was no law which forbade the Jews' return to England." Though, therefore, nothing was done to regularize the position of the Jews, the door was opened to their gradual return. Hence John Evelyn was able to enter in his *Diary* under the date Dec. 14, 1655, "Now were the Jews admitted." But the attack on the Jews by Prynne and others could not go unanswered. Menasseh replied in the finest of his works, *Vindiciae judaeorum* (1656). "The best tribute to its value is afforded by the fact that it has since been frequently reprinted in all parts of Europe when the calumnies it denounced have been revived" (L. Wolf). Among those who used in this way Menasseh's *Vindiciae* was Moses Mendelssohn (*q.v.*). Soon after Menasseh left London Cromwell granted him a pension, but he died, at Middleburg, before he could enjoy it. Menasseh was a friend of Rembrandt, who painted his portrait and engraved four etchings to illustrate his *Piedra gloriosa.* These are preserved in the British Museum.

Adler, "A Homage to Menasseh ben Israel," in *Transactions of the Jewish Historical Society of England,* i. 25–54; also M. Kayserling, *Menasseh ben Israel* (1861).

(I. A.)

MENCIUS, the latinized form of Măng-tsze, "Mr. Măng," or "Măng the philosopher" (*fl.* 3rd cent. B.C.), a Chinese moral teacher whose name stands second only to that of Confucius. His statue or spirit-tablet (as the case may be) has occupied, in the temples of the sage, since our 11th century, a place among "the four assessors," and since A.D. 1530 his title has been "the philosopher Măng, sage of the second degree."

The Măngs or Măng-suns had been in the time of Confucius one of the three great clans of Lû (all descended from the marquis Hwan, 711–694 B.C.), which he had endeavoured to curb. Their power had subsequently been broken, and the branch to which Mencius belonged had settled in Tsâu, a small adjacent principality, the name of which remains in Tsâu hsien, a district of Yenchâu Shan-tung. A magnificent temple to Mencius is the chief attraction of the district city, and thousands of Măngs are to be found in the neighbourhood.

Mencius, who died in the year 289 B.C., lived to a great age—some say to his eighty-fourth year, placing his birth in 372 B.C., and others to his ninety-seventh, placing it in 385. His father died before the child was three; his mother's virtues and dealings with her son were celebrated by a great writer in the 1st century before our era, and for two thousand years she has been the model mother of China. Mencius was forty when he made his first appearance in history.

He intimates that he had been in communication with men who had been disciples of Confucius, and in the doctrines which he had taught Mencius recognized the truth for want of an appreciation of which the bonds of order all round him were being relaxed, and the kingdom hastening to anarchy. When he emerged from Tsâu, he was accompanied by eminent disciples. His intercourse with his followers was not so intimate as that of Confucius had been with the members of his selected circle; and he did not secure from them the same homage and reverent admiration.

More than a century had elapsed since the death of Confucius, and during that period the feudal kingdom of Châu had been showing signs of dissolution and even of approaching anarchy. The sentiment of loyalty to the dynasty had disappeared. Marquesses and other feudal princes of earlier times had usurped the title of king. The smaller fiefs had been absorbed by the larger ones, or reduced to helpless dependence on them. Tsin, after greatly extending its territory had broken up into three powerful kingdoms, each about as large as England. Mencius found the nation nominally one, and with the traditions of two thousand years affirming its essential unity, but actually divided into seven monarchies, each seeking to subdue the others under itself. The consequences were constant warfare and chronic misery.

On lawlessness, wickedness, heresies and misery Mencius looked out from the quiet of his school, and his spirit was stirred to attempt the rescue of the people from misrule and error. "If Heaven," he said, "wishes that the kingdom should enjoy tranquillity and good order, who is there besides me to bring it about?" He formed his plan, and proceeded to put it in execution. He would go about among the different kings till he should find one among them who would follow his counsels and commit to him the entire administration of his government. That obtained, he did not doubt that in a few years there would be a kingdom so strong and so good that all rulers would acknowledge its superiority, and the people hasten from all quarters to crown its sovereign as monarch of the whole of China. This plan was much the same as that of Confucius had been; but, with the bolder character that belonged to him, Mencius took in one respect a position from which "the master" would have shrunk. The former was always loyal to Châu, and thought he could save the country by a reformation; the latter saw the day of Châu was past, and the time was come for a revolution. Mencius's view was the more correct, but he was not wiser than the sage in forecasting for the future. They could think only of a reformed dynasty or of a changed dynasty, ruling according to the model principles of a feudal constitution, which they described in glowing language. They desired a repetition of the golden age in the remote past; but soon after Mencius disappeared from the stage of life there came the sovereign of Ch'in, and solved the question with fire and sword, introducing the despotic empire which has since prevailed.

Attended by several of his disciples, Mencius went for more than twenty years from one court to another, always baffled, and always ready to try again. He was received with great respect by kings and princes. He would not enter into the service of any of them, but he occasionally accepted honorary offices of distinction; and he received gifts which enabled him to live and move about as a man of wealth. He was as fearless and outspoken as John Knox. He lectured great men, and ridiculed them. He unfolded the ways of the old sage kings, and pointed out the path to universal sway; but he could not stir any one to honourable action. He confronted heresy with strong arguments and exposed it with withering sarcasm; but he could work no deliverance in the earth. The last court at which we find him was that of Lû, probably in 310 B.C. The marquis of that state had given office to Yo-chăng, one of Mencius's disciples, and he hoped that this might be the means of a favourable hearing for himself. On the suggestion of Yo-chăng the marquis had ordered his carriage to be yoked, and was about to step into it and proceed to bring Mencius to his palace, when an unworthy favourite stepped in and diverted him from his purpose. The disciple told his master what had occurred, reproaching the favourite for his ill-timed interven-

tion; Mencius, however, said to him, "A man's advancement or the arresting of it may seem to be effected by others, but is really beyond their power. My not finding in the marquis of Lû a ruler who would confide in me and put my lessons in practice is from Heaven."

Mencius accepted this incident as a final intimation to him of the will of Heaven. He had striven long against adverse circumstances, but now he bowed in submission. He withdrew from courts and the public arena. According to tradition he passed the last twenty years of his life in the society of his disciples, discoursing to them, and giving the finishing touches to the record of his conversations and opinions, which were afterwards edited by them, and constitute his works. Mencius was not so oracular, nor so self-contained, as Confucius; but his teachings have a vivacity and sparkle all their own.

Mencius held with Confucius—and it was a doctrine which had descended to them both from the remotest antiquity—that royal government is an institution of God. An ancient sovereign had said that "Heaven, having produced the people, appointed for them rulers, and appointed for them teachers, who should be assisting to God." But how could it be known on what individual the appointment of Heaven had fallen or ought to fall? Mencius concluded that this could be ascertained only from his personal character and his conduct of affairs. The people must find out the will of Heaven as to who should be their ruler for themselves. There was another old saying which delighted Mencius—"Heaven sees as the people see; Heaven hears as the people hear." He taught that, while government is from God, the governors are from the people;—*vox populi vox Dei.* No claim then of a "divine right" should be allowed to a sovereign if he were not exercising a rule for the good of the people. "The people are the most important element in a nation; the altars to the spirits of the land and grain are the second; the sovereign is the lightest." Mencius followed this utterance to its consequences. The monarch whose rule is injurious to the people, and who is deaf to remonstrance and counsel, should be dethroned. In such a case "killing is no murder." But who is to remove the sovereign that thus ought to be removed? First, he would have the members of the royal house perform the task. Let them disown their unworthy head, and appoint some better individual of their number in his room. If they could not or would not do this, he thought, secondly, that any high minister, though not allied to the royal house, might take summary measures with the sovereign, assuming that he acted purely with a view to the public weal. His third and grand device was what he called "the minister of Heaven." When the sovereign had become a pest instead of a blessing, he believed that Heaven would raise up some one for the help of the people, some one who should so conduct himself in his original subordinate position as to draw all eyes and hearts to himself. Let him then raise the standard not of rebellion but of righteousness, and he could not help attaining to the highest dignity. Mencius was in fact counselling rebellion, but he held that the house of Châu had forfeited its title to the throne.

Mencius laid down as essentials of good government care for the general welfare of all the people; the abolition of game laws; a light system of taxation; the execution of public improvements such as drainage and irrigation; liberty of commerce; and a complete and all-embracing system of education.

But after all, unless the people could get food and clothing by their labour, he had not much faith in the power of education to make them virtuous. Give him, however, a government fulfilling the conditions that he laid down, and he was confident there would soon be a people, all contented, all virtuous. Mencius contended that the nature of man is good. "Water," he said, "will flow indifferently to the east or west; but will it flow indifferently up or down? The tendency of man's nature to goodness is like the tendency of water to flow downwards." Sometimes he may seem to express himself too strongly, but an attentive study of his writings shows that he is speaking of our nature in its ideal, and not as it actually is—as we may ascertain, by an analysis of it, like it was intended to be, and not as it has been made to become.

Mencius insists on the constituents of human nature, dwelling especially on the principles of benevolence, righteousness, propriety, and wisdom or knowledge, the last including the judgment of conscience. "These," said he, "are not infused into us from without. Men have these four principles just as they have their four limbs." But man has also instincts and appetites which seek their own gratification without reference to righteousness or any other control. He met this difficulty by contending that human nature is a constitution, in which the higher principles are designed to rule the lower. "Some constituents of it are noble and some ignoble, some great and some small. The great must not be injured for the small, nor the noble for the ignoble."

When he proceeded from his ideal of human nature to account for the actual phenomena of conduct, he was necessarily less successful. "There is nothing good," he said, "that a man cannot do; he only does not do it." But why does he not do it? Against the stubborn fact Mencius beats his wings and shatters his weapons—all in vain.

Above all the sages he extols Confucius, taking no notice of that sage's confession that he had not attained to conformity to his own rule of doing to others as he would have them do to him. No such acknowledgment about himself ever came from Mencius. Therein he was inferior to his predecessor: he had a subtler faculty of thought, and a much more vivid imagination; but he did not know himself nor his special subject of human nature so well. His thoughts were seldom condensed like those of "the master" into aphorisms, and should be read in their connection; but we have from him many words of wisdom that have been as goads to millions for more than two thousand years. For instance:—

"Though a man may be wicked, yet, if he adjust his thoughts, fast, and bathe, he may sacrifice to God."

"The great man is he who does not lose his child-heart."

"Benevolence is the distinguishing characteristic of man. As embodied in his conduct, it may be called the path of duty."

"There is an ordination for everything; and a man should receive submissively what may be correctly ascribed thereto. He who has the correct idea of what Heaven's ordination is will not stand beneath a tottering wall. Death sustained in the discharge of one's duties may be correctly ascribed to Heaven. Death under handcuffs and fetters cannot be correctly so ascribed."

"When one by force subdues men, they do not submit to him in heart. When he subdues them by virtue, in their hearts' core they are pleased, and sincerely submit."

Two translations of the works of Mencius are within the reach of European readers: that by Stanislaus Julien, in Latin (Paris, 1824–1829); and that forming the second volume of Legge, *Chinese Classics* (Hong-Kong, 1862). The latter has been published at London (1875) without the Chinese text. *See* also E. Faber, *The Mind of Mencius, or Political Economy founded on Moral Philosophy,* translated from the German by A. B. Hutchinson (London, 1882).

MENCKEN, HENRY LOUIS (1880–   ), American critic, was born at Baltimore (Md.), Sept. 12, 1880. He attended the Baltimore Polytechnic Institute and in 1899 became a reporter on the Baltimore *Morning Herald.* After other newspaper experience he joined the editorial staff of the Baltimore *Sun,* to which he continued to be attached while engaged in many additional literary activities. He became literary critic for the *Smart Set* in 1908, and in 1914–23 he was joint editor with George Jean Nathan. In 1921 he became contributing editor of the *Nation,* and in 1924 he was one of the two founders of the *American Mercury,* of which he became sole editor in 1925. He is a satirist rather than a critic and represents the viewpoint of the extreme anti-academic element in the literary world.

Among his publications are *Ventures in Verse* (1903); *George Bernard Shaw: His Plays* (1905); *The Philosophy of Friedrich Nietzsche* (1908); *A Book of Burlesques* (1916); *Damn!* (1917), re-issued as *A Book of Calumny* (1919); *A Book of Prefaces* (1918); *The American Language* (1919); *In Defense of Women* (1917); many series of *Prejudices* (1919 *seq.*); and *Americana* (1925). He has also written critical prefaces to works by Brieux, Swift, Stephen Crane, Cabell, and others.

See the compilation *H. L. Mencken* (1920) by Burton Rascoe and others, monographs by Ernest Boyd (1925) and Isaac Goldberg (1925), and Carroll Frey, *A Bibliography of the Writings of H. L. Mencken* (1924).

MENDE, a town of south-eastern France, capital of the department of Lozère, 59 m. N.E. of Millau by rail. Pop. (1926)

5,785. Mende (Mimate) grew up around the hermitage, partly excavated in the side of the Mimat cliff, to which St. Privat, bishop of Javols, retreated after the destruction of that town, and where he was subsequently slain in 408 by the Vandals. In the 14th century the new town became the civil, as it had previously been the ecclesiastical, capital of the Gévaudan district. Mende is situated on the left bank of the Lot, and at the foot of the Causse de Mende. The town is the seat of a bishopric under the archbishop of Albi. Its cathedral of St. Peter was founded in the 14th century by Pope Urban V., a native of the district, but the two towers were added in the early 16th century. Partly destroyed during the devastation of the town by the Protestants in 1579 and 1580, it was rebuilt in the 17th century. A Renaissance tower of the ancient citadel now serves as the belfry of the church of the Penitents, and a 14th century bridge crosses the Lot. The town is a convenient centre for visitors to the gorges of the Tarn. It is the seat of a prefect and a court of assizes, and has a tribunal of first instance and a chamber of commerce. The chief industry is the manufacture of serges and shalloons, known as Mende stuffs, exported to Spain, Italy and Germany.

MENDE is also the name of a sturdy, medium-statured people of Sierra Leone, from French Guinea, resembling the Sosso and speaking a related language.

See Arcin, *La Guinée Française* (1907); Migeod, *The Languages of West Africa* (1911).

MENDELÉYEV, DMITRI IVANOVICH (1834–1907), Russian chemist, the youngest of a family of seventeen, was born at Tobolsk, Siberia, on Feb. 7, 1834. After attending the gymnasium of his native place, he went to study science at St. Petersburg, where he graduated in chemistry in 1856, subsequently becoming *privatdozent.* He became professor of chemistry in the technological institute at St. Petersburg in 1863, and three years later succeeded to the chair in the university. In 1890 he resigned the professorship and in 1893 became director of the Bureau of Weights and Measures, a post which he occupied till his death at St. Petersburg on Feb. 2, 1907.

Mendeléyev's name is best known for his work on the Periodic Law (*q.v.*). Various chemists had traced numerical sequences among the atomic weights of some of the elements and noted connections between them and the properties of the different substances; but it was left to him to give a full expression to the generalization, and to treat it not merely as a system of classifying the elements according to certain observed facts, but as a "law of nature" which could be relied upon to predict new facts. Thus in 1871 he was led by certain gaps in his tables to assert the existence of three new elements so far unknown to the chemist, and to assign them definite properties. These three he called eka-boron, eka-aluminium, and eka-silicon; and his prophecy was completely vindicated within fifteen years by the discovery of gallium in 1871, scandium in 1879, and germanium in 1886. Again, in several cases he ventured to question the correctness of the "accepted atomic weights," on the ground that they did not correspond with the Periodic Law, and here also he was justified by subsequent investigation. Mendeléyev also devoted much study to the nature of solutions, which he looked upon as homogeneous liquid systems of unstable dissociating compounds of the solvent with the substance dissolved. In another department of physical chemistry he investigated the expansion of liquids with heat, and devised a formula for its expression, while so far back as 1861 he anticipated T. Andrews's conception of the critical temperature of gases (*see* LIQUEFACTION OF GASES), by defining the absolute boiling-point of a substance as the temperature at which cohesion and heat of vaporization become equal to zero and the liquid changes to vapour, irrespective of the pressure and volume. He also gave much time to the study of the nature and origin of petroleum.

Mendeléyev's best known book is *The Principles of Chemistry,* which was written in 1868–1870, and has gone through many subsequent editions in various languages (Eng. ed. 2 vols., 1905). He was awarded the Davy medal of the Royal Society in 1882, and in 1905 he received its Copley medal. He was one of the greatest teachers of his time. His lecture room was always thronged with students. "Many of them," writes one of these, "I am afraid, could not follow Mendeléev, but for the few of us who could it was a stimulant to the intellect and a lesson in scientific thinking which must have left deep traces in their development."

See W. A. Tilden, "Mendeléeff Memorial Lecture," *Jour. Chem. Soc.,* 95; P. Walden, "D. I. Mendelejeff" in *Berichte d. deutsch. Chem. Ges.* (1908); T. E. Thorpe, *Essays in Historical Chemistry* (1911); W. A. Tilden, *Famous Chemists* (1921).

MENDELISM is the scientific theory relating to the distributive mechanism of organic inheritance, promulgated in 1866 by the Abbot G. J. Mendel, to interpret certain phenomena revealed by the experimental breeding of plants. Born in a peasant family in 1822, Johann Gregor Mendel became a monk and eventually abbot in the Augustinian monastery at Brünn, in Moravia. He carried on his experiments in the garden of the monastery, where he died in 1884. Mendel took for his problem the question as to the manner in which true-breeding varieties within a species are related. He concentrated his attention upon the mode of inheritance of sharply contrasted pairs of characters. His experimental material was the culinary pea and the pairs of characters with which he dealt are shown below. His method was that of hybridization, keeping accurate pedigree records, and counting the number of individuals in each generation and the numbers of dissimilar kinds. In all cases the result was the same; the first cross (the first filial generation or F_1) exhibited only one of the two alternative characters which had distinguished its parents. The character that prevailed Mendel called the dominant member of the pair, that which was suppressed, the recessive. The F_1 plants were allowed to become self-fertilized and the seeds were harvested separately and sown separately, producing the second filial generation, F_2. This generation was mixed, consisting of individuals exhibiting the dominant character and others exhibiting the recessive, and in every four on the average there were three with the dominant to one with the recessive.

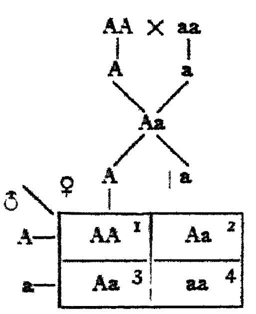
Structure	Property	Characters		Ratio
		Dominant	Recessive	
Seed	Form	5,474 round	1,850 wrinkled	2·96:1
Reserve material in cotyledons	Colour	6,022 yellow	2,001 green	3·01:1
Seed-coats	Form	882 inflated	299 wrinkled	2·95:1
Seed-coats	Colour	705 grey	224 white	3·15:1
Unripe pods	Colour	428 green	152 yellow	2·82:1
Flowers	Position	651 axial	207 terminal	3·14:1
Stem	Length	787 tall	277 dwarf	2·84:1
		14,949 (74·90%)	5,010 (25·10%)	2·98:1 or 3:1

The F_2 individuals were allowed to become self-fertilized and it was found that, whilst every individual exhibiting the recessive character bred true, of those which had exhibited the dominant, in every three on the average there was one which bred true and two which yielded a ratio of 3:1 as had the F_1 individuals.

Having thus collected by observation and controlled experimentation a sufficient number of data to enable him to recognize the orderliness and regularity of his results, Mendel then constructed a working hypothesis referring to the phenomena of segregation and the independent assortment and recombination of factors to account for the observed facts. He postulated that corresponding to every inherited character there are determiners or factors (now often designated *genes*) in the gametes. Each gamete carries a factor for each and every heritable character that the future individual may exhibit and thus an individual arising from the union of two gametes has a double set of factors, each gamete a single set. Characters can be classified as alternative (allelomorphic), *e.g.,* stem length can be either tall or dwarf, and allelomorphic characters are alternative characters of one and the same structure or function. A tall pea can have received the factor for this character by way of both male and female gametes, being duplex for this factor and homozygous for the character, or can have received this factor by way of one gamete and the alter-

native factor for dwarf stem by way of the other, being simplex for each of these factors and heterozygous for the character it exhibits, in this case tall because, for reasons as yet unknown, tall is dominant to dwarf. An individual exhibiting the recessive character of a pair must necessarily be nulliplex for the dominant factor, duplex for the recessive factor, and homozygous for the character it displays. The individual being constitutionally duplex, and the gamete simplex, it follows that into each gamete elaborated by an individual there must pass one or other of each pair of factors in the hereditary constitution. In respect of the factors for all characters for which the individual is homozygous, all gametes will be factorially similar, but in respect of those for characters for which the individual is heterozygous, there will be two sorts of gametes, one carrying the factor for one character of a pair, the other the factor for its alternative, and the two kinds will be elaborated in equal numbers. If, of the two characters, one is dominant, if at the time of fertilization there are equal numbers both of male and of female gametes carrying the dominant and recessive factors respectively (as will be the case for the gametes of the F_1), and if fertilization is at random, then chance will yield on the average in every four, three individuals exhibiting the dominant character of a pair and one exhibiting the recessive. Mendel's law of segregation refers to this clean separation of factors during the formation of the gametes. It can be illustrated by the following scheme.

Let A and a represent the factors corresponding to the dominant and recessive members of a pair of alternative characters.



First parental generation, P_1.
Gametes of P_1. Into each passes one member of each pair. The gametes of either parent are similar because the individuals were homozygous.
First filial generation, F_1. All individuals are heterozygous. Since A is dominant, they will exhibit the dominant character.
Gametes of F_1. *Segregation.* Into each gamete passes one member of each pair of factors. Equal numbers of two kinds of gametes are produced. Two series, male and female, are required.
Second filial generation, F_2.
Individuals exhibiting the dominant character:
Homozygotes, AA, . . 1
Heterozygotes, Aa, . . 2 . . . 3
Individuals exhibiting the recessive character:
Homozygote, aa 4

It is now known that dominance is not an essential feature of Mendelian inheritance; it is commonly not exhibited, the hybrid being intermediate in its characterization. What is essential is the orderly reappearance of the characters of P_1 and of F_1 in F_2 in definite numerical proportions.

Mendel's second law is that of the independent assortment of factors. This is illustrated when in one and the same experiment two different pairs of allelomorphic characters are present. The F_1 exhibit the two dominant members of the two pairs and in F_2 there are on the average in every sixteen individuals nine exhibiting both dominants, three exhibiting the dominant of one pair and the recessive of the other, three exhibiting the other dominant and the other recessive, and one the two recessives. All possible combinations of the four characters are yielded. For the production of these, there must be free assortment and recombination of the four factors concerned. The 9 : 3 : 3 : 1 ratio follows from the co-existence of two 3 : 1 ratios in the same mating. The F_2 of a trihybrid mating, one involving three pairs of allelomorphs, one member of each pair being dominant, is 27 : 9 : 9 : 9 : 3 : 3 : 3 : 1. (*See* HEREDITY, GENETICS, SEX.)

See W. Bateson, *Mendel's Principles of Heredity* (1913); R. C. Punnett, *Mendelism* (1919); F. A. E. Crew, *Heredity* (1928).
(F. A. E. C.)

MENDELSOHN, ERICH (1887–), German architect, was born at Allenstein in East Prussia in 1887, and is now one of the most prominent German architects. Mendelsohn has employed at different times many methods of construction and a wide selection of materials. Among his works may be mentioned the Mosse-haus, Berlin (in collaboration with R. Neutra and R. P. Henning), with its interesting interplay of horizontal and vertical lines, completed in 1923; the Potsdam observatory (Einstein tower), 1927, a poetic conception, moulded rather than erected, which illustrates the dynamic tendency of contemporary architecture, made possible by steel construction; a dye-works at Luckenwalde, 1921, which has a roof in remarkable imitation of crystal formations; a block of offices and shops at Gleiwitz, severely rectangular (1922); and the Mosse-Pavillon at the Pressa Exhibition, Cologne, 1928. It will be apparent that he is less interested in designing dwelling-houses than public buildings.

See *Bauten der Arbeit u. des Verkehrs* (Blauen Bücher), published by Langewiesche; G. A. Platz, *Die Baukunst der neuesten Zeit* (1927).

MENDELSSOHN, MOSES (1729–1786), Jewish philosopher, was born in Dessau in 1729. His father's name was Mendel, and he was later on surnamed Mendelssohn (=son of Mendel). Mendel Dessau was a poor scribe, and his son Moses in his boyhood developed curvature of the spine. His early education was cared for by his father and by the local rabbi, David Fränkel. The latter, besides teaching him the Bible and Talmud, introduced to him the philosophy of Maimonides (*q.v.*). Fränkel removed to Berlin in 1743, where Mendelssohn joined him a little later. With his scanty earnings he bought a Latin copy of Locke's *Essay concerning the Human Understanding,* and mastered it with the aid of a Latin dictionary. In 1750 he became tutor to the children of a wealthy silk-merchant, Isaac Bernhard, who made the young student successively his book-keeper and his partner. In 1754 he was introduced to Lessing. Just as the latter afterwards makes Nathan the Wise and Saladin meet over the chess-board, so did Lessing and Mendelssohn actually come together as lovers of the game. Lessing had already begun his work of toleration, for he had recently produced a drama (*Die Juden,* 1749), the motive of which was to prove that a Jew can be possessed of nobility of character. This notion was being generally ridiculed, but Lessing found in Mendelssohn the realization of his dream. Mendelssohn had written in lucid German an attack on the national neglect of native philosophers (principally Leibnitz), and lent the manuscript to Lessing. Without consulting the author, Lessing published anonymously Mendelssohn's *Philosophical Conversations* (*Philosophische Gespräche*) in 1755. In the same year there appeared in Danzig an anonymous satire, *Pope a Metaphysician* (*Pope ein Metaphysiker*), the joint work of Lessing and Mendelssohn. Mendelssohn now became (1756–59) the leading spirit of Nicolai's important literary undertakings, the *Bibliothek* and the *Literaturbriefe,* and ran some risk (which Frederick's good nature obviated) by somewhat freely criticizing the poems of the king of Prussia. In 1762 he married Fromet Gugenheim, who survived him by 26 years. In the year following his marriage Mendelssohn won the prize offered by the Berlin academy for an essay on the application of mathematical proofs to metaphysics, although among the competitors were Abbt and Kant. In Oct. 1763 the king granted Mendelssohn the privilege of Protected Jew (*Schutz-Jude*)—which assured his right to undisturbed residence in Berlin.

As a result of his correspondence with Abbt, Mendelssohn resolved to write on the immortality of the soul. His *Phädon* (1767) was modelled on Plato's dialogue of the same name. Mendelssohn's work possessed some of the charm of its Greek exemplar. The book was translated into nearly all the European languages, and its author was hailed as the "German Plato," or the "German Socrates."

Mendelssohn resolved to devote his life to the culture and the emancipation of the Jews. He began by his German translation of the Pentateuch and other parts of the Bible. This work (1783) constituted Mendelssohn the Luther of the German Jews. From it, the Jews learned the German language; from it they imbibed culture; with it there was born a new desire for German nationality; as a result of its popularity was inaugurated a new system of Jewish education. Mendelssohn was the first great champion of Jewish emancipation in the 18th century. He put forward his plea for tolerance in *Jerusalem oder über religiöse Macht und Judenthum* (1783; Eng. trans. 1838 and 1852). He asserted the

pragmatic principle of the possible plurality of truths: that just as various nations need different constitutions—to one a monarchy, to another a republic, may be the most congenial to the national genius—so individuals may need different religions. The test of religion is its effect on conduct. This is the moral of Lessing's *Nathan the Wise,* the hero of which is undoubtedly Mendelssohn. Having been taught that there is no absolutely true religion, Mendelssohn's own descendants—a brilliant circle, of which the musician Felix was the most noted—left the synagogue for the church. But despite this, Mendelssohn's theory was found to be a strengthening bond in Judaism.

Mendelssohn's *Morgenstunden, oder über das Dasein Gottes* appeared in 1785, and he died as the result of a cold contracted while carrying to his publishers in 1786 the manuscript of a vindication of his friend Lessing, who had predeceased him by five years.

Mendelssohn had six children. His sons were: Joseph (founder of the Mendelssohn banking house, and a friend and benefactor of Alexander Humboldt), whose son Alexander (d. 1871) was the last *Jewish* descendant of the philosopher; Abraham (who married Leah Bartholdy and was the father of Fanny Hensel and J. L. Felix Mendelssohn-Bartholdy); and Nathan (a mechanical engineer of considerable repute). His daughters were Dorothea, Recha and Henriette, all brilliantly gifted women.

See the biography by his grandson G. B. Mendelssohn prefixed to his *Sämtliche Werke* (7 vols., Leipzig, 1843–44) and by M. Brasch in the edition (2 vols., Leipzig, 1880) of his *Schriften zur Philosophie, Aesthetik und Apologetik;* also M. Kayserling, *M. Mendelssohn's Leben und Wirken* (2nd ed., Leipzig, 1888), and *Moses Mendelssohn Ungedrucktes und Unbekanntes von ihm und über ihn* (2nd ed., Leipzig, 1888); L. Goldstein, *Moses Mendelssohn und die deutsche Ästhetik* (Königsberg, 1904); H. Scholz, *Die Hauptschriften zum Pantheismusstreit zwischen Jacobi und Mendelssohn* (1916).

MENDELSSOHN-BARTHOLDY, JAKOB LUDWIG FELIX (1809–1847), German composer, grandson of Moses Mendelssohn (*q.v.*) was born in Hamburg on Feb. 3, 1809. His father, Abraham Mendelssohn, caused Felix, with his brother and two sisters, to be baptized as Lutheran Christians; and during the French occupation of Hamburg the family migrated to Berlin and lived with Abraham Mendelssohn's mother. Under the teaching of their mother and of other good musicians, Felix and his sister Fanny (some of whose compositions are included in Mendelssohn's songs and *Lieder ohne Worte*), soon showed extraordinary musical talent.

At the age of nine he played in public, and at 11 composed voluminously. He and Fanny played their own (or each other's) pianoforte compositions, and his sister Rebecka sang and his brother Paul played the violoncello. Five symphonies were written for this string-band in 1821, in which year Felix produced unaccompanied motets, two and a half operas and an immense amount of other music. The violin sonata of 1820 was published as op. 4.

In 1821 Mendelssohn, with Zelter as his bear-leader, visited Goethe. It is hard to say which of the two impressed the other most. Goethe had not been lucky in his musical acquaintances. Beethoven had repelled him. And now Goethe met this wonderful grandson of "Nathan der Weise," with gifts equal to Mozart's. The boy soon tried, with partial success, to convert Goethe to the gospel of Beethoven.

Before Mendelssohn was 17 he had composed his wonderful octet (op. 20) and a 13th symphony in C minor which he published as his first. A pianoforte quartet in B minor, the last of three, was dedicated to Goethe. Meanwhile he was making important discoveries apart from his own work. At the age of 12 he had read Bach's *Matthew Passion* in the autograph in the royal library, and was so excited by it that his mother had a copy made for him as a birthday present.

A visit to Paris in 1825 brought him into contact with many famous musicians, notably Rossini and Meyerbeer, and he found congenial friends in the great virtuosos of the pianoforte and violin, Hummel, Rode, Baillot and others. He also showed his compositions to the formidable Cherubini, whom he described as "an extinct volcano still throwing out occasional sparks and ashes." Cherubini astonished all musical Paris by praising Mendelssohn to his face, though in the third person. "Le garçon est riche: il fera bien. Mais il faut couper."

Perhaps Mendelssohn's parents overshot the mark in their anxiety to protect him from the dangers of conceit. He saw no great merit in his own smooth technique and was the less inclined to think that there was anything inherently noble in clumsiness. Yet his quick temper was so manifestly generous that artists like Schumann adored him as man and as musician.

After returning from Paris, Abraham Mendelssohn removed from his mother-in-law's house to a spacious old mansion with a music-room and grounds containing a "Gartenhaus" capable of seating several hundred persons. In Aug. 1826 Felix's overture to *A Midsummer Night's Dream* was performed here. He was only 17½ years old; but in later years he rarely equalled and never surpassed this work, which, written in the years of Beethoven's last quartets, belongs not only to fairyland but to an orchestration which Rimsky-Korsakov might have thought up-to-date.

A full-sized opera, *Die Hochzeit des Camacho,* on an episode in the story of Don Quixote, had been finished in 1825, and was produced under Spontini on April 29, 1827. After one much applauded performance Mendelssohn's opera was shelved, and violently abused by the critics.

This organized failure depressed Mendelssohn, but did not check his activity. Besides his usual flood of composition he collected a choir for the study of Bach's choral works (not one of which was then in print); and he succeeded, in 1829, in persuading the Berlin Sing-Akademie to perform the Matthew Passion, under his direction, with a chorus of some 350 voices. This was the first known performance of a choral work of Bach since his death in 1750.

In April 1829 Mendelssohn paid the first of ten visits to England, the last being shortly before his death, in 1847. From the outset he was received with unparalleled enthusiasm. The Philharmonic Society had forgotten the lesson in conducting given by Spohr in 1820; and Mendelssohn, on his first appearance, was obliged to conduct his C minor symphony from the pianoforte; a useless survival of the days of *continuo* orchestration (*see* INSTRUMENTATION, sec. 4). As Spohr said, "Of the two conductors not one is real; the leader of the orchestra has no score and cannot beat time while he is playing; while the gentleman at the pianoforte has no use for his instrument and cannot control the players." In later visits Mendelssohn changed all that. For this first concert he replaced the minuet of his symphony by a wonderful orchestration of the scherzo of his octet. This remained unpublished until 1911. He introduced Beethoven's concerto in E flat to English audiences and, during a visit five years later, the concerto in G. He was one of the first to play a concerto by heart in public; but though this was no effort to his Macaulayesque memory, he cared so little for display that once, when the score of one of his trios was mislaid, he put another volume upside down on the desk and asked somebody to turn the pages in order that he might not be seen to be playing by heart when his colleagues were playing from notes. After the first London performance of the *Midsummer Night's Dream* overture a friend left the score in a cab; but Mendelssohn rewrote it from memory.

During his visits to England his organ recitals revolutionized English organ-playing, and his productions of *St. Paul* and *Elijah* (the latter receiving its first performance at the Birmingham festival of 1846) established his influence on English music as co-equal with that of Handel.

One thing he emphatically did not establish. He did not found the "Mendelssohn tradition" in conducting. That accusation is one of Wagner's calumnies, and Wagner refutes it in the telling. He tells us that when he conducted in England he found that our overloaded programmes compelled him to concentrate his rehearsal on a few items and pull the rest through by bluff. Mendelssohn had had the same experience in the years from 1829 to 1847, and this was what the orchestral players chose to call "the Mendelssohn tradition." Wagner's vitriolic pen has saved him from having his own bluff immortalized by orchestral old stagers as "the Wagner tradition." The true Mendelssohn tradition was represented by Joachim (*q.v.*). It is a tradition of love and

disreputable class of mendicants, now rarely met with.

MENDIP HILLS, Somersetshire, England. The eastern boundary is formed by the upper valleys of the Frome and Brue, and the depression between them. The range extends from these north-westward with a major axis of about 23 m., while the outliers of Wavering Down and Bleadon Hill continue it towards the Bristol Channel. The range is generally about 6 m. in width. Its south-west face descends to the low "moors" drained by the Axe and other streams, and the towns of Axbridge, Cheddar and Wells Towards the north-east its limits are less clearly defined, being high ground, intersected by narrow vales. A depression, followed by the Radstock and Wells road, strikes across the range; the principal elevations lie west of this, and to the area thus defined the name Mendips is sometimes restricted. The summit of the hills is a gently swelling plateau, which reaches its extreme height in the north—1,068 feet. The Mendips consist principally of Carboniferous Limestone. Fine cliffs and scars occur on the flanks of the plateau, as in the gorge of Cheddar, and there is a wonderful series of caverns, the result of water action. The surface is often broken by deep holes ("swallets") into which streams flow. Some caves have yielded large quantities of animal remains (hyaenas, bears and others) together with traces of prehistoric human occupation. Lead was worked among the Mendips at a very early period. Roman workings have yielded pigs of lead, etc., inscribed with the names of emperors of the 1st and 2nd centuries A.D.

MENDOZA, ANTONIO DE (1490–1552), first Spanish viceroy of New Spain (Mexico), was born probably in 1490, at Alcala la Real, near Granada, the second son of Iñigo López de Mendoza, captain-general of the Christian forces investing Granada. At the age of 45, after military and administrative experience in the wars against the Moors, and as royal chamberlain and ambassador to Hungary, Antonio de Mendoza was appointed "viceroy, governor and president of the audiencia" of New Spain on April 17, 1535, and arrived in Mexico in October of the same year. His administration was marked by broad understanding of the problems at hand, by energy in attacking them and by moderation and integrity. Though obstructed by intrigue at court, opposition among his subordinates, uprisings of the partly subjected Indians and the negro slaves, Mendoza laid the foundation of colonial structure and viceregal procedure in Mexico which endured until the 19th century. He instituted a sound political and financial policy; established means of defence, public works and roads; suppressed a religious rebellion of the natives, north of Guadalajara, known as the Mixton War, 1541–42; inspired discovery and exploration in New Mexico (1540–42, *see* CORONADO), California (1540–43) and the Philippine Islands (1542–44); supported the church in converting, educating and protecting the Indians; stimulated agriculture, mining and industries; and introduced printing (1536). In 1551, having firmly impressed the royal authority upon New Spain and made it the best-organized of Spain's new-world colonies, Mendoza was promoted to the viceroyalty of Peru. He arrived there in Sept. 1551, but his health was failing and he died in Lima on July 21, 1552, the greatest of the Spanish viceroys in the New World.

The best account of Mendoza is by A. S. Aiton: *Antonio de Mendoza* (1927), which contains a full bibliography. (W. B. P.)

MENDOZA, ANTONIO HURTADO DE: *see* HURTADO DE MENDOZA, ANTONIO.

MENDOZA, DIEGO HURTADO DE (1503–1575), Spanish diplomatist, historian, scholar and poet, son of the count of Tendilla and great-grandson of the marquis of Santillana, born at Granada. He served under Charles V. in Italy, and preserved his confidence in spite of the failure of his mission in 1537, when he was sent to England to arrange a marriage between Henry VIII. and the duchess of Milan, as well as a marriage between Prince Louis of Portugal and Mary Tudor. Ambassador at Venice in 1539, he patronized the Aldi, procured copies of the Greek mss. of Cardinal Bessarion, and other rare codices from the monastery of Mount Athos. The first edition of Josephus was printed (1544) from the texts in Mendoza's collection. He was military governor of Siena, represented Spain at the Council of Trent and was special plenipotentiary at Rome from 1547–54. He was never a favourite with Philip II., and a quarrel with a courtier resulted in his banishment from court (June 1568). The remaining years of his life, which were spent at Granada, he devoted to the study of Arabic, to poetry, and to his history of the Moorish insurrection of 1568–70, the *Guerra de Granada* (Lisbon, 1627). In some passages of this work the author deliberately imitates Sallust and Tacitus.

See A. Señan y Alonso, *D. Diego Hurtado de Mendoza . . .* (Granada, 1886); *Calendar of Letters and Papers Foreign and Domestic, Henry VIII.*, vol. xii., xiii.; C. Graux, *Essai sur les origines du fonds grec de l'Escurial* (1880); R. Foulché-Delbosc, *Etude sur la "Guerra de Granada,"* in *Revue Hispanique*, i. (1894), pp. 101–165, 338.

MENDOZA, PEDRO GONZALEZ DE (1428–1495), Spanish cardinal and statesman, fourth son of Iñigo Lopez de Mendoza, marquess of Santillana, was born on May 3, 1428, at Guadalajara. The house of Mendoza claimed to descend from the lords of Lladio in Alava, and to have been settled in Old Castile in the 11th century. Pedro Gonzalez was an example of the worldly, political and martial prelates of the 15th century. Appointed bishop of Calahorra by John II. in 1452, in his secular capacity as civil and military ruler of the town and its dependent district, he led the levies of Calahorra in the civil wars of Henry IV. He fought for the king at the second battle of Olmedo (Aug. 20, 1467), and was wounded in the arm. During these years he became attached to Doña Mencia de Lemus, a Portuguese lady-in-waiting of the queen. She bore him two sons, Rodrigo, who was once selected to be the husband of Lucrezia Borgia, and Diego, the grandfather of the princess of Eboli. (*See* PEREZ, ANTONIO.) In 1468 he became bishop of Siguenza. In 1473 he was created cardinal, promoted to the archbishopric of Seville and named Chancellor of Castile.

During the last years of the reign of Henry IV. Mendoza was the partisan of the Princess Isabella, afterwards queen. He fought for her at the battle of Toro (March 1, 1476), and had a prominent part in placing her on the throne. In 1482 he became archbishop of Toledo. During the conquest of Granada he contributed largely to the maintenance of the army. On Jan. 2, 1492, he occupied the town in the name of the Catholic sovereigns. More soldier and statesman than priest, the "Great Cardinal," as he was commonly called, did not neglect his duty as a bishop. He devoted part of his revenue to charity and endowed the college of Santa Cruz at Valladolid. He died at Guadalajara, Jan. 11, 1495.

See Salazar de Mendoza, *Cronica del gran cardinal Don Pedro Gonzalez de Mendoza* (Toledo, 1625); W. H. Prescott, *History of the Reign of Ferdinand and Isabella* (3 vols., 1838).

MENDOZA, a province of western Argentina, bounded north by San Juan, east by San Luis and the territory of La Pampa, south by the territories of La Pampa and Neuquen, and west by the republic of Chile. Area, 56,502 sq.m.; pop. (1914), 277,535; (1927, estimate), 384,090. The Andes form the western boundary, and a considerable part of the territory is covered by the great Cordillera, its foot-hills and flanking ranges. The eastern part is an arid, sandy, level plain, with extensive saline basins, having no vegetation other than coarse grasses and thickets of low, spiny mimosas and "chañar" (*Gourliaea decorticans*). The fertile, populated districts of the province border on the Cordillera, particularly in the north where several streams from the snow-clad summits supply water for irrigation. The secondary ranges in this part of Mendoza are the Sierra de los Paramillos, which encloses the Uspallata valley, and the Sierra del Tunuyán, which encloses a number of populous valleys drained by the Tunuyán river and its tributaries. One of the largest of these is the Yuco valley. Farther south the country becomes more arid and sparsely populated, and unsubdued tribes of Indians for a long time prevented its exploration. In this region the Sierra de Payén and Sierra del Nevado (otherwise known as the Sierra Quero Matro Pellón) extend in a north-easterly direction. With the exception of the Río Grande in the south-west part of the province, which forms the principal source of the Colorado, all the rivers of the province flow easterly and southerly into the great saline depression of western Argentina, which includes a great part of Men-

doza. San Luis and La Pampa. There are the Mendoza, Tunuyán, Diamante and Atuel, with their numerous tributaries, all discharging into the sluggish river which flows from the Huanacache lagoons, on the San Juan frontier, southward to the marshes and lagoons of La Pampa. The upper part of this brackish, swampy stream is called the Desaguadero, and the lower the Salado. It forms the eastern boundary line of the province down to the 36th parallel. With the exception of the elevated districts of the Andes, the climate of Mendoza is hot and dry. Agriculture is the principal occupation where irrigation can be used, the province having a high reputation for its raisins and wines. Alfalfa is an important product, being grown for fattening the cattle driven through the province to the Chilean markets. The mineral resources of the province are said to be good, but receive little attention. Petroleum is found in the vicinity of San Rafael, on the Diamante river, and it is claimed that coal exists in the same region. Although Mendoza was settled by Spanish colonists from Chile as far back as 1559, its development has been hindered by its isolated position. This isolation was broken in 1884 by the completion of the Argentine Great Western railway to the provincial capital. Since then a railway has been built northward to San Juan, and the Trans-Andean line has been completed through the Andes to connect with the Chilean railway system. In addition to Mendoza, the capital of the province, the principal towns (hardly more than villages) are Guaymallén, Maipú, San Martín, Luján and San Rafael.

MENDOZA, a city of Argentina, capital of Mendoza province, 632 m. by rail W.N.W. of Buenos Aires. Pop. (1914), 58,790. It stands on a plain near the foot of a secondary Andean range called the Sierra de los Paramillos, at an elevation of 2,320 feet. The surrounding district is completely arid, but has been irrigated and is covered with gardens, orchards and cultivated fields. The city is about 15 m. N. of the Mendoza, or Luján river, whose waters are utilized for irrigation and for the requirements of the city by means of a channel which leaves the main river a little above the town of Luján and runs to the Tulumaya river and the lagoons of Huanacache. This channel is called El Zanjón, and is believed to have been opened by Guaymallén, the chief of the Guarpés who inhabited this district at the time of the Spanish conquest, but it is more probably natural. The city is laid out in a regular manner with broad, well-paved streets and numerous public squares. The Zanjón and another stream called the Guaymallén traverse the city, and the principal streets have water flowing through them and are shaded by poplars. The surrounding districts produce fruit, vegetables, alfalfa and cereals. The vineyard industry is first, with large exports of raisins and wine. A modern packing house has been established near the city and employs several hundred workmen. The position on the main route of the Trans-Andean railway across the Andes into Chile, by way of the tunnel under the Uspallata or Cumbre pass (highest point 10,542 ft.), has given the city commercial importance. It has railway connection with the principal cities of the republic, including the ports of Rosario, Buenos Aires and Bahía Blanca, and also with San Juan.

Mendoza was founded by Capt. Pedro del Castillo, who had been sent from Santiago across the Andes in 1559 by García Hurtado de Mendoza, the governor of Chile, to conquer and annex the territory extending north-east to Tucumán. The city was named after Mendoza. It was made the capital of the province of Cuyo, and belonged to Chile down to 1776, when the province was transferred to the newly created viceroyalty of La Plata. It was the headquarters of Gen. San Martín while he was organizing an army for the liberation of Chile, and greatly assisted him with men and money. Under republican administration Mendoza suffered much from revolutions. Moreover, on March 20, 1861, the city was destroyed by an earthquake and a fire which followed. Not a building was left standing, and the loss of life was estimated at 10,000 to 12,000. The French geologist Bravard, who had predicted the catastrophe, was one of its victims.

MENEDEMUS (350?–276? B.C.), Greek philosopher, and founder of the Eretrian school of thought, was born at Eretria. Though of noble birth, he worked as builder and tentmaker until he was sent with a military expedition to Megara, where he formed a life-long friendship with Asclepiades. He was subsequently a pupil of Stilpo and then of Phaedo of Elis, whose school he transferred to Eretria, by which name it was afterwards known. He took a leading part in the political affairs of his city from the time of the Diadochi, and obtained a remission of the tribute to Demetrius. His friendship with Antigonus Gonatas seems to have roused suspicion as to his loyalty, and he sought safety in the temple of Amphiaraus at Oropus, and later with Antigonus, at whose court he is said to have died of grief.

Athenaeus quotes Epicrates as stating that he was a Platonist, but other accounts credit him with having preferred Stilpo. Diogenes Laërtius (ii. 134 and 135) says that he declined to identify the Good with the Useful, and that he denied the value of the negative proposition on the ground that affirmation alone can express truth. Diogenes says that he left no writings, and the Eretrian school disappeared after a short existence.

See H. Mallett, *Histoire de l'école de Mégare et des écoles d'Elis et d'Erétrie* (1845); and the articles MEGARIAN SCHOOL; PHAEDO; STILPO.

MENELAUS (*mĕ-nĕ-lā'us*, Gr. *mĕ-nĕ-lah'ŏs*), king of Sparta, brother of Agamemnon (q.v.) and husband of Helen (q.v.). On the voyage from Troy his fleet was scattered by a storm, which drove him to Egypt. After eight years' wandering, he landed on the island of Pharos, where Proteus revealed to him the means of appeasing the gods and securing his return After a long and happy life in Lacedaemon, Menelaus, as the son-in-law of Zeus, did not die, but was translated to Elysium (Homer, *Odyssey*, iii. iv.). His grave and that of Helen were shown at Therapnae, where he was worshipped as a god (Pausanias iii. 19, 9).

MENELEK II. (SAHALA MARIEM) (1844–1913), emperor of Abyssinia, officially negus negusti (king of kings) of Ethiopia, son of Haeli Melicoth, king of Shoa, was born in 1844, and claimed to be a direct descendant of Solomon by the queen of Sheba. Menelek was the real creator of the modern Abyssinian state. On the death of his father in 1855 he was kept a prisoner at Gondar by Kassai, the governor, who had seized the throne under the title of Theodore III. After the death of Theodore in 1868 he continued to struggle against his successor, the emperor Johannes (better known to Europeans as King John of Abyssinia). Being again unsuccessful, he resolved to await a more propitious occasion; so, acknowledging the supremacy of Johannes, in 1886 he married his daughter Zeodita (b. 1876) to the emperor's son, the Ras Area; he was thereupon declared heir to the empire, and on his side acknowledged the Ras Area as his successor. Ras Area died in May 1888, and the emperor Johannes was killed in a war against the dervishes at the battle of Gallabat (Matemma) on March 10, 1889. The succession now lay between the late emperor's natural son, the Ras Mangasha, and Menelek, but the latter was elected by a large majority on the 4th of November, and consecrated shortly afterwards. Menelek had married in 1883 Taïtu (b. 1854), a princess of Tigré, a lady who had been married four times previously and who exercised considerable influence. Menelek's clemency to Mangasha was ill repaid by a long series of revolts.

In 1889, at the time when he was claiming the throne against Mangasha, Menelek signed at Uccialli a treaty with Italy acknowledging Italian claims to the Asmara district. Finding, however, that according to the Italian view of one of its articles the treaty placed his empire under Italian domination, Menelek denounced it; and after defeating the Italians at Amba-Alagi, he compelled them to capitulate at Adowa in February 1896, and a treaty was signed recognizing the absolute independence of Abyssinia. His French sympathies were shown in a reported official offer of treasure towards payment of the indemnity at the close of the Franco-Prussian War, and in February 1897 he concluded a commercial treaty with France on very favourable terms. He also gave assistance to French officers who sought to reach the upper Nile from Abyssinia, there to join forces with the Marchand Mission; and Abyssinian armies were sent Nilewards. A British mission under Sir Rennell Rodd in May 1897, however, was cordially received, and Menelek agreed to a settlement of the Somali boundaries, to

keep open to British commerce the caravan route between Zaila and Harrar, and to prevent the transit of munitions of war to the Mahdists, whom he proclaimed enemies of Abyssinia.

In 1898 the Sudan was reconquered by an Anglo-Egyptian army and thereafter cordial relations between Menelek and the British authorities were established. In 1889 and subsequent years, Menelek sent forces to co-operate with the British troops engaged against the Somali mullah, Mohammed Abdullah. Menelek had in 1898 crushed a rebellion by Ras Mangasha (who died in 1906) and he directed his efforts henceforth to the consolidation of his authority, and in a certain degree, to the opening up of his country to western civilization. He had granted in 1894 a concession for the building of a railway to his capital from the French port of Jibuti, but, alarmed by a claim made by France in 1902 to the control of the line in Abyssinian territory, he stopped for four years the extension of the railway beyond Dire Dawa. When in 1906 France, Great Britain and Italy came to an agreement on the subject, Menelek officially reiterated his full sovereign rights over the whole of his empire. In May 1909 the emperor's grandson Lij Yasu, or Jeassu, then a lad of thirteen, was married to Romanie (b. 1902), granddaughter of the negus Johannes. Two days later Yasu was publicly proclaimed at Adis Ababa as Menelek's successor. At that time the emperor was seriously ill. He died in 1913. *See* Hentze, *Am Hofe des Kaisers Menelek von Abessynien* (1905); Rossetti, *Storia diplomatica dell Etiopia durante il regno di M II.* (1910).

MENENDEZ DE AVILÉS, PEDRO (1519–1574), Spanish seaman, founder of St. Augustine, Florida, was born at Avilés in Asturias on Feb. 15, 1519. At the age of 14 years he ran away to sea, and was engaged in piracy till he was thirty. In 1549 he was commissioned by the emperor Charles V. to clear the north coast of Spain and the Canaries of French pirates. In 1554 he was appointed captain-general of the "flota" or convoy which carried the trade between Spain and America. The appointment was made by the emperor over the head and against the will of the Casa de Contratacion, or governing board of the American trade. His steady refusal to receive bribes, as the reward for permitting breaches of the regulations, made him unpopular with the merchants, while his high-handed ways offended the Casa de Contratacion. Re-appointed commander in 1557, and knowing the hostility of the Casa, he applied for service elsewhere. Until the close of 1559 ample occupation was found for Avilés in bringing money and recruits from Spain to Flanders. In 1560 he was again appointed to command the flota, and he made a most successful voyage to America and back in that and the following year. His relations with the Casa de Contratacion were, however, as strained as ever. On his return from another voyage in 1563 he was arrested by order of the Casa, and imprisoned for twenty months.

On his release he prepared to sail to the Bermudas to seek for his son Juan, who had been shipwrecked. At that time the French Huguenots were endeavouring to plant a colony in Florida. The Spaniards claimed the country as theirs, and its position on the track of the home-coming trade of Mexico rendered its possession by any other power highly dangerous. Philip II. made an *"asiento"* or contract (March 20, 1565) with Avilés, by which he advanced 15,000 ducats and constituted him proprietor of any colony which he could establish in Florida, on condition that the money was repaid. Avilés sailed on July 28 of the same year with one vessel of 600 tons, ten sloops, and 1,500 men. On Aug. 28 he entered and named the Bay of St. Augustine and began a fort there. He took the French post of Fort Caroline (Sept. 20, 1565) and in October exterminated a body of Frenchmen who, under the Huguenot Jean Ribault, had arrived on the coast of Florida. The Spanish commander, after slaying nearly all his prisoners, hung their bodies on trees, with the inscription, "Not as Frenchmen but as Lutherans." A French sea-captain named Dominique de Gourgues revenged the massacre by capturing in 1568 Fort San Mateo (as the Spanish had renamed Fort Caroline), and hanging the garrison, with the inscription, "Not as Spaniards but as murderers." Till 1567 Avilés remained in Florida, busy with his colony. In that year he returned to Spain. He made one more voyage to Florida, and died on Sept. 17, 1574.

See *The Spanish Settlements within the Present Limits of the United States, Florida, 1562–74,* by Woodbury Lowery (1905).

MENENDEZ PIDAL, RAMON (1869–), Spanish philologist, was born on March 13, 1869, at Corunna, and studied at the universities of Madrid and Toulouse. In 1899 he was appointed to the chair of romance philology at the University of Madrid. In 1907 he was member of a board created for the development of university education in Spain, and in 1913 was appointed counsellor of public instruction for the kingdom. His grammar, text and vocabulary of the *Cantar de Mio Cid* (1908) opened out new possibilities not only to Castilian philology but to historiography in general. Menendez Pidal became the leader of the *Centro de Estudios Históricos,* the main house of learning in philology and historical matters in Spain, and the editor of the *Revista de Filología Española.* His other works include *Primera crónica general* (1906); *L'épopée Castillane à travers la littérature espagnole* (1910); *Gramática Histórica Española* (1914); *Un aspecto en la elaboración del Quijote* (2nd ed. 1924).

MENÉNDEZ Y PELAYO, MARCELINO (1856–1912), Spanish scholar and critic, became famous through his *Ciencia española* (1878), a collection of polemical essays defending the national tradition against the attacks of political and religious reformers. The unbending orthodoxy of this work was, if possible, still more pronounced in the *Historia de los heterodoxos españoles* (1880–81), and the writer was hailed as the champion of the ultramontane party. His lectures (1881) on Calderón established his reputation as a literary critic; and his work as an historian of Spanish literature was continued in his *Historia de las ideas estéticas en España* (1883–91), his edition (1890–1902) of Lope de Vega, his *Antología de poetas líricos castellanos* (1890–1908), and his *Orígenes de la novela* (1905).

MENES, the name of the founder of the 1st Dynasty of historical kings of Egypt. He appears at the head of the lists not only in Herodotus and Manetho, but also in the native Turin Papyrus of Kings and the lists of Abydos, while the list of Sakkara begins with the sixth king of the 1st Dynasty, a fact which may throw some doubt on the supposed foundation of Memphis by Menes. He was probably ruler of Upper Egypt and conquered the separate kingdom of Lower Egypt. His grave was discovered by de Morgan at Negadr in Upper Egypt in 1897.

See EGYPT; K. Sethe, "Menes und die Grundung von Memphis," in his *Untersuchungen zur Geschichte und Alterthumskunde Aegyptens,* iii. 121.

MENGELBERG, WILLEM (1871–), Dutch composer of German race, born at Utrecht on March 28, 1871. He received his musical education at Cologne conservatoire, where he studied piano with Isidor Seiss and composition and conducting with Franz Wüllner. His first post was that of musical director at Lucerne. In 1895 he went to Amsterdam to conduct the Concertgebouw orchestra, which under his direction has become one of the most famous in Europe. From 1907 to 1920 he conducted the Museum concerts at Frankfurt, as well as the Amsterdam series, and directed the choral subscription concerts in both places. Before the World War he regularly visited London as a conductor, and from 1921 onward has been an annual visitor to the United States. On his suggestion the National Symphony and Philharmonic orchestras of New York were amalgamated in 1921. He has also toured extensively with his Amsterdam orchestra. Important festivals conducted by Mengelberg were the Netherlands-Hamburg in 1920, the French Music festival in 1922 and the Strauss celebration in 1924.

MENGENLEHRE: *see* AGGREGATES, THEORY OF.

MENGS, ANTONY RAPHAEL (1728–1779), German painter, was born in 1728 at Aussig in Bohemia, but his father, Ismael Mengs, a Danish painter, established himself finally at Dresden, whence in 1741 he took his son to Rome. The appointment of Mengs in 1749 as first painter to the elector of Saxony did not prevent him from spending much time in Rome, where he became in 1754 director of the Vatican school of painting, nor did this hinder him on two occasions from obeying the call of Charles

III. of Spain to Madrid. There Mengs produced some of his best work, and specially the ceiling of the banqueting-hall, the subject of which was the Triumph of Trajan and the Temple of Glory. After the completion of this work in 1777, Mengs returned to Rome, where he died two years later. Besides numerous paintings in the Madrid gallery, the "Ascension" at Dresden, "Perseus and Andromeda" at St. Petersburg, and the ceiling of the Villa Albani must be mentioned among his chief works. In England, the duke of Northumberland possesses a "Holy Family," and the colleges of All Souls and Magdalen, at Oxford, have altar-pieces by him.

See *Opere di Antonio Raffaello Mengs*, published by G. N. d'Azara (Parma, 1780); G. L. Bianconi, *Elogio storico di Mengs* (Milan, 1780); C. Woermann, *Ismael und Raphael Mengs* (Leipzig, 1893); V. Christoffel, *Der Schriftliche Nachlass des Anton R. Mengs* (1918).

MENGTZE, a city of south China in the south-east of the province of Yunnan (23° 24′ N., 103° 22′ E.), situated in a fertile and well cultivated basin on the high plateau, 4,300 feet above sea-level, and enjoying a climate which, tempered by the high altitude, is equable and healthy despite the latitude. The city was opened in 1888 as a Treaty Port and the seat of the French overland trade between Tongking and Yunnan. This overland trade has continued to increase with the result that Mengtze is a flourishing frontier port. It is 40 miles distant from its junk port, Manhao, which is situated at a lower level (900 feet) on the Red River. Before the Yunnan Railway, which connects Haiphong and Yunnan-fu via Mengtze, was opened to traffic in 1910, imports from Haiphong were conveyed along the Red River route by steamer and native craft as far as Manhao, and thence by coolies or pack animals to Mengtze for distribution throughout Yunnan. The bulk of the imports to Mengtze continue inland under transit pass as far as Kweichow. The value of the whole trade has developed yearly.

In 1924, for example, net foreign imports were 14,823,747 Hk. Taels, net Chinese imports were 584,678, and exports 9,976,363, making a total of 25,384,788. Of this total value, direct foreign trade represents 98%. The total Maritime Customs Revenue at Mengtze in the same year amounted to Hk. Taels 790,779. The greater part of both import and export trade of Mengtze is with Hongkong and most of the remainder with Tongking and Annam. Tin (in slabs) is by far the chief export. About 90% of the total Chinese output of tin comes from south Yunnan and of this almost the whole is exported either via Mengtze and the Red River or by rail, to Haiphong and so to Hongkong where it is refined and marketed. Prior to the construction of the railway (under French enterprise) almost the whole output of tin went from Mengtze down to Haiphong via the Red River passage. In 1925, the Mengtze export was 8,860 tons, and railway transport 8,554 tons. Textiles (chiefly cotton), sugar (refined and candy), metals, kerosene and matches are the chief imports.

MENHADEN (*Brevoortia tyrannus*), a Clupeoid fish of the western Atlantic, related to the shads (*q.v.*), but distinguished by the pectinated scales, and by the very long and exceedingly numerous gill-rakers. The menhaden reaches a length of 18 in.; it feeds on plankton, particularly microscopic plants, and approaches the coast to breed in very large shoals. It is the object of an important fishery, being valuable for oil and manure.

MÉNIÈRE'S DISEASE, a form of auditory vertigo, first described in 1861. It usually attacks persons of middle age whose hearing has been previously normal and depends upon haemorrhage into the labyrinth, followed by more or less complete deafness in either or both ears. The attack usually sets in with dizziness, noises in the ears, nausea, vomiting and staggering gait, and the patient may suddenly fall down unconscious. The seizures are usually paroxysmal, occurring at irregular intervals of days or weeks. Between the attacks the equilibrium may be disturbed, there being marked nystagmus and unsteadiness of gait. The attacks of vertigo tend to become less frequent and may entirely pass away, but the deafness may remain permanent. The treatment is very unsatisfactory.

MENIN (Flemish *Meenen*), town of Belgium, province of West Flanders on the Lys 7m. S. of Courtrai. Pop. (1925) 18,769. It manufactures linen and flannel, and in the neighbourhood are extensive tobacco plantations. It was first fortified in 1578, and in 1685 Vauban made it one of the strongest places on the French frontier, but the fortifications were razed in 1748 by the Treaty of Aix-la-Chapelle.

MENINGITIS, a term in medicine applied to inflammation affecting the membranes of the brain (cerebral meningitis) or spinal cord (spinal meningitis) or both.

Tuberculous meningitis (or *Acute Hydrocephalus*) is a disease due to inflammation of the meninges of the brain produced by *B. tuberculosis*. It is most common in children under ten years of age, but may affect adults and is a local manifestation, dependent upon local conditions of a generalized miliary tuberculosis the origin of which is often situated in the bronchial or mesenteric glands.

Certain features characterize the disease in each of its three stages. The premonitory symptoms are mostly nutritive. Wasting and loss of strength often precede the characteristic phenomena of the disease. The patient, if a child, becomes listless, easily fatigued, loses appetite, and is restless at night. There is headache and unusual irritability. These symptoms may persist during many weeks or the disease may come on suddenly. Onset generally begins with vomiting, convulsions or wryneck and with obstinate constipation. Headache is constant, intense and accompanied by a peculiar and characteristic cry especially at night. There is intolerance of light and sound, temperature is 100°–104°, yet the pulse is rather slow and irregular; breathing is irregular. Such symptoms, after one to two weeks, are followed by the stage of depression in which the patient becomes quieter from the existence of partial stupor. Vomiting ceases, there is less fever, pulse and breathing are slower and shallower and there is little suffering. The pupils are often dilated or unequal and scarcely respond to light; there may be squint or drooping of an eyelid. The patient can be roused, but is irritable and otherwise lies in apathy. In the final stage there is generally return of fever, convulsions, perhaps paralysis of limbs, and coma is profound though swallowing remains. Death is sudden in a fit, or gradual from exhaustion and takes place within three weeks from the onset of symptoms. Though much can be done to avert the onset of the original tuberculous infection (*see* TUBERCULOSIS) no measure is known whereby tuberculous meningitis, once it has started, can be cured or a fatal event averted.

Pathologically the brain shows a yellow fibrinous inflammatory exudation beneath the pia mater and particularly in the lozenge shaped space at the base and in the Sylvian fissure. On floating some of the membrane in water minute tubercles may often be seen along the course of the Sylvian vessels.

In what is known as *suppurative*, or *simple acute meningitis* (non-tuberculous), the disease arises from various causes, *e.g.*, middle ear disease, cerebral abscess, and the symptoms are similar to those described above.

In *posterior-basic meningitis*, inflammation of the membranes investing the posterior basis of the brain and the spinal cord, the chief symptoms are fever, with severe pain in the back or loins shooting downwards into the limbs (which are the seat of frequent painful involuntary startings), accompanied with a feeling of tightness round the body.

The local symptoms bear reference to the portion of the cord the membranes of which are involved. Thus when the inflammation is located in the cervical portion the muscles of the arms and chest are spasmodically contracted, and there may be difficulty in swallowing or breathing, or embarrassed heart action, while when the disease is seated in the lower portion, the lower limbs and the bladder and rectum are the parts affected in this way. At first there is excited sensibility (hyperaesthesia) in the parts of the surface of the body in relation with the portion of cord affected. As the disease advances these symptoms give place to those of partial loss of power in the affected muscles, and also partial anaesthesia. These various phenomena may entirely pass away, and the patient after some weeks or months recover; or, on the other hand, they may increase, and end in permanent paralysis.

Cases of posterior basic meningitis are now regarded as sporadic

and somewhat peculiar examples of spinal meningitis (*q.v.*) or cerebro-spinal meningitis. Still, William Hunter and George Nuttall isolated an organism similar to the diplococcus intracellularis (or meningococcus), while Henry Koplik in New York found cases of typical posterior basic meningitis due to the diplococcus intracellularis. The treatment is that for spinal meningitis.

MENINSKY, BERNARD (1891–), British painter, was born in Russia. He studied art at the Slade school, London, in Paris and in Italy. He was an official artist during the World War and one of his pictures of soldiers arriving at a London station from the front is in the Tate gallery. Other pictures are at the Imperial War museum, and at the galleries of Aberdeen, Manchester and Dublin. He is a member of the London group, with a clear and constructive sense of plastic form. His first important exhibition was given in London in 1919 at the Goupil gallery. A series of his drawings were published in *Mother and Child* (1920).

MENIPPUS, of Gadara in Coele-Syria, Greek cynic and satirist, lived during the 3rd century B.C. According to Diogenes Laërtius (vi. 8) he was originally a slave, amassed a fortune as a money-lender, lost it, and committed suicide through grief. His works (written in a mixture of prose and verse) are all lost. The Menippean satires of M. Terentius Varro, fragments of which give an idea of this kind of composition, were called after him (*see* Teuffel-Schwabe, *Hist. of Roman Literature*, § 165, 3).

BIBLIOGRAPHY.—F. Ley, *De vita scriptisque Menippi cynici* (Cologne, 1843); R. Helm, *Lucian und Menipp* (1906); C. Wachsmuth, *Sillographorum graecorum reliquiae* (1885), with an account of Menippus and similar writers. Menippus found an imitator in later times in Justus Lipsius, and in the authors of the famous *Satyre Menippée* (1593; latest editions by C. Marcilly, Paris, 1882; J. Frank, Oppeln, 1884), written against the Holy League during the reign of Henri IV.

MENKEN, ADAH ISAACS (1835–1868), American actress, was born in New Orleans, the daughter of a Spanish Jew. Her original name was Dolores Adios Fuertes. Left in poverty at the age of 13, she made her first appearance as a dancer in her native city. Successful there and in other southern cities, including Havana, she afterwards aspired to act in serious parts. In 1856 she married John Isaacs Menken, translated Adios to Adah, and thus took the name she thereafter bore through various matrimonial ventures. In 1864 she appeared at Astley's in London as Mazeppa, a performance of an athletic dramatic type suited to her fine physique. In England and France she became intimate with many literary men—Swinburne, Charles Reade, Dickens (to whom she dedicated in 1868 a volume of verse, *Infelicia*), Gautier and Dumas the elder. Paris saw her for a hundred nights in *Les Pirates de la Savane,* and she also played in Vienna and London. She died in Paris on Aug. 10, 1868.

MENNONITES, a body of religionists taking their name from Menno Simons (*see* below), who maintain a form of Christianity which, discarding the sacerdotal idea, owns no authority outside the Bible and the enlightened conscience, limits baptism to the believer, and lays stress on those precepts which vindicate the sanctity of human life and of a man's word. There was no hierarchy (as with the Familists), but "exhorters" chosen by the members, among them "elders" for administering baptism and the Lord's Supper. The place of origin of the views afterwards called Mennonite was Zürich, where in 1523 a small community left the state church and adopted the tenet of believers' baptism. Unlike other Reformers, they denied at once the Christian character of the existing church and of the civil authority, though, in common with the first Christians, it was their duty to obey all lawful requirements of an alien power. By Protestants as much as by Catholics this position was not unnaturally regarded as subversive of the established foundations of society. Hence the bitter persecutions which, when the safety of toleration was not imagined, made martyrs of these humble folk, who simply wished to cultivate the religious life apart from the world. There was something in this ideal which answered to that mediaeval conception of separation from the world which had leavened all middle-class society in Europe; and the revolt from Rome had prepared many minds to accept the further idea of separation from the church, for the pursuit of holiness in a society pledged to primitive discipline. Hence the new teaching spread rapidly from Switzerland to Germany, Holland and France. In Holland the Mennonites have always been numerous. An offshoot from them at Rhijnsburg in 1619, founded by the four brothers, farmers, Van der Kodde, and named Collegianten from their meetings, termed *collegia* (thus, as not churches, escaping the penal laws), has been compared to the Plymouth Brethren, but differed in so far as they required no conformity of religious opinion, and recognized no office of teacher. With them, as Martineau notes, Spinoza had "an intense fellow-feeling." Later, the exiled Socinians from Poland (1660) were in many cases received into membership. There had previously been overtures, more than once, for union with Mennonites on the part of Polish Socinians, who agreed with them in the rejection of oaths, the refusal to take human life, the consequent abstinence from military service and magisterial office, and in the Biblical basis of doctrine; differences of doctrinal interpretation precluded any fusion. (X.)

See W. J. Kühler, art. "Mennonites" in Hastings, *Encyclopaedia of Religion and Ethics,* with reference to the sources.

IN AMERICA

The first colony of Mennonites in America settled in Germantown, Pa., in 1683, to escape severe persecution in Europe. They became pioneers in this and other sections, living hardy and useful lives, and holding to freedom of conscience, opposition to war and slavery and such common practices as insurance and interest on money lent. For many years they did not think it necessary to build churches or parsonages or to provide salaries for their ministers or bishops, or special training to fit them for their calling. Strict adherence to the languages they brought with them from Europe—Dutch, German, Russian—strictness or laxity in doctrines or discipline, including the "ban" or excommunication, caused many divisions among them, so that there are a dozen or more separate bodies of Mennonites in the United States and Canada. Among these are the "Old" or Mennonite Church, the oldest and largest division (40,000 members in 1928), who still use the "Pennsylvania Dutch" tongue; the General Conference Mennonite Church (20,000 members), which seeks to heal divisions; the Old Order Amish (8,600 members), which still uses the hymns of the old *Ausbund* of 1571 and tunes which have never been printed; the Mennonite Brethren in Christ (8,600 members), also conservative. Some Mennonites have been opposed to nearly everything modern, including Sunday schools, missions and revivals, but rapid changes are taking place and not a few colleges, publishing houses and missionary enterprises are supported by them. Also there has been a remarkable increase in the number of church edifices, Sunday schools and salaried ministers. Evangelism has developed greatly in the last half century. A large number of ministers have entered upon a travelling plan, supported by $1,000,000 or more, which has been very successful. There were in 1927 about 115,000 members in America, 90,000 in the United States and about 25,000 in Canada.

BIBLIOGRAPHY.—C. Henry West, *Mennonites of America* (1910); *The Mennonites* (1920, Berne, Ind.); Daniel Kaufman, *Mennonite History* (1927); also a *Year Book* put out by the Mennonite publishing house. (H. K. C.)

MENNO SIMONS (1492–1559), religious leader, was born in 1492 at Witmarsum, Friesland. He was ordained priest, and was curate at Pingjum, near his native place when he began to read Luther's tracts, to study the New Testament and to question infant baptism. The execution, in 1531, at Leeuwarden, of the tailor Sicke Freerks, who had been rebaptized at Emden, introduced further questions. Menno was not satisfied with the inconsistent answers which he got from Luther, Bucer and Bullinger. In 1532 he exchanged his curacy for a living at Witmarsum. Anabaptism of the Münster type repelled him. A brother of Menno joined the insurgent followers of John Matthyszoon, and was killed at Bolsward (April 1535), and on Jan. 12, 1536, Menno left the Roman communion. There were now among the Anabaptists four parties, the favourers of the Münster faction, the Batenburgers, extremists, the Melchiorites and the Obbenites

For a time Menno remained aloof from both Melchior Hofman and Obbe Philipsz. Before the year was out, yielding to the prayer of a few who had left the Münster faction, he became their minister, and was set apart (Jan. 1537) to the eldership at Groningen, with imposition of hands by Obbe Philipsz, who is regarded as the actual founder of the Mennonite body. In fact, Obbe left the body and is stigmatized as its Demas. Menno repudiated the formation of a sect; those who had experienced the "new birth" were to him the true Christian church. His Christology was in the main orthodox, though he rejected terms (such as Trinity) which he could not find in Scripture, and held a Valentinian doctrine of the celestial origin of the flesh of Christ. His church discipline was drawn from the Swiss Baptists. Neither baptism (by pouring on the head) nor the Lord's Supper (with the accompaniment of feet-washing) conferred grace; they were divine ordinances which reflected the believer's inward state. Marriage with outsiders was prohibited. Oaths and the taking of life were absolutely forbidden; hence the magistracy and the army were for the Mennonite unlawful callings; but magistrates were to be obeyed in all things not prohibited by Scripture.

Menno was an active missioner; his changes of place, often compulsory, are difficult to trace. He was apparently much in East Friesland till 1541; in North Holland, with Amsterdam as centre, from 1541 to 1543; again till 1545 in East Friesland (where he held a disputation at Emden with John à Lasco in 1544); till 1547 in South Holland; next, about Lübeck; at Wismar in 1553–54 (holding disputations with Martin Micronius at Norden); lastly at Wüstenfelde, a village between Hamburg and Lübeck, where he died on Jan. 13, 1559.

The collection of Menno's *Opera Omnia Theologica* (Amsterdam, 1681), folio, in a Dutch version, comprises 23 tractates, with reference to nine unprinted. A selection (*Gedenkblätter*) from his writings, in a German version, was edited by J. Mannhardt (Danzig, 1861) with an appendix from the writings of Dirk Philipsz (1504–70), brother of Obbe, and Menno's henchman. His writings are published in English at Elkhart, Indiana. *See* R. Barclay, *Inner Life of Religious Societies of the Commonwealth* (1876) for a good account of Mennonite anticipations of Quaker views and practices; F. C. Fleischer, *Menno Simons, eene Levensschets* (1892); V. M. Reimann, *Mennonis Simonis qualis fuerit vita* (1894); S. Cramer, in Hauck's *Realencyklopädie* (1903); a separate article in the same, *Mennoniten*, by S. Cramer, gives a survey of the origin and ramifications of the movement in Europe and America.

MENOMINEE. This Algonkin tribe of Indians, of the Central group, has lived since its discovery early in the 17th century, about Menominee river, north-west of Lake Michigan. They lived largely on wild rice (*Zizania*), and were generally at war with their Algonkin neighbours. Some 1,700 survive in Wisconsin; the original population was little if any larger. *See* W. J. Hoffman, *Bur. Am. Ethn. Rep. XIV.*, 1896; A. E. Jenks, *ibid.*, xix., 1901; A. Skinner, *Am. Mus. Nat. Hist. Anth. Pap.*, vol. xiii. 1913–15, *Indian Notes and Monographs,* vol. iv. 1920, 1921.

MENOMINEE (mẹ-nŏm′ ĭn-ē), a city of the Upper Peninsula of Michigan, U.S.A., on Green bay (Lake Michigan) at the mouth of the Menominee river, opposite Marinette (Wisconsin). It is on federal highway 41, and is served by the Chicago and North Western, the Chicago, Milwaukee, St. Paul and Pacific, the Wisconsin and Michigan and (by car-ferry through the Sturgeon Bay canal and across the lake to Frankfort) the Ann Arbor railways, and lake steamers. The population was 8,907 in 1920 (21% foreign-born white) and was 10,320 in 1930 (by Federal census). The commerce of the harbour (including Marinette) amounted in 1926 to 822,468 tons (valued at $62,130,625) of which 481,911 tons was car-ferry traffic. Menominee has important manufactures, including the largest baby-carriage factory in the country. The county agricultural college was founded here in 1907. In 1634 Nicollet found the Menominee Indians (an Algonquian tribe) living at the mouth of the river. A trading post was established in 1799; permanent settlement began in 1833; the village became the county seat in 1864, and was chartered as a city in 1883. The name is a Chippewa word for wild rice.

MENOMONIE, a city of western Wisconsin, U.S.A., on the Red Cedar river, 65 m. E. of Saint Paul; the county seat of Dunn county. It is on Federal highway 12, and is served by the Chicago, Milwaukee, St. Paul and Pacific and the Chicago, St. Paul, Minneapolis and Omaha railways. Pop. (1920) was 5,104. It is the trade centre and shipping point for a rich farming region, and has brickyards and several other manufacturing industries. In earlier days it was one of the great lumbering centres of the North-west. Most of its public institutions were founded and endowed by James Huff Stout (1848–1910) who came here from Saint Louis in 1889 and made a considerable fortune as a lumberman. Chief among them is the Stout institute, established by him in 1893 as a training school for boys and girls in the manual arts and domestic economy; expanded in 1903 to train teachers for these subjects; taken over by the State in 1911, and since then administered (as one of the State teachers colleges. The enrolment is about 600. Menomonie was settled about 1846 and was chartered as a city in 1882.

MENOPAUSE (CLIMACTERIC), a medical term meaning primarily the cessation of menstruation, but has come to connote the permanent cessation of the monthly periods that forms the most obvious sign that the reproductive life of a woman has come to an end. Translated into popular language it is "the change of life."

The cessation of menstruation is but the outward indication of internal changes of which the primary one is the cessation of ovarian activity. Menstruation (*q.v.*) is determined by the periodic ripening and bursting of small sacs in the ovary containing the egg-cells. Associated with these cyclical changes in the ovary are internal chemical (metabolic) changes in the body, in which other glands of internal secretion, particularly the thyroid and pituitary, play a part with the ovarian secretions. The result of the withdrawal of the ovary and its secretions is that the time of adjustment is sometimes associated with disordered health.

The age at which the menopause occurs has wide variations, but is usually between 45 and 50. The way in which the menopause occurs is also very variable. Menstruation may end suddenly and completely and without warning or it may gradually cease by diminishing losses and lengthening intervals spread over a year or more; occasionally, but not to the extent credited by the women themselves, these irregular periods may be accompanied by profuse losses.

Normally the adjustment to these internal bodily changes is made without disturbance of health of mind or body, or at most with trifling discomforts. Such as do arise are liable to be exaggerated in certain individuals and may require medical treatment. The commonest psychical change is mental depression with lack of energy, sleeplessness, headaches and neuralgias and disordered sensations of various kinds. It is the time at which the childless woman may think herself pregnant and even have a phantom enlargement of the abdomen and mock labour pains. In those exposed to mental stress at this time or hereditarily predisposed, there are increased risks of insanity, which would appear to be greater in the more educated and cultured classes. Among the nervous phenomena the most common are "heats" and "flushes" with reddening of the face and neck, sometimes accompanied by sweating, which may be momentary or last for some minutes. More commonly a later effect, but sometimes beginning before the menopause is a tendency to adiposity.

A *premature menopause* may occur at any age from disease of the ovaries or other glands of internal secretion or grave nutritional disorder, but is occasionally met with before 40 as the result of a serious illness or profound emotional stress. An *artificial menopause* is produced by the complete removal of both ovaries or by the destruction of their function by radium or X-rays. The earlier in a woman's life it is brought about, the more severe are the symptoms produced, the psychical and nervous disorders being specially exaggerated.

From the medical standpoint the most important feature of the menopause is concerned with the fact that as reproductive activity wanes there is a tendency to overgrowth (obesity, goitre) and new-growth (tumours) of the uterus and ovary, for which a special watch must be maintained. Irregular bleeding is usually the first sign of cancer of the womb and increased menstrual losses of fibroid tumours and both are prone to be ascribed by women to

the "change of life" and their early stages to be disregarded. Also abdominal enlargement is liable to be considered as due to obesity when it may be tumour-formation. Hence it is important that a thorough investigation be made of all women in whom this time of life presents any marked deviation from the normal, particularly in the direction of excessive bleeding from the womb. (J. S. Fa.)

MENSA and **MAREA,** semi-nomad pastoral tribes of Africans occupying part of the Abyssinian highlands included in the Italian colony of Eritrea, and the adjacent coast plains of the Red Sea, the Marea chiefly in the valley of the Khor Anseba, the Mensa dwelling farther north. These tribes claim Arab origin, tracing their descent from an uncle of the Prophet. Under Abyssinian rule they were Christians, but became Mohammedans in the 19th century. They speak a dialect of Tigrin (Abyssinian). On the death of a Marea the head of every dependent *tigré* or slave family must give his heirs a cow. The tribes punish an illegitimate birth by putting parents and child to death.

MENSDORFF-POUILLY-DIETRICHSTEIN, ALBERT, Count von (1861–), Austro-Hungarian diplomatist, was born at Lemberg on Sept. 5, 1861, the second son of Alexander von Mensdorff-Pouilly, Prince Dietrichstein. In 1886 he was attached to the Austrian embassy in Paris, and transferred in 1889 to London, where he was ambassador from 1904 to August 1914. He supported every attempt to avert the danger of the World War, and was repeatedly entrusted during the War with missions directed towards peace, including the important but fruitless negotiations with General Smuts in Switzerland, Dec. 1917.

MENSHIKOV, ALEXANDER DANILOVICH, Prince (1663?–1729), Russian statesman, was born not earlier than 1660 nor later than 1663. At the age of twenty he was gaining his livelihood in the streets of Moscow as a vendor of meat-pies. François Lefort, Peter's first favourite, took him into his service and finally transferred him to the tsar. On the death of Lefort in 1699, Menshikov succeeded him as prime favourite. Ignorant, brutal, grasping and corrupt as he was, he deserved the confidence of his master. He could drill a regiment, build a frigate, administer a province, and decapitate a rebel with equal facility. During the tsar's first foreign tour, Menshikov worked by his side in the dockyards of Amsterdam, and acquired a thorough knowledge of colloquial Dutch and German. He took an active part in the Azov campaigns (1695–96), and superseded Ogilvie as commander-in-chief during the retreat before Charles XII. in 1708, subsequently participating in the battle of Holowczyn, the reduction of Mazepa, and the crowning victory of Poltava (June 26, 1709), where he won his marshal's bâton. From 1709 to 1714 he served during the Courland, Holstein and Pomeranian campaigns, but then, as governor-general of Ingria, with almost unlimited powers, was entrusted with a leading part in the civil administration. Menshikov was the right hand of the tsar in all his gigantic undertakings. But every time the tsar returned to Russia he received fresh accusations of peculation against "his Serene Highness." Peter's first serious outburst of indignation (March 1711) was due to the prince's looting in Poland. On his return to Russia in 1712, Peter discovered that Menshikov had winked at wholesale corruptions in his own governor-generalship. Peter warned him "for the last time" to change his ways. Yet, in 1713, he was implicated in the famous Solov'ey process over the export of corn, in the course of which it was demonstrated that he had defrauded the government of 100,000 roubles. He only owed his life on this occasion to a sudden illness. In the last year of Peter's reign fresh frauds and defalcations of Menshikov came to light, and he was obliged to appeal for protection to the empress Catherine. It was chiefly through the efforts of Menshikov and his colleague Tolstoi that, on the death of Peter, in 1725, Catherine was raised to the throne. During her short reign (February 1725–May 1727), Menshikov was practically absolute. He contrived to prolong his power after Catherine's death by means of a forged will and a *coup d'état.* While his colleague Tolstoi would have raised Elizabeth Petrovna to the throne, Menshikov set up the youthful Peter II., son of the tsarevich Alexius, with himself as dictator during the prince's minority. He now aimed at establishing himself definitely by marrying his daughter Mary to Peter II. But the old nobility overthrew him, and he was deprived of all his dignities and offices and expelled from the capital (Sept. 9, 1727). He died in exile at Berezov, Siberia, on Nov. 12 (O.S.), 1729.

See G. V. Esipov, *Biography of A. D. Menshikov* (Rus.) (St. Petersburg, 1875); N. I. Kostomarov, *The History of Russia in the biographies of her great Men* (Rus.), vol. ii. (St. Petersburg, 1888, etc.); R. Nisbet Bain, *The First Romanovs* (London, 1905); ibid. *The Pupils of Peter the Great,* ch. 2–4 (Westminster, 1897). (R. N. B.; X.)

MENSHIKOV, ALEXANDER SERGEIEVICH, Prince (1787–1869), great-grandson of the preceding, born on Sept. 11, 1787, accompanied the emperor Alexander throughout his campaigns against Napoleon, and retired from army service in 1823. At the time of the dispute as to the Holy Places he was sent on a special mission to Constantinople, and when the Crimean war broke out he was appointed commander-in-chief by land and sea. He commanded the Russian army at the Alma and in the field operations round Sevastopol. In March 1855 he was recalled. He died on May 2, 1869 at St. Petersburg.

MENSTRUATION. Normal menstruation consists in the escape of from 4 to 6 oz. of blood together with mucus from the uterus at intervals of 28 days (more or less). Menstrual blood does not coagulate under ordinary circumstances. The flow begins at the age of puberty, the average age of which in England is between 14 and 16 years. It ceases between 45 and 50 years of age, and this is called the menopause or climacteric period, commonly spoken of as "the change of life." Both the age of puberty and that of the menopause may supervene earlier or later according to local conditions. Very rarely the menstrual flow may be replaced by haemorrhage from distant organs (epistaxis, haematemesis, haemoptysis); this is called *vicarious menstruation.* Menstruation is closely associated with ovulation (*see* Embryo).

The usual disorders of menstruation are : (1) *amenorrhoea* (absence of flow), (2) *dysmenorrhoea* (painful flow), (3) *menorrhagia* (excessive flow), (4) *metrorrhagia* (excessive and irregular flow).

Amenorrhoea may arise from physiological causes, such as pregnancy, lactation, the menopause; constitutional causes, such as phthisis, anaemia and chlorosis, febrile disorders, some chronic intoxications, such as morphinomania, and some forms of cerebral disease; local causes, which include malformations or absence of one or more of the genital parts, such as absence of ovaries, uterus or vagina, atresia of vagina, imperforate cervix, disease of the ovaries, or sometimes imperforate hymen. The treatment of amenorrhoea must be directed towards the cause. In anaemia and phthisis menstruation often returns after improvement in the general condition, with good food and good sanitary conditions, an outdoor life and the administration of iron or other tonics. In local conditions of imperforate hymen, imperforate cervix or ovarian disease, surgical interference is necessary. Amenorrhoea is permanent when due to absence of the genital parts.

The causes of dysmenorrhoea (*see* Women, Diseases of) are classified as follows: (1) ovarian, due to disease of the ovaries or Fallopian tubes; (2) obstructive, due to some obstacle to the flow, as stenosis, flexions and malpositions of the uterus, or malformations; (3) congestive, due to subinvolution, chronic inflammation of the uterus or its lining membrane, fibroid growths and polypi of the uterus, cardiac or hepatic disease; (4) neuralgic; (5) membranous. The foremost place in the treatment of dysmenorrhoea must be given to aperients and purgatives administered a day or two before the period is expected. By this means congestion is reduced. Hot baths are useful, and various drugs. Medicinal treatment is, however, only palliative, and flexions and malpositions of the uterus must be corrected, stenosis treated by dilatation, fibroid growths if present removed, and endometritis when present treated by local applications or curetting according to its severity.

Menorrhagia (*see* Women, Diseases of) signifies excessive bleeding at the menstrual periods. Constitutional causes are purpura, haemophilia, excessive food and alcoholic drinks and warm climates; while local causes are congestion and displacements of

the uterus. endometritis, subinvolution, retention of the products of conception, new growths in the uterus such as mucous and fibroid polypi, malignant growths, tubo-ovarian inflammation and some ovarian tumours.

Metrorrhagia is a discharge of blood from the uterus, independent of menstruation. It always arises from disease of the uterus or its appendages. Local causes are polypi, retention of the products of conception, extra uterine gestation, haemorrhages in connection with pregnancy, and new growths in the uterus.

In the treatment of both menorrhagia and metrorrhagia the local condition must be carefully ascertained. When pregnancy has been excluded, and constitutional causes treated, efforts should be made to relieve congestion. Uterine haemostatics, as ergot, ergotin, tincture of hydrastis or hamamelis, are of use, together with rest in bed. In uncomplicated uterine haemorrhage local treatment with radium is very beneficial. Fibroid polypi and other new growths must be removed. Irregular bleeding in women over 40 years of age is frequently a sign of early malignant disease, and should on no account be neglected. (*See* also GYNAECOLOGY.)

MENSURATION, that branch of mathematics which deals with the quantitative measurement of length, areas and volumes; or, in a more limited sense, with so much of this subject as is not ordinarily treated under Geometry or Trigonometry. Mensuration of continuous graphs, *i.e.*, of figures which may be regarded as traced out by a moving ordinate, is usually known as *Quadrature* (*see* §6). The present article mainly gives formulae, without proofs.

MENSURATION OF GEOMETRICAL FIGURES

1. **Areas of Plane Rectilinear Figures.**—(i.) We begin with some simple plane figures. The square, rectangle, parallelogram and triangle may all be regarded as particular cases of the *trapezium* (U.S.A. usage, trapezoid, the word "trapezium" being generally dropped), which is a quadrilateral with two parallel sides. If the sides are a and b, and the distance between them is h, the area of the trapezium is $h\cdot\frac{1}{2}(a+b)$. In the case of the triangle, for instance, b is zero, so that the area is $\frac{1}{2}ha$, *i.e.*, half the product of a side by the perpendicular distance of the opposite angle from it.

(ii.) If the two parallel sides of a trapezium are at right angles to one of the remaining sides, the figure is called a *right trapezium.* The two parallel sides are the *sides*, the side at right angles to them is the *base*, and the fourth side is the *top*. The area is the product of the base by the mean of the two sides.

(iii.) A figure such as $ABCDEFSM$ (fig. 1), bounded by a base MS, two sides MA and SF at right angles to the base, and a rectilinear top $ABCDEF$, is called a *trapezoid.* (In U.S.A., generally referred to as a general quadrilateral, "trapezoid" being used for "trapezium.") It can be split up into a series of right trapezia by drawing perpendiculars BN, CP, DQ, ER. One or both of the extreme trapezia may be a triangle. This would be the case, *e.g.*, if in fig. 1 F and S coincide.

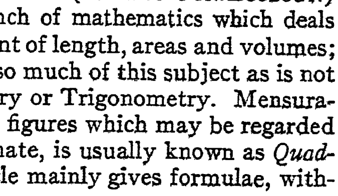


FIG. 1

(iv.) The area of any rectilinear figure may be found in various ways, as for example:

(*a*) The figure may be divided into triangles. The quadrilateral, for instance, can be treated as made up of two triangles, and its area is the product of half the length of one diagonal by the sum of the perpendiculars drawn to this diagonal from the other two angular points.

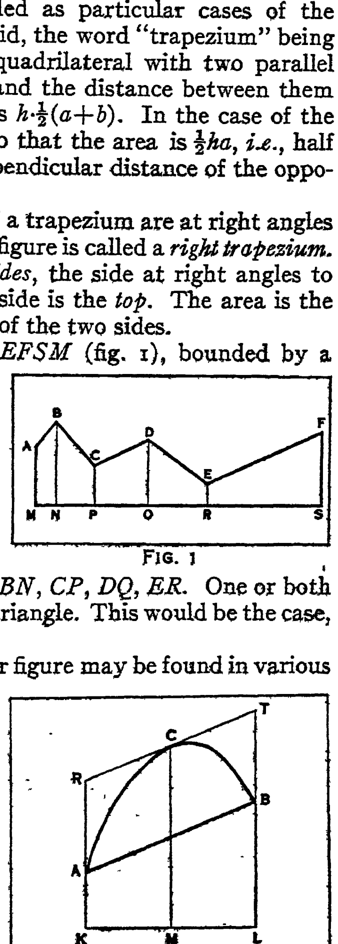

FIG. 2

(*b*) The figure may, by drawing a straight line through it, be divided into two trapezoids.

2. **Surfaces and Volumes of Solids.**—The solid figures with which we are concerned may be grouped as of various types, some coming under more than one type.

(i.) The *prism* is a figure bounded by two parallel planes, all sections by planes parallel to these planes being congruent figures with corresponding points lying on parallel lines. The length of any one of these lines is the length of the prism. The section at right angles to the lines is the *cross-section*. This definition includes the cube, the parallelepiped and the cylinder. The surface of a prism (excluding the two ends) is $=$(perimeter of cross-section)$\times$length; the volume is $=$(area of cross section) $\times$length.

(ii.) The *prismoid* (or *prismatoid*) may be defined as a solid figure with two parallel plane rectilinear ends, each of the other (*i.e.*, the lateral) faces being a triangle with an angular point in one end of the figure and its opposite side in the other. Two adjoining faces in the same plane may together make a trapezium. More briefly, the figure may be defined as a polyhedron with two parallel faces containing all the vertices. The definition covers prism, pyramid and frustum of a pyramid; the cylinder, cone and frustum of a cone may be regarded as limiting cases.

The volume of a prismoid is $\frac{1}{6}h(A+4C+B)$, where h is the perpendicular distance between the two ends, A and B are the areas of the ends, and C is the area of a section parallel to the ends and midway between them. This is the *prismoidal formula:* it applies to other figures than the prismoid, *e.g.*, to the sphere (*see* §13).

In the case of a cylinder, $A=B=C$; in the case of a pyramid or a cone A is 0, and C is one-fourth of B, so that the volume is $\frac{1}{3}hB$; in the case of a frustum of a pyramid or a cone $C^{\frac{1}{2}}$ is the mean of $A^{\frac{1}{2}}$ and $B^{\frac{1}{2}}$, and the volume is therefore $\frac{1}{3}h[A+(AB)^{\frac{1}{2}}+B]$.

(iii.) The surface (excluding the ends) of a prismoid is *developable, i.e.*, it can be unrolled flat on a plane. Hence the area of the curved surface of a right circular cone is $=\frac{1}{2}$(slant height) $\times$ (perimeter of base).

(iv.) The *sphere* is not a prismoid, but the prismoidal formula is applicable to its volume. If a is the radius of a sphere, then

Volume of sphere $=\frac{4}{3}\pi a^3=\frac{2}{3}$ vol. of circumscribing cylinder,
Surface of sphere $=4\pi a^2=$ curved surface of circumscribing cylinder
$=\frac{2}{3}$ total surface of circumscribing cylinder.

These formulae are due to Archimedes.

(v.) The *wedge*, in the most general sense, is formed by cutting a triangular prism by any two planes (not intersecting within the prism). Its volume is $=$(mean of the 3 parallel edges)$\times$(area of cross-section).

3. **Moments and Centroid.**—The ideas of moment and of centroid (centre of gravity) are extended to plane figures, surfaces and solids. Let F be a plane figure, L any straight line in its plane. Suppose F to be divided up into a large number n of equal elements. Let Σ be the sum of the products obtained by multiplying the area of each element by its distance from L. Then the limit of Σ when n is made indefinitely great is called the *moment*, or *first moment*, of F with regard to L. The *centroid* of F is a point G in F (or fixed with regard to F) such that, wherever L may be, this moment is equal to the product of the whole area of F by the distance of G from L. The centroid of a surface in general or of a solid is defined in the same way, moments being taken with regard to planes. The proof of the existence of a centroid is the same as the proof of the existence of the centroid of a material body. (*See* MECHANICS.) Moments of higher order than the first, *i.e.*, *second moments*, *third moments*, $\cdots$ are obtained by multiplying the elements by the squares, cubes, $\cdots$ of their distances from the line or plane.

4. **Moments About Central Line or Plane.**—When we have found moments of a plane figure with regard to a line in the plane, or of a surface or a solid with regard to a plane, we may require to find the moments about a line or plane through the centroid. Taking the case of a plane figure, let the area be M_0', and let the moments as found be M_1', M_2', M_3', $\cdots$, M_q'; and let x be the distance of the centroid from the original line. Then the first moment with regard to the central line is $M_1'-xM_0'$; this is 0, so that $x=M_1'/M_0'$. The qth moment with regard to the

central line is

$$M_q = M_q' - qxM'_{q-1} + \frac{q(q-1)}{2!}x^2M'_{q-2} - \cdots$$
$$\cdots + (-)^{q-1}qx^{q-1}M_1' + (-)^q x^q M_0';$$

and the last two terms are together $= +(-)^{q-1}(q-1)x^qM_0'$. The formula is the same for the moment of a surface or a volume with respect to a plane.

5. **Solids and Surfaces of Revolution.**—The solid or surface generated by the revolution of a plane closed figure or a plane continuous line about a straight line in its plane, not intersecting it, is a *solid of revolution* or *surface of revolution*, the straight line being its *axis*. The revolution need not be complete, but may be through any angle.

The two important theorems are:—

(i.) If any plane figure revolves about an external axis in its plane, the volume of the solid generated by the revolution is equal to the product of the area of the figure and the distance travelled by the centroid of the figure.

(ii.) If any line in a plane revolves about an external axis in the plane, the area of the curved surface generated by the revolution is equal to the product of the length of the line and the distance travelled by the centroid of the line.

These theorems were discovered by Pappus of Alexandria (*c.* A.D. 300, but possibly as early as the first century), and were made generally known by Guldinus (*c.* A.D. 1640). They are sometimes known as *Guldinus's Theorems*, but are more properly described as the *Theorems of Pappus*. The theorems are of use, not only for finding the volumes or areas of solids or surfaces of revolution, but also, conversely, for finding centroids or centres of gravity. They may be applied, for instance, to finding the centroid of a semi-circle or of the arc of a semi-circle.

QUADRATURE

6. Quadrature is, in its most general sense, the mensuration of areas. In the more limited sense in which it is used in this article, it is, viewed arithmetically, the process of expressing an integral in terms of certain values of the integrated quantity; viewed geometrically, it is the process of expressing the area of a particular kind of plane figure, called a trapezette, in terms of certain of its ordinates. These may be regarded as different aspects of the same process, if, on the one hand, the integrated quantity is represented by a graph, or if, on the other hand, the area of the figure is found by integration. The process is also called *mechanical quadrature* or *numerical integration*. The word may be taken as covering the determination not only of the area of a trapezette but also of its moments.

The extension of the methods of quadrature to solid figures is *cubature*: it will be convenient to treat these as two parts of one subject. We shall therefore proceed under the following heads:—I. Area of trapezette in terms of ordinates; II. Moments of trapezette in terms of ordinates or areas; III. Cubature.

I. AREA OF TRAPEZETTE IN TERMS OF ORDINATES

7. A *trapezette* is a figure of the kind with which we are familiar as the graph of a continuously varying positive function. It is bounded by a base, two sides, called the *bounding ordinates*, and an upper boundary which is a curved line; if this line meets the base at either extremity of the figure, the bounding ordinate is zero. Any line drawn from and at right angles to the base to meet the upper boundary is an *ordinate* of the figure. The figure may be regarded as traced out by an ordinate which moves from one extremity of the base to the other extremity.

8. **Notation.**—The moving ordinate of the trapezette will be denoted by u, and the *abscissa* of this ordinate, *i.e.*, the distance of its foot from a certain fixed point or origin O on the base (or the base produced), will be denoted by x, so that u is some function of x. The breadth of the trapezette, *i.e.*, the distance between its bounding ordinates, will be denoted by H. The *mid-ordinate* is the ordinate mid-way between the bounding ordinates.

The data of a trapezette are usually its breadth and either the bounding ordinates or the mid-ordinates of a series of minor trapezettes or strips into which it is divided by ordinates at equal distances. If there are m of these strips, and if the breadth of each is h, so that $H=mh$, it is convenient to write x in the form $x_0+\theta h$, and to denote it by x_θ, the corresponding value of u being u_θ. The data are then either the bounding ordinates $u_0, u_1, u_2, \cdots, u_m$ of the strips or their mid-ordinates $u_{\frac{1}{2}}, u_{\frac{3}{2}}, \cdots, u_{m-\frac{1}{2}}$.

The *central ordinate* is the ordinate through the centroid (*see* §3) of the trapezette. Its distance from any straight line parallel to the ordinate is equal to the mean distance of the trapezette from the line.

9. **Types of Formula.**—The formulae that we have to consider are of five types. In the first four the ordinates are supposed to be at equal distances.

(i.) The two trapezoidal rules.

(ii.) Rules such as Simpson's, in which more weight is given to some ordinates than to others.

(iii.) The rules (i.) with corrections depending on the extreme values.

(iv.) The rules (ii.) with corrections depending on the extreme values.

(v.) Formulae which involve ordinates taken at unequal intervals.

The formulae of types (i.) and (ii.) are called "rules." This name is given to a formula which is made up of repetitions of a simpler formula. Suppose, for instance, that m is even and $=2n$, so that the m strips of the trapezette can be grouped in pairs. Then, as will be seen presently, *Simpson's formula* gives $\frac{1}{3}h(u_0+4u_1+u_2)$ as the area of the first pair; taking this for each pair, we get *Simpson's rule* ($\fallingdotseq$ denoting approximate equality):

$$\text{Area} \fallingdotseq \tfrac{1}{3}h(u_0+4u_1+u_2)+\tfrac{1}{3}h(u_2+4u_3+u_4)+\cdots$$
$$\cdots+\tfrac{1}{3}h(u_{2n-2}+4u_{2n-1}+u_{2n})$$
$$\fallingdotseq \tfrac{1}{3}h(u_0+4u_1+2u_2+4u_3+2u_4+\cdots$$
$$\cdots+2u_{2n-2}+4u_{2n-1}+u_{2n}).$$

10. **Type (i.): Trapezoidal.**—Type (i.) covers two rules.

(*a*) The *trapezoidal rule*, ordinarily so-called, applies when we know the bounding ordinates $u_0, u_1, u_2, \cdots, u_m$. The area given by this rule is called the *chordal area*, and is denoted by C_1. The formula is

$$\text{Area} \fallingdotseq C_1 \equiv h(\tfrac{1}{2}u_0+u_1+u_2+\cdots+u_{m-1}+\tfrac{1}{2}u_m). \qquad (1)$$

(*b*) The *trapezoidal rule for mid-ordinates* applies when we know the mid-ordinates $u_{\frac{1}{2}}, u_{\frac{3}{2}}, u_{\frac{5}{2}}, \cdots, u_{m-\frac{1}{2}}$. The area given by the rule is called the *tangential area*, and is denoted by T_1. The formula is

$$\text{Area} \fallingdotseq T_1 \equiv h(u_{\frac{1}{2}}+u_{\frac{3}{2}}+\cdots+u_{m-\frac{1}{2}}). \qquad (2)$$

In each case, the formula is obtained by taking each strip separately and assuming that its top is a straight line, *i.e.*, that the strip is a trapezium. Taking the first strip, let KA and LB in fig. 2 be u_0 and u_1, and let MC be $u_{\frac{1}{2}}$. Then the "*chordal*" area of the strip is found by replacing the arc ACB by the chord AB, so that the area is $\frac{1}{2}KL(KA+LB)=\frac{1}{2}h(u_0+u_1)$; and the "tangential" area is found by replacing the arc by the tangent RT, so that the area is $KL.\,MC=hu_{\frac{1}{2}}$. Taking the sum of all the strips, we obtain C_1 in the one case and T_1 in the other.

11. **Type (ii.): Weighted.**—Under type (ii.) we shall only consider cases in which the data are the bounding ordinates $u_0, u_1, u_2, \cdots$. There are corresponding formulae for cases in which the data are the mid-ordinates $u_{\frac{1}{2}}, u_{\frac{3}{2}}, u_{\frac{5}{2}}, \cdots$, but they are not so important.

We have used C_1 to denote the chordal area $h(\frac{1}{2}u_0+u_1+u_2+\cdots+\frac{1}{2}u_m)$. Now suppose that m is even and $=2n$. Then we can get a different chordal area by considering only $u_0, u_2, u_4, \cdots, u_{2n}$. We call this C_2, so that

$$C_2 \equiv 2h(\tfrac{1}{2}u_0+u_2+u_4+\cdots+u_{2n-2}+\tfrac{1}{2}u_{2n}).$$

Generally, suppose that p is a factor of m. Then we write

$$C_p \equiv ph(\tfrac{1}{2}u_0+u_p+u_{2p}+\cdots+u_{m-p}+\tfrac{1}{2}u_m);$$

this being the chordal area when we only take $u_0, u_p, u_{2p}, \cdots$ into account. The "rules" we are considering are obtained by combining the C's in various ways.

The following are the most important rules of this type. In each case, as stated in §9, the rule is made up of repetitions of a formula. The "formula" and the "rule" are both given; "A" denoting the area given by the "rule."

(a) m a multiple of 2 (*Simpson's rule*).

$$\text{Area}(u_0 \text{ to } u_2) \simeq \tfrac{1}{3}h(u_0+4u_1+u_2) \tag{4}$$
$$A \simeq \tfrac{1}{3}(4C_1-C_2) \tag{4A}$$
$$\simeq \tfrac{1}{3}h(u_0+4u_1+2u_2+4u_3+2u_4+\cdots +4u_{m-1}+u_m). \tag{4B}$$

(b) m a multiple of 3 (*Simpson's second rule*).

$$\text{Area}(u_0 \text{ to } u_3) \simeq \tfrac{3}{8}h(u_0+3u_1+3u_2+u_3) \tag{5}$$
$$A \simeq \tfrac{1}{8}(9C_1-C_3) \tag{5A}$$
$$\simeq \tfrac{3}{8}h(u_0+3u_1+3u_2+2u_3+3u_4+\cdots +3u_{m-1}+u_m). \tag{5B}$$

(c) m a multiple of 4.

$$\text{Area}(u_0 \text{ to } u_4) \simeq \tfrac{2}{45}h(7u_0+32u_1+12u_2+32u_3+7u_4) \tag{6}$$
$$A \simeq \tfrac{1}{45}(64C_1-20C_2+C_4). \tag{6A}$$

(d) m a multiple of 6 (*Weddle's rule*).

$$\text{Area}(u_0 \text{ to } u_6) \simeq \tfrac{3}{10}h(u_0+5u_1+u_2+6u_3+u_4+5u_5+u_6) \tag{7}$$
$$A \simeq \tfrac{1}{10}(15C_1-6C_2+C_3). \tag{7A}$$

(e) m a multiple of 12.

$$A \simeq \tfrac{4}{5}(2C_1-C_2)+\tfrac{1}{35}(8C_3-C_4). \tag{8}$$

12. **A Method of Construction.**—The formulae given in the preceding section are not all obtained in the same way. They could all be found by a modification of the method mentioned later in §16. But the first three were originally obtained by making certain suppositions as to the upper boundary. For (a) two strips were taken together, and the top was supposed to be a parabola passing through the tops of three ordinates; for (b) three strips were taken, and the curve was supposed to be of the third degree; and for (c) four strips were taken, and the curve was supposed to be of the fourth degree.

For detailed consideration, (a) will be sufficient. We can use fig. 2; KA, MC, LB being the three ordinates u_0, u_1, u_2. The curve being a parabola, the tangent RCT is parallel to the chord AB. The area of the trapezium $AKLB$ is $h(u_0+u_2)$; and that of $RKLT$ is $2hu_1$. The true area $AKLBCA$ exceeds the former by the segment ACB, and falls short of the latter by the small pieces (spandrils) RAC and CBT. But we know that, for a parabola, the former difference is double the latter. We must therefore take a weighted mean of the two expressions, in the ratio of 1 : 2; *i.e.*, the area is

$$\tfrac{1}{3}h(u_0+u_2)+\tfrac{2}{3}\cdot 2hu_1=\tfrac{1}{3}h(u_0+4u_1+u_2).$$

We could, of course, have obtained this result analytically. If $u=p+qx+rx^2$, the area is $p(x_2-x_0)+\tfrac{1}{2}q(x_2{}^2-x_0{}^2)+\tfrac{1}{3}r(x_2{}^3-x_0{}^3)$; and this can be reduced to the above form by using the relations $u_0=p+qx_0+rx_0{}^2$, $u_1=$ etc., $u_2=$ etc., $h=\tfrac{1}{2}(x_2-x_0)$.

The general formula, when u is a polynomial in x of degree k, is:

$$\text{Area } (u_0 \text{ to } u_k)=h(g_0u_0+g_1u_1+g_2u_2+\cdots+g_ku_k), \tag{9}$$

where

$$g_r=\frac{(-1)^{k-r}}{r!(k-r)!}\int_0^k t(t-1)\cdots(t-r+1)(t-r-1)\cdots(t-k)dt. \tag{10}$$

This is, in effect, the *Newton-Cotes formula*.

13. **The Prismoidal Formula.**—An important application of quadrature-formulae is to finding the volume of a solid figure in terms of the areas of parallel cross-sections. In particular, suppose that a solid is bounded by two parallel planes, and that the area of the section by a plane parallel to these, at distance x from one of them, is of the form $p+qx+rx^2+sx^3$. Then, as is easily seen by drawing a graph of the areas of cross-sections, Simpson's formula applies to the volume of the solid; so that, if the areas of the ends are S_0 and S_2, and the area of the mid-section is S_1, the volume is $\tfrac{1}{6}H(S_0+4S_1+S_2)$, where H is the total breadth. This is called the *prismoidal formula*; it applies not only to prismoids but also to the cone, the sphere and the ellipsoid.

14. **The Euler-Maclaurin Theorem.**—For further progress, we have to use the *Euler-Maclaurin theorem*, discovered independently by Euler and by Maclaurin. The principle of this important theorem is that the difference between the trapezoidal area $\tfrac{1}{2}h(u_0+u_1)$ and the true area of the strip u_0 to u_1 can be expressed as the difference of the values, for $u=u_0$ and $u=u_1$, of a function which only involves derivatives of u; *i.e.*, that

$$\int_{x_0}^{x_1} udx=\tfrac{1}{2}h(u_0+u_1)+\Big[\phi\,(x)\Big]_{x=x_0}^{x=x_1}, \tag{11}$$

where $[\phi(x)]_{x=x_0}^{x=x_1}$ means $\phi(x_1)-\phi(x_0)$. The formula for $\phi(x)$ is

$$\phi(x)=-\tfrac{1}{12}h^2u'+\tfrac{1}{720}h^4u'''-\tfrac{1}{30240}h^6u^{\mathrm{v}}+\tfrac{1}{1209600}h^8u^{\mathrm{vii}}-\cdots \tag{12}$$

This theorem is exact if u is a polynomial in x; it is sufficiently exact in a good many other cases.

Applying this theorem to the successive strips, we get

$$\text{Area } (u_0 \text{ to } u_m)=C_1+\Big[\phi\,(x)\Big]_{x=x_0}^{x=x_m}, \tag{13}$$

which is the Euler-Maclaurin theorem.

An important feature of the theorem is that the terms in $\phi(x)$ involve h^2, h^4, $h^6 \cdots$, so that by increasing the number of the strips we make a much greater decrease in the magnitude of the corrective terms.

Another important point, which does not directly concern us here, is that we can transpose the terms so as to give a general formula for expressing a sum in terms of an integral (*cf.* CALCULUS OF DIFFERENCES).

To make the theorem applicable to quadrature, when u is not given explicitly in terms of x, we have to convert the derivatives hu', h^3u''', $\cdots$, into the equivalent expressions involving central differences. If we only know u_0, u_1, u_2, $\cdots$, u_m we do not know the central differences of u_0 and u_m; in this case two courses are open to us. We can express the derivatives in terms of the advancing differences of u_0 and the receding differences of u_m—*Gregory's formula*— or we can still use the central-difference formulae if we continue the series of differences forwards and backwards at the extremities.

15. **Type (iii.): Trapezoidal with Corrections.**—Expressing the derivatives in (12) in terms of central differences, we get

$$A=C_1+h\Big[-\tfrac{1}{12}\mu\delta u+\tfrac{11}{720}\mu\delta^3u-\tfrac{191}{60480}\mu\delta^5u+\cdots\Big]_{x=x_0}^{x=x_m} \tag{14}$$

as the corrected trapezoidal formula. The corrected trapezoidal formula for mid-ordinates is

$$A=T_1+h\Big[\tfrac{1}{24}\delta u-\tfrac{17}{5760}\delta^3u+\tfrac{367}{967680}\delta^5u-\cdots\Big]_{x=x_0}^{x=x_m}. \tag{15}$$

16. **Type (iv.): Weighted with Corrections.**—The Euler-Maclaurin formula gives us a method of constructing formulae such as those of Type (ii.), with additional terms to make the formula exact. Thus, to find a formula which would give a correct result if u were of the form $p+qx+rx^2+sx^3$, we must find one such that the term in u' in the [ ] disappears. Suppose that m is even and $=2n$. Then we have, the values for [ ] being throughout x_0 and x_m,

$$A=C_1+[-\tfrac{1}{12}h^2u'+\text{ terms in } u''' \text{ etc.}],$$
$$A=C_2+[-\tfrac{1}{3}h^2u'+\text{ terms in } u''' \text{ etc.}];$$

whence it follows that

$$3A=4C_1-C_2+[\text{terms in } u''', \text{ etc.}],$$

which, as we should expect, is Simpson's formula with corrections.

The following are the exact formulae corresponding to (*a*)-(*e*) of §11.

$$\text{(i.)}\quad A=\tfrac{1}{3}(4C_1-C_2)+\left[-\tfrac{1}{180}h^4u'''+\tfrac{1}{1512}h^6u^{\text{v}}-\cdots\right] \tag{16}$$
$$\text{(ii.)}\quad A=\tfrac{1}{8}(9C_1-C_3)+\left[-\tfrac{1}{80}h^4u'''+\tfrac{1}{336}h^6u^{\text{v}}\cdots\right] \tag{17}$$
$$\text{(iii.)}\quad A=\tfrac{1}{45}(64C_1-20C_2+C_4)+\left[-\tfrac{2}{945}h^6u^{\text{v}}+\cdots\right] \tag{18}$$
$$\text{(iv.)}\quad A=\tfrac{1}{10}(15C_1-6C_2+C_3)+\left[-\tfrac{1}{840}h^6u^{\text{v}}+\cdots\right] \tag{19}$$
$$\text{(v.)}\quad A=\tfrac{1}{35}(56C_1-28C_2+8C_3-C_4)+\left[-\tfrac{1}{2100}h^8u^{\text{vii}}+\cdots\right] \tag{20}$$

These formulae are not of great practical importance, but are useful as showing the relative accuracy of the various formulae.

17. **Degree of Accuracy.**—In applying any of the above formulae to a concrete case, it should be borne in mind that their accuracy depends on the nature of the case.

(1) If u is a polynomial in x, of whatever degree, the Euler-Maclaurin theorem, and therefore also the formulae of §§15 and 16, are exact, provided we take sufficient terms.

(2) If u is a definite function of x, other than a polynomial, the series of corrective terms in any of these formulae is not usually convergent; and the degree of accuracy has to be examined in each case.

(3) The cases in which u is only known to be some function of x are usually cases in which the u's are the result of observation and are liable to error; and in these cases an excessive accuracy in the formula itself is of no advantage.

18. **Numerical Example.**—For a numerical example, suppose that the relation between u and x is that $u=10/(x+20)$, and that we want the area of the graph of u from $x=0$ to $x=6$. We know from the Integral Calculus that this area is

$$\int_0^6 \frac{10}{x+20}dx=10(\log_e 26-\log_e 20)=2\cdot 62364\,26.$$

The values of u, and their differences (including some at the end which depend on values of u not shown here), are given in the following table:—

x	u	1st diff.	2nd diff.	3rd diff.
		−	+	−
		2632		41
0	.50000		251	
		2381		34
1	.47619		217	
		2164		30
2	.45455		187	
		1977		21
3	.43478		166	
		1811		22
4	.41667		144	
		1667		15
5	.40000		129	
		1538		16
6	.38462		113	
		1425		11

The sequence of differences shows that we can safely use the ordinary methods.

(i.) The trapezoidal rule gives

$$A\simeq h(\tfrac{1}{2}u_0+u_1+u_2+u_3+u_4+u_5+\tfrac{1}{2}u_6)$$
$$\simeq 2\cdot 62450,$$

since h is here $=1$.

(ii.) Since the number of strips is even, we can use Simpson's rule. This gives

$$A\simeq\tfrac{1}{3}h(u_0+4u_1+2u_2+4u_3+2u_4+4u_5+u_6)$$
$$\simeq 2\cdot 62365.$$

(iii.) The correction for the trapezoidal rule is

$$\left[-\tfrac{1}{12}\mu\delta u+\tfrac{11}{720}\mu\delta^3u\right]_{x=0}^{x=6}=-\cdot 00085.$$

The corrected value is therefore

$$A\simeq 2\cdot 62450-\cdot 00085\simeq 2\cdot 62365.$$

Thus (ii.) and (iii.) both give a fairly good result.

19. **Type (v.): Unequal Intervals.**—Under Type (v.) come two classes of cases.

(i.) When the given u's are not at equal intervals, the area is to be obtained by expressing the variable u in terms of x by Lagrange's formula (INTERPOLATION) and integrating.

(ii.) If we are free to choose the u's, we may want to choose them to satisfy some condition; *e.g.*, that we should restrict ourselves to a few ordinates, and place them so as to get the most accurate value possible for the area; or that the coefficients of the u's should all be equal. Under this head come certain formulae due to Gauss and Chebyshef (Tchebychev).

II. MOMENTS OF TRAPEZETTE

20. The moments of a trapezette with regard to a line L parallel to its ordinates are defined on the same principle as the moments of a lamina. Let L be at a distance X from the axis of u. We suppose the area to be divided into a very large number of very small equal elements dS. To find the rth moment M_r', we multiply each element dS by its $(x-X)^r$ and add the results. The limit of this sum when all the elements are made indefinitely small is M_r'.

We need only consider moments about the axis of u, so that $X=0$. The moments about the central ordinate ("moments about the mean") are denoted by $M_1, M_2, M_3, \cdots$; the formulae for obtaining these from $M_1', M_2', M_3', \ldots$ are given in §4.

21. **Ordinates Given.**—When the data are $u_0, u_1, u_2, \ldots, u_m$, the rth moment is the area of a trapezette whose ordinates are $x_0^r u_0,\ x_1^r u_1, \cdots, x_m^r u_m$. This area is to be found by a quadrature-formula.

22. **Areas Given.**—When, as is usually the case in the theory of statistics, the data are the areas of the strips (of breadth h) of the trapezette, there are two methods of calculating the moments of the trapezette. The areas of the m strips are denoted by $a_{\frac{1}{2}}, a_{\frac{3}{2}}, a_{\frac{5}{2}}, \cdots, a_{m-\frac{1}{2}}$, the total area being $A\equiv a_{\frac{1}{2}}+a_{\frac{3}{2}}+a_{\frac{5}{2}}\cdots+a_{m-\frac{1}{2}}$.

(i.) The first method involves an integration by parts. Let A_k be the sum of the areas from $a_{\frac{1}{2}}$ up to $a_{k-\frac{1}{2}}$ inclusive, so that

$$A_k\equiv a_{\frac{1}{2}}+a_{\frac{3}{2}}+a_{\frac{5}{2}}+\cdots+a_{k-\frac{1}{2}},\ A_m\equiv \text{total area}=A.$$

Then the rth moment is

$$M_r=x_m^r A_m-rT_{r-1},$$

where T_{r-1} is the area of a trapezette whose ordinates, at successive distances h, are

$$0,\ x_1^{r-1}A_1,\ x_2^{r-1}A_2,\cdots, x_m^{r-1}A_m.$$

This area is to be found by a quadrature-formula. The method applies to all cases in which this can be done.

(ii.) The principle of the second method is similar to that of the Euler-Maclaurin theorem. The rth moment of each strip, say the strip from u_0 to u_1, is split up into two portions, one of which is easily calculated from the data, while the other is of the form $\psi_r(x_1)-\psi_r(x_0)$, $\psi_r(x)$ being a certain function of u and of the derivatives of u and of x^r. The procedure is as follows:

(*a*) We regard the area of each strip as massed at its mid-ordinate, and thus obtain a *raw moment*

$$N_r'=x_{\frac{1}{2}}^r a_{\frac{1}{2}}+x_{\frac{3}{2}}^r a_{\frac{3}{2}}+\cdots+x_{m-\frac{1}{2}}^r a_{m-\frac{1}{2}}. \tag{22}$$

We have then to introduce certain corrections.

(*b*) The simplest case is that of a *double-tailed* figure, *i.e.*, a figure whose upper boundary has close contact with the base at its extremities. In this case we only require the *corrections for massing*. The corrected moments are then given by the formulae (N_0', of course, being A)

$$\begin{aligned}
M_1'&\simeq N_1'\\
M_2'&\simeq N_2'-\tfrac{1}{12}h^2N_0'\\
M_3'&\simeq N_3'-\tfrac{1}{4}h^2N_1'\\
M_4'&\simeq N_4'-\tfrac{1}{2}h^2N_2'+\tfrac{7}{240}h^4N_0'\\
M_5'&\simeq N_5'-\tfrac{5}{6}h^2N_3'+\tfrac{7}{48}h^4N_1'
\end{aligned} \tag{23}$$

(c) If the figure is not double-tailed, we require also the *corrections for abruptness*, which consist in adding $\psi_r(x_m)-\psi_r(x_0)$, as described above, to the expressions given in (23).

These corrections are due to W. F. Sheppard, and are known as Sheppard's corrections, though this name is sometimes given to the corrections for massing alone.

III. CUBATURE

23. The solid figure which corresponds to the trapezette is called a *briquette*. It is bounded by a pair of parallel planes, another pair of parallel planes at right angles to these, a base at right angles to these four planes (and therefore rectangular), and a top which is a surface of any form but such that every ordinate from the base cuts it in one point and one point only. The briquette may usually be regarded as divided into a number of minor briquettes by two sets of parallel planes, the distances between consecutive planes of each set being equal. If the breadth of the briquette is H one way and K the other, and it is divided into m slabs of breadth h by the one set of planes, and into n slabs of breadth k by the other set, then $H=mh$, $K=mk$. The position of an ordinate u is given by its co-ordinates with reference to two planes parallel to the two pairs of bounding planes; if these co-ordinates are $x=x_0+\theta h$ and $y=y_0+\phi k$, the length of the ordinate may be denoted by $u_{\theta\phi}$.

A process of cubature can usually be regarded as the combination of two processes of quadrature, so that cubature-formulae can easily be derived from quadrature-formulae. Suppose, for instance, that m is a multiple of 2 and n is a multiple of 3, and that u is a polynomial of degree not exceeding 3 in x and 3 in y. Then we can group the minor briquettes in sets of 2×3, as

Diagram 1.

u_{00}	u_{10}	u_{20}
u_{01}	u_{11}	u_{21}
u_{02}	u_{12}	u_{22}
u_{03}	u_{13}	u_{23}

Diagram 2.

$\frac{1}{3}\times\frac{3}{8}$	1	4	1
1	1	4	1
3	3	12	3
3	3	12	3
1	1	4	1

shown in diagram 1; taking one such group, we can regard the area of each section at right angles to the x-axis as found by Simpson's second formula; and, representing each area by an ordinate of a graph, we can use Simpson's formula to find the area of this graph, which represents the volume of the group of 6 briquettes. The result is an expression in which the coefficient of each u in diagram 1 is as shown in diagram 2. Or, as an alternative method of getting this result, we can use operators. What we want is the value of a double-integral. We can express the result of integrating with regard to x in the form $\frac{1}{3}h(1+4E+E^2)u_{00}$, where E denotes the result of changing from x to $x+h$ (*see* CALCULUS OF DIFFERENCES); and the integration with regard to y has the effect of operating with $\frac{3}{8}k(1+3E'+3E'^2+E'^3)$, where E' has a corresponding meaning. The combination of the two operations gives the result shown in diagram 2.

The formulae for the corrections of massing (§22) can be obtained in the same way. Suppose we are dealing with a briquette whose top has close contact with the base all along its boundary, and that we want the moment due to multiplying each element of the volume by x^py^q. Let the raw moment obtained by massing the volume of each minor briquette along its mid-ordinate be denoted by N'_{pq}. Then the corrected expressions for the moments are given by the formulae

$$\begin{aligned} M'_{11} &\simeq N'_{11} \\ M'_{21} &\simeq N'_{21}-\tfrac{1}{12}h^2N'_{01} \\ M'_{12} &\simeq N'_{12}-\tfrac{1}{12}k^2N'_{10} \qquad (24)\\ M'_{22} &\simeq N'_{22}-\tfrac{1}{12}k^2N'_{20}-\tfrac{1}{12}h^2N'_{02}+\tfrac{1}{144}h^2k^2N'_{00} \\ M'_{31} &\simeq N'_{31}-\tfrac{1}{4}h^2N'_{11}, \quad \text{etc.} \end{aligned}$$

where N'_{00} is the total volume of the briquette. (W. F. S.)

BIBLIOGRAPHY.—There is a large number of text-books on ordinary mensuration. R. M. Milne, *Mensuration and Elementary Solid Geometry* (1923), has a wide range. As to quadrature *see* INTERPOLATION: *Bibliography.*

MENTAL DEFICIENCY. Mental defectiveness, as defined by the British Mental Deficiency act 1927 is, "a condition of arrested or incomplete development of mind existing before the age of eighteen years, whether arising from inherent causes or induced by disease or injury." Mental deficiency, which is often inherited as a Mendelian recessive (*see* HEREDITY, MENDELISM), is to be distinguished from ordinary insanity (*q.v.*), in which there is a definite abnormality of the mind, whereas mental deficiency is due to arrested development of an otherwise normal mind, sometimes owing to deficiency of the secretion of the thyroid gland (*see* HORMONE, ENDOCRINOLOGY). Legislation both in England and elsewhere has recognized the essential difference between mental deficiency and lunacy and the class of so-called "mental defectives" is generally dealt with by laws differing from those affecting the insane. These laws are based mainly on a recognition of (*a*) the educational, (*b*) the social and racial problem created by the presence of uncontrolled mentally defective persons in the community.

Great Britain and Ireland.—In England the Mental Deficiency act of 1913 was the outcome of the Report (1912) of the Royal Commission on the Care and Control of the Feebleminded appointed in 1908, and embodied a considerable number of its recommendations. The Mental Deficiency act 1927 introduces certain amendments of the 1913 act.

The Elementary Education (Defective and Epileptic Children) act 1899, gave to local education authorities power to provide special schools (day or residential) for mentally defective children between the ages of 7 and 16 who, not being either dull or backward or idiots or imbeciles, were capable of benefiting by the education provided in such schools. Under the Elementary Education (Defective and Epileptic Children) act of 1914 these powers were made compulsory, and both acts were embodied in Part V., sections 51–9 of the Elementary Education act 1921. Attendance at such schools may be enforced by a magistrate, provided it is clearly for the child's benefit that he should attend a special school. Owing to the War and to the relatively high cost of these schools many authorities have failed to provide sufficient, in some cases, any special schools; there is practically no school provision for defective children in rural areas. The estimated number of defective children is calculated at eight to ten per thousand of the school population. The latter figure is probably the more accurate. This gives an estimated total of from 42,000 to 52,000 (approximately) defective children to be provided for, but provision has only been made for 16,292 children in 170 day and 20 residential schools. In addition, the local education authorities must notify the local control authority of children who are incapable of benefiting from education in special schools or who need to be placed under supervision or guardianship or given institutional care on leaving school. There are 109 occupation day centres, mainly in urban areas, for children excluded from schools, run for the most part by local voluntary mental welfare associations; after-care committees and the above associations look after the children who have left special schools, try to find them employment, supervise them at home and establish handicraft centres for them.

The Mental Deficiency Acts.—The Board of Control, a section of the Ministry of Health, administers the Lunacy and the Mental Deficiency acts. The local control authorities are statutory mental deficiency committees of county and county borough councils whose duty it is to provide for defectives, only when they can be certified as idiots, imbeciles, feebleminded or moral defectives, and who in addition are either (*a*) neglected, without visible means of support, cruelly used, etc.; (*b*) found guilty of any criminal offence and liable to be sent to or actually sent to an industrial school or prison; (*c*) notified by the local education authorities as ineducable or as needing institutional care on leaving a special school; (*d*) having given birth to or being pregnant of an illegitimate child whilst in receipt of poor relief. The duty of the authority is (*a*) to ascertain the defectives they must deal with, (*b*) provide supervision by visiting and watching over the defective at home. This supervision is carried out either by specially appointed officers or by voluntary associations to whom statutory duties are delegated by the local authority. If this supervision is

insufficient the authority may (*c*) send defectives to a certified institution under orders or (*d*) place them under guardianship under orders, *i.e.*, under the charge of an individual having the powers of a parent over them. This order is made by a magistrate on a petition supported by two medical certificates. Orders are renewable by visiting justices at the end of each of the first two years, then every five years. The authorities must also provide suitable training or occupation for defectives who are under supervision or guardianship, or have been sent to an institution.

Local authorities are required to provide certified institutions for defectives; they can also send defectives to institutions provided by other committees. The War prevented the development of institutions and a number of poor law institutions have been approved for the reception of defectives under orders. The Royal Commission estimated that there were 4·6 per thousand defectives in the population. Some 60,234 or 1·59 per thousand have been ascertained but only 20,091 defectives were in institutions or under guardianship under the act in Jan. 1927, many being found in institutions and homes as rescue cases, paupers, etc.

The difficulties are: incomplete ascertainment of defective children, which handicaps preventive measures; lack of special educational facilities for training defectives; lack of institution accommodation for adult defectives; lack of recognition of mental defect in cases coming before the courts. Greater efforts are being made to safeguard the community and the defective by segregation of defectives with anti-social tendencies in institutions.

Scotland.—The Mental Deficiency act for Scotland, 1913, does not differ very materially from the English act but the local authorities are local boards of control and the parish councils. There were 2,764 certified mental defectives on Jan. 1, 1927. A Scottish Association for Mental Welfare was established in 1922. There is also an active movement for the establishment of a large colony for the feebleminded.

Ireland.—The Mental Deficiency act does not apply to Northern Ireland. There is only one institution for defectives in the whole of Ireland but certain religious communities intend opening others.

British Empire.—Legislation in other parts of the British Commonwealth is generally modelled on the English Mental Deficiency act, 1913.

In South Australia a Mental Deficiency act was passed in 1913; in Tasmania in 1920. The Mental Deficiency board, then established, published in 1925 a report on a mental survey of the prisoners in Hobart gaol. In Melbourne and Sydney special schools and classes for mentally defectives and backward children are being established.

The Mental Disorders act of 1916 regulates the care of defectives in the Union of South Africa. A national council for the care of the feebleminded watches over the interests of individual defectives and guides public opinion.

In Canada a Federal act dealing with immigration prohibits the entry of mental defectives into the country. Each provincial government provides grants for the organisation of special classes for mentally deficient children in school attendance. Ontario, Alberta, Saskatchewan, Manitoba and Nova Scotia have made institutional accommodation for 1,500 cases. Several of the larger cities including Toronto, Winnipeg and Vancouver provide routine mental examinations for school children and for juvenile court cases, and since 1928 the Canadian national committee for mental hygiene has been conducting surveys throughout the Dominion to determine the prevalence and significance of the problem. Alberta has recently passed an act for the sterilisation of the feebleminded.

In New Zealand the Mental Defectives act of 1911 and the Education act of 1914 are the acts under which day schools, one or two residential schools and some institutions are established. A committee of enquiry (1925) under the Ministry of Health recommended the establishment of a eugenic board for the compilation of a register of mental defectives and made recommendations for the sterilisation of certain mentally defective persons.

European Countries.—The work among mentally defective persons in other countries follows much the same lines as are indicated in the description given below. The classification of defect differs somewhat in different countries, and a class of "moral defectives" is not universally recognised. Almost all countries have now made some provision for mentally defective persons, but the problem is still inadequately met.

In France, mental defectives are dealt with under the law for the *aliénés* passed as long ago as 1838 which has not been amended. Under this law persons can be placed in institutions at the request of their families, or by order of the prefect, if they are considered dangerous or in need of protection. Some difficulty is found in dealing with cases needing treatment but not institutional care but the work of treating the feebleminded at psychiatric clinics is likely to develop since the establishment of a clinic at Paris in 1921. A law passed in 1919 recommends special classes for children but does not make them compulsory.

In Italy the class *imbecili morali* is recognised. No exact figures are available as to the number of defectives. A general law on the protection of children was in preparation in 1926. There are only eight institutions set aside for the mentally defective; accommodation, 761 persons. Madame Montessori's educational methods (*q.v.*) were based on the experience gained among defective children in Rome.

Another educational pioneer Dr. Ovide Decroly of Brussels similarly first interested himself in the study of defectives and later adapted his methods in use in his special school in Brussels to the teaching of normal children. His methods have been adopted in many of the elementary schools in Brussels. Belgium has a remarkable institution, the colony at Gheel, whose origin goes back to the 6th century, when a shrine was built to St. Dymphna, a martyred Irish saint. The principle of the Colony of some 20,000 inhabitants caring for 2,000 *aliénés* is freedom and home-life in the families of the citizens. Other similar colonies have been founded in the country.

The institutional care of the feebleminded in Holland is almost entirely in private hands, but special schools exist in the towns.

The Scandinavian countries have a good system of special schools and several institutions, and considerable attention has been given to the training of defectives.

It is estimated that there are in Denmark between 6,000 and 7,000 mentally defective persons in a population of 3,500,000 but there are no exact statistics. There are four large institutions, accommodating about 3,450 persons, and private homes taking 350 patients. Special schools are not compulsory but they are established in most of the large towns such as Copenhagen, which has a school for 700. A Marriage act is on the statute book which prohibits marriage with a mentally deficient person.

Developments in Austria have been considerable since the War. There are special schools and classes for 2,794 children and 20 institutions for the care and instruction of 1,498 mentally defective and epileptic children.

Germany has a fine special school system, with schools in about 600 different places. There are in all about 3,500 classes in these schools, with accommodation for 67,000 children. Most of the special school children have had two years' trial in the elementary school, and those who are not able at the age of six to profit by the elementary school can attend a *Vorklasse* before being drafted into the special or normal schools. In Mannheim since the beginning of the century and later in Charlottenburg, Frankfurt-on-Main and other towns, a system of so-called *Forderklassen* has been established for the backward child whose mental difficulties may be due to exterior or physical causes and not to mental defect. In other towns there are classes for those who in later years of school life remain backward.

The Institut J. J. Rousseau in Geneva has been of inestimable value in the scientific study of the child. The founder Prof. Ed. Claparède has proceeded on the principle that the abnormal and normal child should be studied at the same time, and the institute has now become a laboratory for the study of the child in all his manifestations. In 1928 preparatory classes were established for children who cannot keep up with the lowest class. There are also "work-classes" which have more manual work even than the special schools. The employment schemes in institutions are

admirably organised. The Basle institution was opened in 1916 for the paid employment of defectives and a work and welfare home for girls, with similar aims was opened in 1924 at Komtz, near Berne.

The United States.—The care of mental defectives in the United States is regulated and controlled entirely by the individual States. At the present time, there are 57 State institutions: every State except Utah, Nevada, New Mexico and Arizona has its own institution for mental defectives while some of the older and larger States have more than one. New York, for instance, has five, New Jersey, three, Massachusetts, three, Pennsylvania, three. These institutions frequently have a capacity of from 1,000 to 3,000 inmates.

Each institution has a school department for all those who are able to profit by school attendance. The curriculum comprises little or none of the academic studies, reading, writing, and counting, but is predominantly manual and industrial work. The older inmates work on the farm, in the shops, kitchens, dining rooms, etc., insofar as their mental condition permits. Practically all the work of the institution is done by them—under supervision. The ideal of the institution is to make the children happy. This is accomplished by giving them occupation that is pleasant and agreeable. The children are committed to these institutions by the County Court and their maintenance is provided for by the State or in some instances, by the counties.

Property valuation of the State institutions in 1923 was: real estate $35,407,762.01; personal property, $6,078,330.14. This is a total of $1,226.71 per patient. The real estate comprised 44,465 ac. or 1·31 ac. per patient. Of this approximately one third was under cultivation.

In addition to State institutions, there are 66 private institutions, usually licensed by the State, but managed for profit. Some of them give most excellent and expert training. Others are little more than custodial. Besides these, many public school systems provide special classes for defective children. These children live in their own homes, go to school as do other children, and devote their time to learning manual work and trades. (H. H. Go.)

MENTAL HYGIENE: *see* PSYCHOTHERAPY, etc.

MENTAL SCIENCE, (a) the science of the mind, psychology; (b) modern systems which seek to apply the power of the mind to the healing of mental and bodily ills. Taking as basis the doctrine that the Consciousness is the one reality, and that all ills are effects of disharmony in Consciousness, this school undertakes the cure of these ills by harmonization of Consciousness; the final development being the growth of a class of mental healers, giving both present and absent treatment.

MENTAL TESTS: *see* INTELLIGENCE TESTS.

MENTAWEI, a group of islands off the west coast of Sumatra, D.E. Indies. They include Siberut, Sipura and Pageh (Pagai), or Nassau. They are volcanic, and sunken coral reefs render them dangerous to approach. The islands generally are covered with thick forests. There are a few small rivers in Siberut. Pop. (1920), 8,310. The people are considered to be of Caucasian origin, probably related to the very early indigenous peoples of Sumatra, and pre-Batak. The Mentawei islanders have golden-brown skins, black hair, dark eyes, and broad and flat noses; the men are of middle height, the women short and thick-set. They tattoo and have a custom resembling one of Hawaii—wearing flowers in the hair and behind the ears. They have an inflexible moral code, knowing nothing of divorce and punishing adultery with death. The man is the head of his own family and marriage is either endogamic or exogamic. Polygamy is not practised. Their religion is nature-worship, oblations being made in the forest to nature-spirits: they have no idols, nor temples, but are known to set up a bamboo cylinder in the forest and decorate it with scraps of cloth, leaves, and flowers, a rite which may be phallic in origin. They are governed by village chiefs. Houses are of bamboo and *atap* on piles.

Although a peaceful folk amongst themselves, the Mentawei islanders carry arms, chiefly the bow, with poisoned arrows, and before Dutch influence became sufficiently assertive they were wont to raid neighbouring coasts, and even to attack small trading vessels. Agricultural development is at a low stage but they grow fruit, coco-nuts, sugar-cane and tobacco. They are keen hunters and fishers and collect forest products. They are good boat-builders. The islanders are fond of feasts, accompanied by much drum-beating and dancing; their language resembles that of the Karo Bataks. No roads exist, nor is there any regular communication with the mainland. (E. E. L.)

MENTEITH or **MONTEITH,** a district of south Perthshire, Scotland, roughly comprising the territory between the Teith and the Forth. Formerly it was a stewartry and gave the title to an earldom. The title was first held by Gilchrist, a Celtic chief ennobled by Malcolm IV., and passed successively to Walter Comyn, to a branch of the Stewarts, and finally to the Grahams, becoming extinct in 1694. The lake of Menteith, situated 2½ m. S. of Loch Vennachar measures 1½ m. long by 1 m. broad, and contains three islands. On Inchmahome (Gaelic, "the Isle of Rest") are the ruins of an Augustinian priory founded in 1238 by Walter Comyn. The island was the residence of Queen Mary, when a child of five, for a few months before her departure to France in 1548. On Inch Talla stands the ruined tower of the earls of Menteith, dating from 1428. The village of Port of Monteith (pop. of parish, 940), on the north shore of the lake, is 3¼ m. from the station of the same name on the L.N.E.R. Forth and Clyde line.

MENTHOL: *see* CAMPHORS.

MENTONE (Fr. *Menton*), a town in the department of the Alpes Maritimes in south-east France, on the shore of the Mediterranean, about 15 m. by rail E. of Nice. Pop. (1926) 19,599. Mentone was probably the Lumone of the Itineraries, but no Roman remains exist. After having belonged to the counts of Ventimiglia and a noble Genoese family, it was purchased about the middle of the 14th century by the Grimaldis, lords of Monaco. During the First Republic and the First Empire it belonged to France, but in 1815 it reverted to the prince of Monaco, who subjected it to such exactions that in 1848 its inhabitants proclaimed the town (with Roquebrune on the west) independent, under the protection of Sardinia. In 1860 both Mentone and Roquebrune were purchased by France from the prince of Monaco, and added to the department of the Alpes Maritimes then formed out of the county of Nice, ceded the same year to France by Sardinia. The town is built in the form of an amphitheatre on a rocky promontory, which divides its semicircular bay into two portions. Below, along the seashore, is the town of hotels and foreigners, while above, and inaccessible to wheeled vehicles, is that of the native Mentonese, with steep, narrow and dark streets, around the strong castle which was once its protection against pirates. In the old town is the church of St. Michel, partly rebuilt since an earthquake in 1887. Facing south-east, and sheltered on the north and west by mountains, the bay of Mentone has a good climate and is frequented by invalids. The mean for the year is 61° F, while that for the winter is about 46° F. Frost occurs on the average only once in ten years. Mentone has almost tropical vegetation, lemon-trees, olive-trees and pines rise in successive stages on surrounding slopes.

MENTOR, in Greek legend, the son of Alcimus and friend of Odysseus (*q.v.*), who makes him guardian of his household (*Od.*, ii., 226). In Fénelon's *Télémaque* he plays a prominent part, giving

the hero much good advice: hence the modern use of mentor for adviser, sage counsellor.

MENUS. The literal interpretation of the word menu is "minute detail," and it is used to denote the particulars of the different courses of a meal. A menu should be drawn up for every meal, however simple or elaborate, in order that the food may be well balanced and that variety may be introduced and the food made interesting.

The compilation of elaborate menus demands a knowledge of cookery in all its branches without which a meal would not be well planned, whilst the arrangement of simple home meals, although requiring less culinary skill, needs careful thought in order that the food may be well planned, varied and economical.

Monotony is the chief difficulty encountered when catering for the average household, where the amount of money which can be spent on food is limited.

Menu Making.—A full dinner menu comprises the following courses: Hors D'oeuvres; Potage or Soup; Poisson or Fish; Entree; Releve or Remove; Rôti or Roast; Entremet; Dessert; Coffee. But it is only for elaborate meals that all are introduced; the tendency to-day being for simpler and shorter repasts.

Careful consideration should be given to several points of which the following are the most important:—(1) The number of guests and the cost to be incurred. (2) The ability of the cook and the facilities of the kitchen. It would be unreasonable to expect a cook, working single handed, to prepare an elaborate hot meal of many courses. A capable and experienced person can cook and serve a dinner for six or eight guests provided some dishes included in the menu can be prepared in advance. (3) The taste of the guests. When possible one or two of the guests' favourite dishes should be introduced. (4) The season. In hot weather light and easily digested food should be selected, with plenty of fresh fruit and vegetables, whilst during the winter months more heat-giving and fat-forming food is preferable. Full use should be made of food that is in season. (5) The food value of the meal. When planning meals, whether elaborate or simple, thought should be given to the food value of each course, and a special effort made to provide a well-balanced meal. Therefore, some knowledge of the classification of the different foods and their food value is necessary. (*See* DIET AND DIETETICS.)

(D. D. C. T.)

MENZEL, ADOLPH FRIEDRICH ERDMANN VON (1815–1905), German artist, was born at Breslau on Dec. 8, 1815. Left an orphan in 1832, Menzel had to maintain his family. In 1833 Sachse of Berlin published his first work, an album of pen-and-ink drawings reproduced on stone, to illustrate Goethe's little poem, "Künstlers Erdenwallen." He executed lithographs in the same manner to illustrate *Denkwürdigkeiten aus der brandenburgisch-preussischen Geschichte*, pp. 834–836; "The Five Senses" and "The Prayer," as well as diplomas for various corporations and societies. From 1839 to 1842 he produced 400 drawings, reviving at the same time the technique of engraving on wood, to illustrate the *Geschichte Friedrichs des Grossen* by Franz Kugler. Later works are: *Friedrichs des Grossen Armee in ihrer Uniformirung, Soldaten Friedrichs des Grossen*, and finally, by order of the king Frederick William IV., he illustrated the works of Frederick the Great, *Illustrationen zu den Werken Friedrichs des Grossen* (1843–49).

Meanwhile Menzel devoted himself to the art of painting and he soon produced a great number and variety of pictures, always showing keen observation and honest workmanship. Among the most important of these works are "The Forge" (1875) and "The Market-place at Verona." Invited to paint "The Coronation of William I. at Koenigsberg," he produced an exact representation of the ceremony without regard to the traditions of official painting. Menzel died at Berlin on Feb. 9, 1905. He was the first painter to be given the order of the Black Eagle. The national gallery in Berlin contains 43 of his most important paintings.

MEPHISTOPHELES, in the Faust legend, the name of the evil spirit in return for whose assistance Faust signs away his soul. The origin of the conception and name has been much debated. In *Dr. Faust's Höllenzwang* "Mephistophiel" is one of the seven great princes of hell; "he stands under the planet Jupiter, his regent is named Zadkiel, an enthroned angel of the holy Jehovah." The origin of the idea of Mephistopheles in Faust's mind is thus clear. He was one of the evil demons of the seven planets, the *Maskim* of the ancient Akkadian religion, a conception transmitted through the Chaldeans, the Babylonians and the Jewish Kabbala to mediaeval and modern astrologers and magicians. This suggests a plausible theory of the origin of the name. In the ancient Mesopotamian religion the Intelligence of the planet Jupiter was Marduk, "the lord of light," whose antithesis was conceived as the lord of darkness. According to C. Kiesewetter (*Faust in der Geschichte und Tradition*, p. 163), then, Mephistopheles (or rather Mephostopheles) is "he who loves not light" (Gr. μὴ φῶς φιγεῖν). Schröer, however, prefers the derivation from Hebr. *Mephiz*, destroyer, and *tophel*, liar (*Faust*, ed. 1886, i. 25), which is supported by the fact that nearly all the names of devils in the 16th century magic books are derived from the Hebrew.

Kiesewetter, applying to the Faust legend the principles of modern psychical research, held that Mephistopheles had a real existence for Faust, the medium and somnambulist, as the objectification of his own "transcendental substance," appearing in various guises—as a bear, as a little bald man, as a monk, etc.—but always recognizable as the same "familiar." However this may have been, the Mephistopheles of the Faust-books, who combined the qualities of the devil of theology with those of the kobold of German myth, was certainly an objectification of the ideas of the age, which believed in kobolds and went in constant terror of the devil.

The Mephostophiles of the Faust-books and the puppet plays passed with little or no modification into literature as the Mephistophilis of Marlowe's *Faustus*. Mephistophilis has the kobold qualities; he not only waits upon Faustus and provides him with sumptuous fare, he indulges in horse-play and practical joking of a homely kind. He is, however, also the devil, as the age of the Reformation conceived him—a fallen angel who has not forgotten the splendour of his first estate, and who pictures to Faust the glories of Heaven in order to accentuate the horrors of the Hell to which he triumphantly drags him. Goethe's Mephistopheles is altogether another conception. Some of his traditional qualities are indeed preserved; the scene in Auerbach's *Keller* shows that he has not altogether shed his character as kobold, and, like the planet-spirits of the old magic, he appears alternately in animal and human shape. He is also identified with the devil; thus, in accordance with old German tradition, he is dressed as a nobleman (*ein edler Junker*), all in red, with a little cape of stiff silk, a cock's feather in his hat, and a long pointed sword; at the witches' Sabbath on the Brocken he is hailed as "the knight with the horse's hoof," and Sybel in Auerbach's *Keller* is not too drunk to notice that he limps. But his limp is the only indication that he is Lucifer fallen from Heaven. He could not, like Marlowe's Mephistophilis or Milton's Satan, regretfully paint the glories of the height from which he has been hurled; for he denies the distinction between high and low, since "everything that comes into being deserves to be destroyed." He is, in short, not the devil of Christian orthodoxy, a spirit conscious of the good against which he is in revolt, but akin to the evil principle of the older dualistic systems, with their conception of the eternal antagonism between good and evil, light and darkness, creation and destruction. (*See* FAUST.) (W. A. P.)

MEPPEL, a town in the province of Drente, Holland, 16½ m. by rail N. by E. of Zwolle. Pop. (1926) 12,108. It is situated at the confluence of a number of canals and rivers which communicate with the Zuider Zee by the Meppeler Diep, and rose rapidly into prominence in the 19th century. It trades in butter, eggs, cattle and pigs. Bleaching, dyeing and shipbuilding are also carried on.

MEQUINEZ, a city of Morocco, situated 514 metres above the sea, about 70 m. from the west coast and 36 m. W.S.W. of Fez, on a long spur in a plain bounded on the north by the massif of Jebel Zerhoun and on the south by the plateaux of mid-Atlas on the borders of the Wad Bou Fekrane, on the road to Rabat,

in 33° 56′ N., 5° 50′ W. The town wall, with its four-cornered towers, is pierced by nine gates. A lower wall of wider circuit protects the luxuriant gardens in the outskirts. Mequinez, at a distance, appears a city of palaces, but it possesses few buildings of any note except the palace and the mosque of Mulai Ismaïl, which serves as the royal burying-place. The palace, founded in 1634, was described in 1821 by John Windus in his *Journey to Mequinez* (London, 1825) as "about 4 m. in circumference, the whole building exceeding massy, and the walls in every part very thick; the outward one about a mile long and 25 ft. thick." The interior is composed of oblong courtyards surrounded by buildings and arcades. These buildings are more or less square, with pyramidal roofs ornamented outside with green glazed tiles, and inside with richly carved and painted woodwork in Mauresque style. The walls are tiled to a height of 4 or 5 ft., and above they are finished in plaster, whitewashed or carved into filigree work.

The ancient stables are particularly fine. One may note also some beautiful gateways, especially Bab-Mansour-el-Euldj (18th century), on the square El-Hedim, Bab-el-Khamis, on the west of the Mellah. Outside the walls to the north-west is the tomb of Sidi-Mohammed-ben-Aïssa, patron of Meknès and of the religious brotherhood of the Aïssaouas, so well known for its strange rites; they gather in great numbers at Meknès at the time of the festival of the saint. The new town stretches to the east of the original one, in a very open situation, near the railway station, which links it with Fez, Tangiers and Casablanca. Meknès is a makhzen or imperial town, one of the residences of the sultan. On the account of its geographical position in the middle of vast, fertile plains at the exit from the mid-Atlas and Jebel Zarhoun, it seems marked out for a great future. The population is 29,930, of which 18,682 are Muslim, 6,325 Jews and 4,923 Europeans.

Meknès is named from the great Zenata tribe of the Miknassa. It was at first an Almohade citadel called Tagraret. Its great importance dates from the 17th century; it was the favourite residence of Moulai-Ismaïl, who, during his long reign of 55 years, raised there the buildings which have given to Meknès the name of "Moroccan Versailles." Gen. Moinier entered it on June 8, 1911, and the surrounding region was afterwards pacified.

See O. Houdas, *Monographie de Meknès,* traduit de l'arabe (Paris, 1885); Ed. Arnaud, *Monographie de la region de Meknès* (Casablanca, 1917).

MERANO, a town of northern Italy, in the province of Bolzano, 20 m. N.W. of it by the Val Venosta railway, which runs to Malles Venosta, 37 m. N.W.: thence roads run to Landeck and the Lower Engadine by the Reschen Scheideck pass, or to the latter by the Münster valley and the Ofen pass. Pop. (1921) 19,185 (town); 21,312 (commune). The town is at a height of 1,001 ft., at the foot of the vine-clad Küchelberg, and on the right bank of the Passeria River, above its junction with the Adige. The name includes several adjacent villages, Maia Alta and Bassa being on the left bank of the Passeria, while Gratsch is on its right bank and north-west of the main town. The most noteworthy building is the parish church (14th to 15th centuries) but there are many handsome modern buildings and promenades for visitors. Merano is a resort for consumptives by reason of the pure air and the lack of wind and rain in the winter. It is also visited in spring for the whey cure and in autumn for the grape cure.

To the north-west, on the Küchelberg, is the half-ruined castle of Tirolo (2,096 ft.), the original seat of the family which gave its name to the county. Merano is first mentioned in 857. From the 12th century to about 1420 it was the capital of the Tirol, but then gave way to Innsbruck.

MERBECK (or MARBECK), **JOHN** (d. *c.* 1585), English theological writer and musician, was organist of St. George's, Windsor, about 1540. Four years later he was convicted of heresy and sentenced to the stake, but received a pardon through intervention of Gardiner, bishop of Winchester. In 1550 Merbeck published his *Booke of Common Praier noted* intended to provide for musical uniformity in the use of the First Prayer Book of Edward VI. Merbeck's object was to provide a "playne tune" for the daily offices of the church. His "playne tune" is defined by H. C. Colles in Grove's *Dictionary* as being "neither 'plain-song' in the technical sense (notes of undefined value) nor mensural music (notes of strict value), but a typically English compromise between the two, designed to guide the singer in his new problem of singing an accentual language in place of a quantitative language." Other principles triumphed, but in the 19th century Merbeck's excellent work was recognized. His *Booke* was reprinted in 1844 and the sung Eucharist in the English Church is largely based on his work. Merbeck compiled the first English concordance of the Bible, and several devotional and controversial works of a strongly Calvinistic character. A number of his musical compositions are preserved in manuscript in the British Museum, and at Oxford and Cambridge. He died, probably while still organist at Windsor, about 1585. His son, ROGER MERBECK (1536–1605), was the first registrar of the College of Physicians in London, and chief physician to Queen Elizabeth.

MERCANTILE (or COMMERCIAL) **AGENCIES.** The name given in America to organizations designed to collect, record and distribute to regular clients information relative to the standing of commercial firms. In Great Britain and some European countries trade protective societies, composed of merchants and tradesmen, are formed for the promotion of trade, and members exchange information regarding the standing of business houses. These societies had their origin in the associations formed in the middle of the 19th century for the purpose of disseminating information regarding bankruptcies, assignments and bills of sale. The mercantile agency in the United States is a much more comprehensive organization. It came into existence after the financial crisis of 1837. Trade in the United States had become scattered over a wide territory. Communication was slow and the town merchant was without adequate information as to the standing of many business men seeking credit. Undoubtedly the severity of the collapse of 1837 was due in part to the insufficiency of this information. New York merchants, who had suffered so severely determined to organize a headquarters where reports regarding the standing of customers could be exchanged. Lewis Tappan (1788–1873), founder of the *Journal of Commerce* (1828) and a prominent anti-slavery leader, undertook the work and established in New York (1841) the Mercantile Agency, the first organization of its kind. The system has been widely developed since.

MERCANTILE MARINE: *see* SHIPBUILDING, SHIPPING, HISTORY OF.

MERCANTILE SYSTEM. The name given to the economic policy which developed in Europe at the close of the middle ages. The doctrine of the mercantile system, stated in its most extreme form, made wealth and money identical, and regarded it therefore as the great object of a community so to conduct its dealings with other nations as to attract to itself the largest possible share of the precious metals. Each country's interest was to export the utmost possible quantity of its own manufactures and to import as little as possible of those of other countries, receiving the difference of the two values in gold and silver. This difference is called the balance of trade, and the balance is favourable when more money is received than is paid. Governments might resort to all available expedients—prohibition of, or high duties on, the importation of foreign wares, bounties on the export of home manufactures, restrictions on the export of the precious metals—for the purpose of securing such a balance.

But this statement of the doctrine, though current in textbooks, does not represent correctly the views of all who belonged to the mercantile school. Many members of that school were much too clear-sighted to entertain the belief that wealth consists exclusively of gold and silver. The mercantilists may be best described, as W. G. F. Roscher remarked, not by any definite economic theorem which they held in common, but by a set of theoretic tendencies, commonly found in combination, though severely prevailing in different degrees in different minds. The underlying principles may be enumerated as follows: (1) the importance of possessing a large amount of the precious metals; (2) an exaltation (*a*) of foreign trade over domestic, and (*b*) of the industry which works up materials over that which provides them; (3) the value of a dense population as an element of national strength; and (4) the employment of State action in furthering artificially

the attainment of the ends proposed.

The discoveries in the New World had led to a large development of the European currencies. The old feudal economy, founded principally on dealings in kind, had given way before the new "money economy," and the dimensions of the latter were everywhere expanding. Circulation was becoming more rapid, distant communications more frequent, city life and movable property more important. The mercantilists were impressed by the fact that money is wealth *sui generis,* that it is at all times in universal demand and that it puts into the hands of its possessor the power of acquiring all other commodities. The period, again, was marked by the formation of great States, with powerful governments at their head. These governments required men and money for the maintenance of permanent armies, which, especially for the religious and Italian wars, were kept up on a great scale. Court expenses, too, were more lavish than ever before and a larger number of civil officials was employed. The royal domains and dues were insufficient to meet these requirements, and taxation grew with the demands of the monarchies. Statesmen saw that for their own political ends industry must flourish. But manufactures make possible a denser population and a higher total value of exports than agriculture; they open a less limited and more promptly extensible field to enterprise. Hence they became the object of special governmental favour and patronage, whilst agriculture fell comparatively into the background. The growth of manufactures reacted on commerce, to which a new and mighty arena had been opened by the establishment of colonies. These were then viewed simply as estates to be worked for the advantage of the mother countries and the aim of statesmen was to make the colonial trade a new source of public revenue. Each nation, as a whole, working for its own power and the greater ones for predominance, they entered into a competitive struggle in the economic no less than in the political field, success in the former being indeed, by the rulers, regarded as instrumental to pre-eminence in the latter. A national economic interest came to exist, of which the government made itself the representative head. States became a sort of artificial hothouse for the rearing of urban industries. Production was subjected to systematic regulation, with the object of securing the goodness and cheapness of the exported articles, and so maintaining the place of the nation in foreign markets. The industrial control was exercised, in part directly by the State, but largely also through privileged corporations and trading companies. High duties on imports were resorted to, at first perhaps mainly for revenue, but afterwards in the interest of national production. Commercial treaties were a principal object of diplomacy, the end in view being to exclude the competition of other nations in foreign markets, whilst in the home market as little room as possible was given for the introduction of anything but raw materials from abroad. The colonies were prohibited from trading with other European nations than the parent country, to which they supplied either the precious metals or raw produce purchased with home manufactures. Under the Mercantile System a colony was thus regarded as a hewer of wood and drawer of water for the Mother Country. For Britain, the loss of the North American colonies was a major consequence of the doctrine.

That the efforts of governments for the furtherance of manufactures and commerce under the mercantile system were really effective towards that end is admitted by Adam Smith, and cannot reasonably be doubted, though doctrinaire free-traders have often denied it. Technical skill must have been promoted by their encouragements; whilst new forms of national production were fostered by attracting workmen from other countries, and by lightening the burden of taxation on struggling industries. Communication and transport by land and sea were more rapidly improved; and the social dignity of the industrialist was enhanced.

Such a mercantile policy had been already practised in the 14th and 15th centuries, thus preceding any formal exposition or defence of its speculative basis. At the commencement of the 16th century it began to exercise a widely extended influence. Charles V. adopted it, and his example contributed much to its predominance. Henry VIII. and Elizabeth conformed their measures to it. The leading States soon entered on a universal competition for manufacturing and commercial preponderance. Through almost the whole of the 17th century the prize, so far as commerce was concerned remained in the possession of Holland, Italy having lost her former ascendancy by the opening of the new maritime routes, and Spain and Germany being depressed by protracted wars and internal dissensions. The admiring envy of Holland felt by English politicians and economists appears in such writers as Raleigh, Mun, Child and Temple. Cromwell, by his Navigation Act, which destroyed the carrying trade of Holland and founded the English empire of the sea, and Colbert, by his whole economic policy, domestic and international, were the chief practical representatives of the mercantile system.

See G. Schmoller, *The Mercantile System* (Eng. trans., 1896); also the articles, BALANCE OF TRADE; FREE TRADE; PROTECTION; PHYSIOCRATIC SCHOOL, etc.

MERCAPTANS are organic chemical compounds of similar type to the alcohols (*q.v.*) but containing sulphur in the place of oxygen. They are thus thioalcohols or thiols. Their generic name is derived from "mercurio aptum" which refers to the formation of characteristic crystalline mercury salts by the interaction of the thiols with mercuric oxide.

Mercaptans may be either aliphatic or aromatic. *Ethyl mercaptan,* $C_2H_5{\cdot}SH$, a typical aliphatic thiol, is a volatile liquid boiling at 36·2 C and sparingly soluble in water; it has a disagreeable smell. It is made by warming calcium ethyl sulphate with aqueous potassium hydrosulphide, and also by passing sulphuretted hydrogen into a solution of aluminium bromide in ethyl bromide, when a crystalline product, $AlBr_3{\cdot}C_2H_5Br{,}H_2S$, separates which yields the mercaptan on treatment with water. Ethyl mercaptan is used commercially in the production of the drugs sulphonal (*q.v.*), trional and tetronal.

Phenyl mercaptan, $C_6H_5{\cdot}SH$, the simplest aromatic thiol, is a liquid boiling at 169·5° C, and is prepared by acting on benzenediazonium chloride (*see* DIAZO-COMPOUNDS) successively with potassium ethyl xanthate and caustic alkali.

MERCARA, the capital of the province of Coorg, in Southern India, situated on a plateau about 4,000 ft. above the sea. Pop. (1921), 5,675. It consists of two quarters: the fort, containing the public offices, the old palace, and the residence of the commissioner; and the native town of Mahadevapet.

MERCATOR, GERARDUS [latinized form of GERHARD KREMER] (1512–1594), Flemish mathematician and geographer, was born at Rupelmonde, in Flanders, on March 5, 1512. He studied at Bois-le-Duc and at Louvain where he met Gemma Frisius, a pupil of Apian of Ingolstadt, from whom he derived much of his inclination to cartography and scientific geography. In 1534 he founded his geographical establishment at Louvain; in 1537 he published his earliest known map, now lost (*Terrae sanctae descriptio*). In 1537–40 he executed his survey and map of Flanders (*Exactissima Flandriae descriptio*), of which a copy exists in the Musée Plantin, Antwerp. At the order of Charles V., Mercator made a complete set of instruments of observation for the emperor's campaigns. In 1538 appeared Mercator's map of the world in (north and south) hemispheres, rediscovered in 1878 in New York; this work shows Ptolemy's influence still dominant over Mercatorian cartography. In 1541 he issued the celebrated terrestrial globe, which he dedicated to Nicolas Perrenot, father of Cardinal Granvelle: this was accompanied by his *Libellus de usu globi,* which is said to have been presented to Charles V. In 1551 a celestial globe followed. In 1533 Mercator had retired for a time from Louvain to Antwerp, partly to avoid inquiry into his religious beliefs; in 1544 he was arrested and prosecuted for heresy, but escaped serious consequences. He now accepted in 1552 the chair of cosmography at the newly established University of Duisburg. The organization of the university was adjourned, and never completed in Mercator's lifetime; but he now became cosmographer to the duke and permanently settled on German soil. Soon after this, however, he paid a visit to Charles V. at Brussels, and presented the emperor with a *cosmos,* a celestial sphere enclosing a terrestrial, together with an explanatory *Declaratio:* this work marks an era in the observation of

longitude by magnetic declination, perfected by Halley. Charles rewarded the author with the title of *imperatorii domesticus* (*Hofrath* in the epitaph at Duisburg).

In 1554 Mercator published his great map of Europe in six sheets, three or four of which had already been pretty well worked out at Louvain; a copy of this was rediscovered at Breslau in 1889. Herein Mercator begins to emancipate himself from Ptolemy; thus Ptolemy's 62° for the length of the Mediterranean, reduced to 58° in the globe of 1541, he now cuts down to 53°. On Oct. 28, 1556, he observed an eclipse at Duisburg; in 1563 he surveyed Lorraine, at the request of Duke Charles, and completed a map of the same (*Lotharingiae descriptio*); but it is uncertain if this was ever published. In 1564 he engraved William Camden's map of the British Isles; in 1568 he brought out his *Chronologia, hoc est temporum demonstratio . . . ab initio mundi usque ad annum domini 1568, ex eclipsibus et observationibus astronomicis.* In the same year was published his memorable planisphere for use in navigation, the first map on "Mercator's projection," with the parallels and meridians at right angles (*Nova et aucta orbis terrae descriptio ad usum navigantium accommodata*). Improvements were introduced in this projection by Edward Wright in 1590; the more general use of it dates from about 1630, and largely came about through Dieppese support. In 1572 Mercator issued a second edition of his map of Europe; in 1578 appeared his *Tabulae geographicae ad mentem Ptolemaei restitutae et emendatae;* and in 1585 the first part (containing Germany, France and Belgium) of the *Atlas, sive cosmographicae meditationes de fabrica mundi,* in which he planned to crown his work by uniting in one volume his various detailed maps, so as to form a general description of the globe.

In 1585 he adapted his *Europe* to the *Atlas;* in 1587, with the help of his son Rumold, he added to the same a world-map (*Orbis terrarum compendiosa descriptio*), followed in 1590 by a second series of detailed maps (Italy, Slavonia, Greece and Candia). The rest of the regional and other plans in this undertaking, mostly begun by Gerard, were finished by Rumold. The designs are accompanied by cosmographical and other dissertations, some of the theological views in which were condemned as heretical. (*See* the Duisburg edition of 1594, folio.) In 1592 Mercator published, two years after his first apoplectic stroke, a *Harmonia evangeliorum.* He died on Dec. 5, 1594, and was buried in St. Saviour's church, Duisburg. With Ortelius he helped to free geography from the tyranny of Ptolemy; his map and instrument work is noteworthy for its delicate precision and admirable detail.

MERCENARY, one who serves or acts solely for motives of personal gain (Lat. *mercenarius,* from *merces,* reward, gain), particularly a soldier who offers himself for service in any army which may hire him. (*See* also CONDOTTIERE.)

MERCERIZING. The term applied to a process of treating cotton and other vegetable fibres with certain chemical reagents, especially caustic soda, whereby considerable improvement in some properties of the material is effected. Caustic soda solution of over 13·5% strength (30°Tw) causes cotton to shrink considerably and to become stiff and translucent. The two latter properties are lost on washing with water, but the threads become coarser and stronger so that a piece of treated calico appears closer and thicker than the original cloth. These observations were first recorded by John Mercer (1843) who suggested the use of 45°Tw caustic soda for obtaining cotton of improved strength and dyeing properties. The treated cotton has a greater affinity for direct, sulphur and vat colours than untreated cotton. The production of crimp effects—by printing caustic soda thickened with British gum on to calico—first suggested by Mercer was revived in 1890–91 and is frequently used, but it was about the only application of mercerizing without tension or as Mercer termed it *sodaizing* or *fulling* to attain a large measure of commercial success. In 1844 Depoully and Garnier produced crimps on union fabrics by submitting the material to the action of cold caustic soda. The cotton contracts and the wool and silk remain unaltered. The caustic soda is removed by washing and treating with dilute acid and again washing. The production of a *permanent* lustre as the result of treating cotton in a stretched condition (*under tension*) with caustic soda and washing until tension slackens was discovered and patented by H. Lowe in 1889 with a supplementary patent in 1890. The importance of Lowe's discovery was not recognized until 1895 when Thomas and Prevost repatented his invention. Their patent was subsequently annulled on the ground that it had been anticipated. The natural lustre of cotton can be seen when the fibre is viewed by reflected light under the microscope, but cotton mercerized under tension shows a spun silk-like lustre to the naked eye. Considerable change in the appearance of the cross section of the cotton fibre as seen in the microscope is effected by mercerizing. It is especially noticeable that the fibres appear more rounded. This has probably much to do with the appearance of lustre in the threads of yarn or cloth mercerized. No doubt many of the researches which have been carried out with the object of determining the cause of the lustre (a subject which has given rise to much controversy), have been undertaken with the object of ascertaining whether it would be possible to obtain lustre without applying tension to the cotton and thereby avoiding the use of somewhat elaborate machinery for large scale work. It has been proposed to add substances such as silicate of soda and glycerine to the alkali but these are only applied in conjunction with the device of applying tension.

Machines for mercerizing are designed to secure uniform impregnation and tension with the minimum volume and waste of caustic soda solution. Efficient washing is a matter of great importance. An efficient type of yarn mercerizing machine is constructed with a pair of strong steel rollers placed horizontally, arranged to rotate with reversing motion and fitted with hydraulic pistons for moving them apart when a comparatively shallow trough containing caustic soda 60°Tw is drawn into position under them. The yarn which is at first loosely passed over the rollers is stretched out, then allowed to shrink and again stretched. After a few minutes it is submitted to the action of a squeezing roller, which is caused to press against one of the stretching rollers, and is washed in the stretched condition with hot water from spurt pipes above. The caustic washings are collected by means of a separate trough from which they are conveyed to the recovery plant. In *warp* mercerizing the tension is supplied by double nip squeezing rollers placed at each end of the first of a set of four tanks or boxes each provided inside with guide rollers.

Mercerizing Piece Goods.—For *pieces* stentering machines are used. In these two endless chains carry clips which run in slotted grooves in the horizontal frame of the machine which is about 40ft. in length. The clips nip the cloth automatically on either side as it is fed into the machine from an impregnating bath and tension rollers (warp), at the same time the two rows of clips diverge and when the cloth has travelled about one-third of the length of the machine it is stretched slightly beyond its original width. At this point the cloth meets a spray of water from spurt pipes. The tension slacks and the mercerizing is effected. When the piece arrives at the end of the machine the clips open and release it. It is most economical and satisfactory to mercerize before bleaching, but the recovery and concentration

of the caustic soda (usually carried out in multiple effect evaporating plant) is not attained without difficulty for it is always contaminated with impurities, the constituents of the cotton which has been treated. The action of caustic soda on bleached cotton is complete in 30 seconds, but in the case of unbleached cotton an appreciable time is taken in wetting out the material. In order to save this time, or boiling out to some extent before mercerizing or the risk of uneven treatment, some people make use of certain agents for the purpose of effecting rapid wetting. The product *Prestabit* is stated by Rath (1928) to be very efficient in this respect. Cotton mercerized under tension has a greater affinity for colouring matters than ordinary cotton but not quite so much as that mercerized without tension. Mercerized cotton which is dried before dyeing takes up less colour than that dyed in a moist or air dried condition. Air dry untreated cotton contains 7·8% moisture, air dry mercerized cotton 12·6%.

CLIP FOR GRIPPING CLOTH, ONE OF AN ENDLESS CHAIN OF CLIPS ARRANGED ON BOTH SIDES OF A MERCERIZING MACHINE, IN ORDER TO GRASP THE SELVEDGE WITHOUT TEARING THE CLOTH

The action of caustic soda on cotton was regarded by Mercer as a chemical reaction in which one molecule of cellulose combined with one of caustic soda; by washing with water the radicle Na_2O is replaced by H_2O. In 1852 J. H. Gladstone found that the composition corresponded to $2C_6H_{10}O_5 \cdot NaOH$. This is in agreement with the moisture content of the washed and air dried mercerized cotton. Since 1900 many workers have attempted to determine the composition of alkali cellulose and some have cast doubt on the chemical nature of the action but it is evident that beyond a certain concentration (about 32°Tw) there are distinct signs of chemical action and the amount of caustic soda (of usual mercerizing strength) taken up by cotton agrees closely with Gladstone's formula. Knecht and Platt (1925) conducted a series of nine experiments using solutions of caustic soda from 20°–100°Tw. The amount of caustic soda taken up was 12·3% at 40°Tw and above that strength it was practically constant. Ermen and Jenkins (1927), using a similar method with certain modifications, found 15·7% caustic soda absorbed between 35° and 50°Tw caustic soda, but after that an increasing amount of caustic absorbed (25%) with 82°Tw. It is very difficult quantitatively to manipulate small experiments with caustic soda above 70°Tw. The space lattice of mercerized ramie cellulose as developed from X-ray data has been the subject of investigations by O. L. Sponsler and W. H. Dore (July 1928), who find definite evidence of action above a critical concentration of 13% caustic soda. With hot caustic soda a greater concentration is required and ice cold caustic may be of a lower concentration for mercerizing.

The colouring matter benzopurpurine may be utilized in testing for mercerization, by dyeing the cotton a full shade of red and then destroying the colour with titanous chloride in dilute hydrochloric acid solution. Just before the colour entirely disappears mercerized cotton shows a pink colour, untreated cotton remains blue until the colour vanishes. The ratio of the amount of benzopurpurine 4B taken up by untreated and mercerized cotton supplies a means of estimating the extent of mercerization. A test with a solution of iodine in potassium iodide together with a zinc chloride solution depends upon the indication of a blue colour in the case of mercerized cotton. Treatment with a mixture containing 320 cu.cm. sulphuric acid, 120°Tw and 260 cu.cm. formaldehyde 40% for 2min. and washing increases the affinity of mercerized cotton for chlorazol sky blue to such a great extent that it is still more easily distinguished from ordinary cotton treated with the reagent.

Many other reagents besides caustic soda modify the properties of cotton in a similar manner. Some of these were known to Mercer, sulphuric acid of 105°Tw and zinc chloride 145°Tw being included in the first patents. Nitric acid of 83°Tw acts very similarly to caustic soda and Knecht has shown that a compound with one molecule of nitric acid per molecule of cellulose is formed. It is decomposed by washing with water. Marshall finds that the lustre of China grass is improved by treating with nitric acid 83°Tw without tension. The lustre of linen is improved by mercerizing. Viktorov (1925) showed that in mercerizing linen there was a fall in strength which might amount to 10% but with 53°Tw caustic soda a 40% increase in dyeing affinity for direct colour was observed. (E. Hr.)

MERCHANDISE MARKS. The first attempt to make the falsification of trade marks a criminal offence was in the British Merchandise Marks act 1862. After the international convention for the protection of industrial property, made at Paris in 1883, to which Great Britain acceded in 1884, the Merchandise Marks act 1887 was passed generally to make better provision for the protection of merchandise. It was amended in 1891, 1894 and 1911. By these statutes, a person is guilty of an offence, punishable on indictment or summary conviction by fine or imprisonment, who does any of the five following acts, unless he proves as regards the first four of them that he acted without intent to defraud (there is a special defence to No. v. which is noted below): (i.) forges any trade mark, or makes, disposes of, or has in his possession for such purpose any die or instrument; (ii.) falsely applies any trade mark or a colourable imitation of any trade mark to goods; (iii.) applies any false trade description to goods; (iv.) causes any of the above offences to be committed; (v.) sells or exposes for sale, or has in his possession for sale, trade or manufacture, any goods or things to which any forged trade mark or false trade description is applied, or any trade mark or colourable imitation of a trade mark is falsely applied, unless *the defendant* proves that, having taken all reasonable precautions, he had no ground to suspect the genuineness of the mark, etc., and also that on demand he gave to the prosecutor all the information in his power as to the person from whom he obtained the goods, or proves that he acted "innocently."

"Trade description" is defined as any descriptive statement or other indication as to the number, quantity (not *quality,* it should be observed), or weight, place or mode of production, or the material of the goods, or as to their being subject to an existing patent, privilege or copyright. The test of what is a trade description depends upon the understanding of the trade and not on scientific correctness (*Fowler* v. *Cripps,* 1906, I K.B. 16).

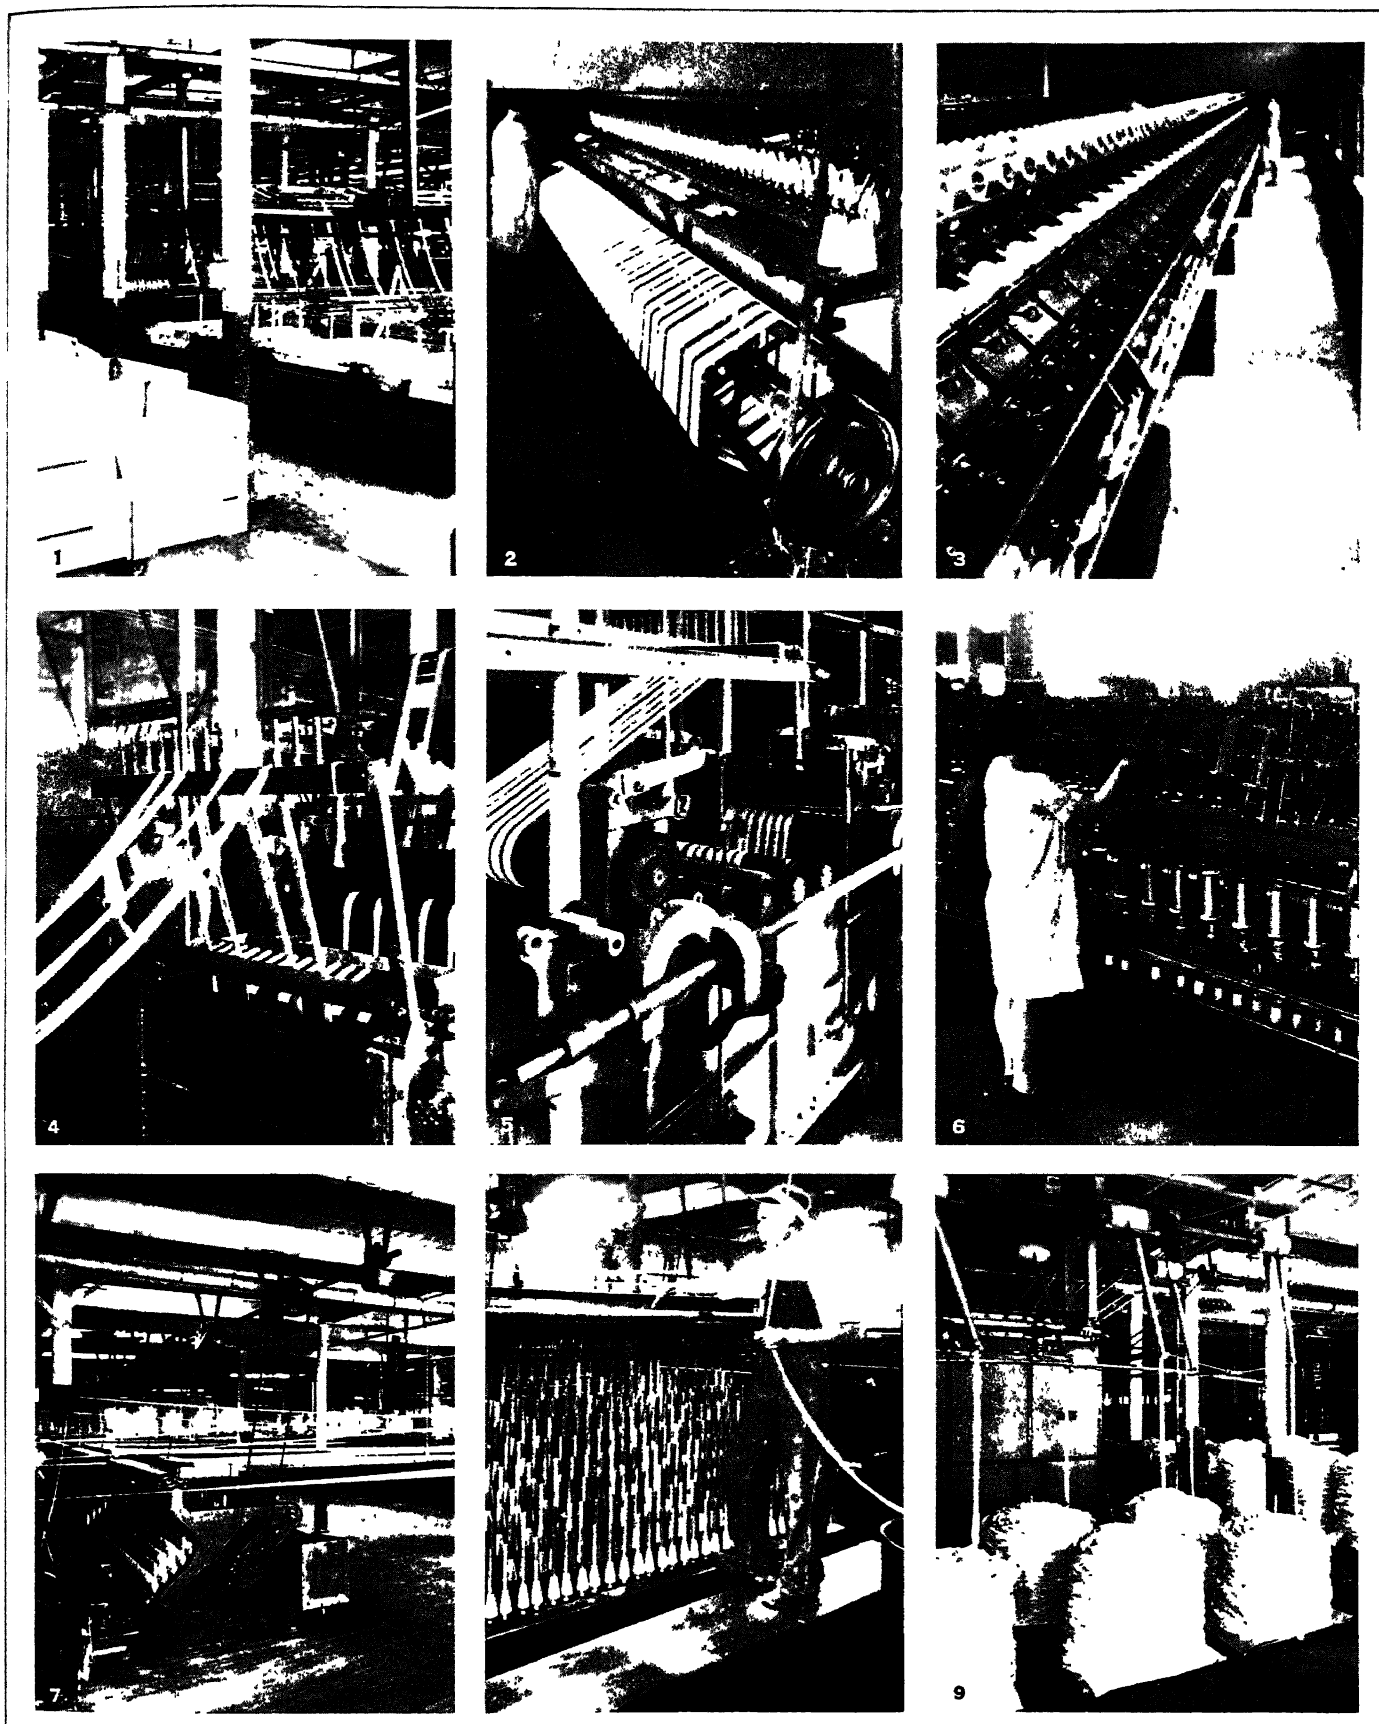
On a prosecution for any of these offences there is a power to forfeit the things found although no one is convicted. If the offender is indicted (it is in his option to be tried in this way) the punishment is fine and imprisonment, the latter not to exceed two years. On summary conviction the punishment is not to exceed, for a first offence, four months' imprisonment, with or without hard labour, and a fine of £20; and for any subsequent offence six months' imprisonment and a fine of £50. Any person procuring the commission of an offence outside the United Kingdom can be punished; a search warrant for offending goods can be issued by a justice; but prosecutions must be commenced within three years of the offence or one year of its discovery. (X.)

THE UNITED STATES

Under the Federal laws, providing for the registration and protection of merchandise marks or trade marks, infringement suits are brought in the Federal courts and the penalty for infringement is three times the amount of the verdict recovered. The statute law provides for injunctions and in a damage suit the plaintiff, if successful, shall be entitled to the defendant's profits in addition to the damages sustained. There are also provisions with penalties for fraudulent registrations and for imitating trade marks.

In addition to Federal laws safeguarding rights to merchandise marks, the various States have laws on the use and abuse of trade mark rights. The New York Penal law defines a trade mark as a mark used to indicate the maker, owner or seller of an article of merchandise and includes names, letters, words, devices, emblems.

Offence against a trade mark is a misdemeanour and punishable for the first offence by a fine of not less than 50 dollars nor more than 500 dollars, or by imprisonment for not more than a year, or both. For each subsequent offence the penalty is imprisonment for not less than 30 days, nor more than a year, or by both such



BY COURTESY OF THE STANDARD-COOSA-THATCHER COMPANY

VARIOUS PROCESSES USED IN MERCERIZING

1. Chemical immersion of cotton in caustic soda solution. 2. Reeling yarn to skeins. 3. Cone winders. 4. Warp dyeing. 5. Warp mercerizing machine. 6. Backwinding skeins of dyed mercerized yarn. 7. Quilling (preparing yarn for reeling onto cones). 8. Quiller in operation. 9. Finishing the mercerizing process

imprisonment and a fine of not less than 500 dollars or more than 1,000 dollars.

Some offences against trade marks include: (a) falsely making, counterfeiting or affixing the trade mark of another without the owner's consent; (b) knowingly selling, keeping or offering for sale an article to which is attached a false or imitation trade mark; (c) possessing a counterfeit trade mark or anything for the purpose of counterfeiting a trade mark; (d) knowingly selling or offering for sale goods represented to be the product of any person other than himself unless in original package and under the mark of the manufacturer; (e) selling or exposing for sale goods in bulk to which no trade mark is attached and representing the same as manufactured by one not the manufacturer; (f) knowingly selling or offering for sale any article of merchandise and by representation, name, mark or advertisement or otherwise making any false representations as to the person by whom the same was made or as to the propriety of any mark thereon. Other sections prohibit the refilling and reselling of trade marked bottles and vessels and keeping them with intent to refill and resell. (*See* TRADE MARKS.)

The General Business Law of New York provides that anyone engaged in the manufacture of certain enumerated products may register a trade mark by filing it in the proper county clerk's office and with the secretary of State. It also contains prohibitions in regard to the use of such trade marks by those other than the owner. Penalties are named for violations of this article. In other States, there are similar laws. (H. A.)

MERCHANT, a trader, one who buys and sells goods for profit. The term is now usually confined to a wholesale dealer or one who trades on an extended scale with foreign countries.

MERCHANT ADVENTURERS, a famous early English trading company. (*See* CHARTERED COMPANIES.)

MERCHANT BANKERS. Private banking firms which do not conduct an ordinary banking business but confine themselves chiefly to acceptance and loan issuing. In most cases they have been evolved out of merchant firms engaged in foreign commercial business; whose foreign connections and activities caused large amounts of foreign exchange to pass through their hands, and they were at one time the dominant figures in the London exchange market, though they had already left most of this business to smaller firms. Foreign exchange in the period before the World War was largely taken over by the London branches of the foreign banks, from whom it has since been again taken over by the English banks. Foreign trade connections also, by making their name and standing familiar to banks and merchants in all countries, made bills drawn on them universally acceptable and so developed the growth of their activity in acceptance, by which, on payment of a commission, they placed their names at the disposal of less eminent firms, and allowed bills to be drawn on themselves for transactions in which they were not directly concerned.

The foreign connections of such firms and their high prestige also led to their being applied to by foreign Governments, municipalities and other borrowers who desired to raise loans in the London market, and their wealth and high standing in the opinion of the investing public gave them exceptional qualifications for this task. By a gradual evolution they largely abandoned their activities as merchants and concentrated them on acceptance and loan-issuing. As bankers in the ordinary sense of the word were not until lately admitted on the board of the Bank of England, it was chiefly recruited from the ranks of the merchant bankers. Their acceptance business has lately been subject to keen rivalry on part of the joint stock banks both in England and America (where acceptance was first permitted to the national banks by the Federal Reserve Act), but their prestige and long experience as issuing houses are still unrivalled. (*See* MONEY MARKET.)

MERCHANT-SHIPPER: *see* EXPORTS: *Exports in Practice.*

MERCIA, one of the kingdoms of Anglo-Saxon England. The original kingdom seems to have lain in the upper basin of the Trent, comprising the greater part of Staffordshire, Derbyshire and Nottinghamshire and the northern parts of Warwickshire and Leicestershire. The name (*Merce*) seems to denote men of the March, and presumably was first applied when this district bordered upon the Welsh. In later times Mercia successively absorbed all the other territories between the Humber and the Thames except East Anglia, and some districts even beyond the Thames.

The origin of the kingdom is obscure. The royal family, according to Felix, *Life of St. Guthlac,* were called Iclingas. Icel, their ancestor, may have been the founder of the kingdom, but nothing is known of him. The family, however, claimed descent from the ancient kings of Angle (*cf.* Offa I. and Wermund). The first Mercian king of whom we have any record was Cearl, who apparently reigned about the beginning of the 7th century, and whose daughter Cwoenburg married Edwin, king of Deira. During Edwin's reign Mercia was subject to his supremacy, though it may have been governed throughout by princes of its own royal family. Its first prominent appearance in history may be dated in 633, when the Mercian prince Penda joined the Welsh king Cadwallon in overthrowing Edwin. According to the Saxon Chronicle, Penda began to reign in 626, and fought against the West Saxons at Cirencester in 628. In the Mercian regnal tables, however, he is assigned a reign of only twenty-one years, which, as his death took place in 654 or 655, would give 634 as the date of his accession, presumably on the overthrow of Edwin, or perhaps on that of Cadwallon. During the reign of Oswald Penda clearly reigned under the suzerainty of that king. In 642, however, Oswald was slain by Penda in a battle at a place called Maserfeld, which has not been identified with certainty. During the early part of Oswio's reign the Northumbrian kingdom was repeatedly ravaged by the Mercians, and on one occasion (before 651) Penda almost captured the Northumbrian royal castle at Bamborough. At the same time he extended his influence in other directions, and expelled from the throne of Wessex Coenwalh, who had divorced his sister. Indeed, at this time nearly all the English kingdoms must have acknowledged his supremacy. The Middle Angles, whose territory included the counties of Northampton, Rutland, Huntingdon, and parts of Bedfordshire, Cambridgeshire, Leicestershire and Lincolnshire, formed a dependent principality under his son Peada. At this time also the territory corresponding to the modern counties of Cheshire, Shropshire and Herefordshire seems to have been occupied. The last of these counties is said some time later to have been under the government of another son of Penda, named Merewald. In 654 or 655 Penda again invaded Northumbria, with a huge army divided into thirty *legiones,* each under a royal prince, among whom were Aethelhere, king of East Anglia, and several Welsh kings. He was slain, however, by Oswio, at a river called the Winwaed. Mercia then came again under Northumbrian rule. Peada, the eldest son of Penda, was allowed to govern the part south of the Trent, while north Mercia was put in charge of Northumbrian officials. Penda, although he did not prohibit the preaching of Christianity, had remained a heathen to the end of his life. His death was followed by the conversion of his kingdom. Peada had embraced Christianity on his marriage with a daughter of Oswio, and under him the first Mercian bishopric was founded. Shortly afterwards Peada was murdered, but in 658 the Mercians rose under his younger brother Wulfhere and threw off the Northumbrian supremacy.

Wulfhere seems to have been a vigorous ruler, for he extended the power of Mercia as far as it had reached in the days of his father, and even farther. According to the Chronicle he invaded Wessex as far as the Berkshire Downs in 661. At the same time he conquered the Isle of Wight, which he gave to Aethelwalh, king of Sussex. Between 661 and 665 he was defeated by the Northumbrian king Ecgfrith and had to give up Lindsey. In 675 he again fought with the West Saxons under Aescwine, and shortly afterwards died. His brother Aethelred, who succeeded him, invaded Kent in the following year, and in 679 fought a battle on the Trent against Ecgfrith, by which he recovered Lindsey. After this, however, we hear little of Mercian interference with the other kingdoms for some time; and since it is clear that during the last 15 years of the 7th century Wessex, Essex, Sussex and Kent were frequently involved in strife, it seems likely that the Mercian king had somewhat lost hold over the south of England. In 704 Aethelred resigned the crown and became a monk,

leaving his kingdom to Coenred, the son of Wulfhere. Coenred also abdicated five years later and went to Rome. Ceolred, the son of Aethelred, who succeeded, fought against the West Saxon king Ine in 715. On his death in the following year Aethelbald, a distant relative, came to the throne, and under him Mercian supremacy was fully restored over all the English peoples south of the Humber. After his murder in 757 the Mercian throne was held for a short time by Beornred. He was expelled the same year by Offa, who soon restored the power of Mercia, which seems to have suffered some diminution during the later years of Aethelbald. Offa's policy was apparently the extinction of the dependent kingdoms. In his reign the dynasties of Kent, Sussex and the Hwicce seem to have disappeared, or at all events to have given up the kingly title. In 787 he associated his son Ecgfrith with him in the kingdom, and after his death (796) Ecgfrith reigned alone for a few months. On the death of Ecgfrith the throne passed to Coenwulf, a descendant of Pybba, father of Penda. In 821 Coenwulf was succeeded by his brother Ceolwulf, who was deprived of the throne in 823, being succeeded by Beornwulf. In 825 Beornwulf was defeated by Ecgberht, king of Wessex, and in the same year he was overthrown and slain by the East Angles. The supremacy now passed to Wessex.

In 827 Ludeca, the successor of Beornwulf, was slain in battle with five of his earls. Wiglaf, who succeeded him, was expelled two years later by Ecgberht, but regained the throne in the following year. He died, probably in 839, and was succeeded by Berhtwulf, who reigned until 852. Under these later kings Mercia seems to have extended from the Humber to the Thames, including London, though East Anglia was independent, and that part of Essex which corresponds to the modern county of that name had been annexed to Wessex after 825. Berhtwulf was succeeded in 852 by Burgred, who married Aethelswith, daughter of Aethelwulf. His power seems to have been more or less dependent on the West Saxons. In 853, with the assistance of Aethelwulf he reduced North Wales to subjection. Again in 868 he called upon the West Saxon king Aethelred for assistance against the Danes under Loobrok's sons, who at this time invaded Mercia after their overthrow of the Northumbrians at York. No battle took place, and the Mercians subsequently made peace with the Danes. In 872 the Danes occupied London on their return from invading Wessex, after which a truce was again made. In 873 the Danes encamped at Torksey, Lincolnshire, and although another truce ensued, they advanced in the following year to Repton, and Burgred was driven from the kingdom. He went to Rome, where he remained until his death. In 874 Ceolwulf, a king's thegn, was made king by the Danes, and definitely acknowledged their overlordship. In 877, after the second invasion of Wessex, the Danes seem to have taken the eastern part of Mercia into their own hands. How long Ceolwulf reigned over the western portion is unknown. About 884 the most important person in English Mercia was an earl, Aethelred, who accepted the suzerainty of Alfred, and in or before 887 married his daughter Aethelflaed. Aethelred and Aethelflaed appear to have had practically regal power, though they did not use the royal title. In 886 London, which had been recovered by Alfred from the Danes, was restored to Aethelred. During the invasion of 893–97 English Mercia was again repeatedly ravaged by the Danes; but in the last of these years, by the united efforts of Alfred and Aethelred, they were at length expelled. In the following years the government was carried on by Aethelred and Aethelflaed, who after her husband's death co-operated with her brother Edward the Elder in the great campaigns which led to the conquest of Danish Mercia. After her death in 918 her daughter, Aelfwyn was soon deprived of the government by Edward, and English Mercia was definitely annexed to Wessex.

From this time onwards its existence as a separate kingdom was at an end, though during the last years of Eadwig's reign the Mercians and Northumbrians set up Eadgar as king. In the last century of the Saxon period the earls of Mercia frequently occupied a semi-royal position. The most important of these were Aelfhere under Eadgar, Edward and Aethelred, Eadric Streona, and Leofric, under Edward the Confessor.

Authorities.—Bede, *Historia Ecclesiastica* (ed. C. Plummer, Oxford, 1896); *Anglo-Saxon Chronicle* (ed. Earle and Plummer, Oxford, 1899); W. de G. Birch, *Cartularium Saxonicum* (1885–93).

(F. G. M. B.)

MERCIÉ, MARIUS JEAN ANTONIN (1845–1916), French sculptor and painter, was born in Toulouse on Oct. 30, 1845. He entered the École des beaux arts, Paris, and in 1868 won the Grand Prix de Rome. He made his name with the bronze statue "David" (1872) now in the Luxembourg museum in Paris, and the "Gloria Victis" for which he received the medal of honour of the Salon. Other popular successes were a relief, "The Genius of the Arts" (1877), now in the Tuileries, and a similar work for the tomb of Michelet in Père la Chaise. Mercié was appointed professor at the École des beaux arts, and was elected to the Académie Française in 1891.

His sculptures include "Le Souvenir" (1885), a monument of "Louis-Philippe and Queen Amélie" for their tomb at Dreux, and a stone group of "Justice" at the hôtel de ville, Paris. Among his paintings are a "Venus" (1883) and "Michael Angelo studying Anatomy" (1885). He died on Oct. 14, 1916.

MERCIER, DÉSIRÉ (1851–1926), Belgian cardinal, was born Nov. 21, 1851, at Braine-l'Alleud in the Walloon part of Brabant, of a bourgeois family. He studied at Malines. On April 5, 1874, he was ordained priest, a disciple of Aquinas. After two years at the university of Louvain, he was appointed professor of philosophy at the lesser seminary of Malines (1877). In 1880 Leo XIII., who wished to promote the study of Thomism, invited Cardinal Dechamps, Archbishop of Malines, to found a chair of Thomist philosophy at Louvain. The choice of the Cardinal fell on the young Abbé Mercier, who was appointed in 1882. Before assuming his new duties, the new professor studied in Paris under Charcot. While teaching psychology, logic, criteriology, metaphysics and ontology to his Louvain students, including a large number of laymen, he followed closely the research work of his colleagues, according to the tradition of the scholasticists, who combined theological and scientific studies.

In 1886 the Pope conferred a Roman prelateship upon him, and in 1888–9 issued two briefs urging the necessity of founding an Institut Supérieur de Philosophie at Louvain. This institute was finally opened in 1894 and included, besides the chair of philosophy held by Mgr. Mercier, chairs of cosmology, physics, sociology, etc., held first by his colleagues and later by the pupils he had formed. The institute published the *Revue Néoscolastique* and became the centre of Neo-Thomism which exerted considerable influence on Catholic thought all over the world. In 1906 Mgr. Mercier was appointed Archbishop of Malines, and in 1907 he was created a cardinal. He used his influence with his priests and his flock to break down the barriers existing between the members of the clergy and the laymen, to eliminate all class distinctions between the Catholic bourgeoisie and the labourers, and to bring about a better understanding between Catholics and non-Catholics.

On Aug. 20, 1914, while the Belgian Army was retreating upon Antwerp and the Germans were entering Brussels, the Cardinal was abruptly summoned to Rome to take part in the election of a successor to Pius X. Shortly after his return to Malines, he issued a pastoral letter, "Patriotism and Endurance," protesting against the burning of Louvain and the other excesses committed by the German army, and defining the position of the Belgian people towards the occupying Power. The Belgians, he said, owed, in soul and conscience, neither respect nor allegiance to this authority, which was not lawful, but must accept German regulations so long as they did not violate their duty to their country, the army alone having the right to resist openly the invaders' power. In spite of pressure exerted upon him by the German authorities, he maintained this attitude, protesting publicly in his sermons and pastorals against the arbitrary decrees of the governor-general, especially concerning the deportation of workmen and the administrative separation of the country, and urging the people, at the same time, to remain confident in the final victory of their just cause. In Jan. 1916 the Cardinal took a second journey to Rome and brought back a most cordial message from the Pope. He proclaimed, in his next pastoral letter,

that "The moral triumph of Belgium, in the eyes of civilization and history, is already an accomplished fact." In Oct. 1918, on the eve of the retreat of the German troops, the Cardinal received a message from the Governor greeting him as the "revered spiritual leader of the Belgian people" and announcing to him that prisoners and deportees would shortly recover their liberty.

After the War, Cardinal Mercier took part in the informal conversations which took place at Malines following the "appeal to all Christian people" issued by the Lambeth Conference of 1920. The first conference took place between Cardinal Mercier, Mgr. van Roey (his successor as archbishop of Malines), and Abbé Portal, on the one side, and the Dean of Wells, the Bishop of Truro (Rev. W. H. Frere) and Lord Halifax on the other. Bishop Gore, Dr. B. J. Kidd, Mgr. Batiffol and Abbé Hemmer took part in the third Conference, held in 1923. A full account of these conversations, which concentrated on doctrinal and historical rather than on administrative questions, was issued by the Archbishop of Canterbury at the end of the same year. In the spring of 1924 Cardinal Mercier celebrated the jubilee of his ordination. He died in Brussels on Jan. 23, 1926. (E. CA.)

His works include *Manual of Mod. Scholastic Philosophy*, by M. and professors of Louvain, trans. T. L. and S. A. Parker (1916–17); *Origins of Contemp. Psychology*, trans. W. H. Mitchell (1918). *See* also *Cardinal Mercier's own Story* (trans.) (1900); L. Noël, *Le Card. Mercier* (1920); G. Raemakkers, *Le grand cardinal belge* (1926); and *Conversations at Malines 1921–25* (1927).

MERCIER, HONORÉ (1840–1894), Canadian lawyer and statesman, was the son of Jean Baptiste Mercier, farmer, and of Marie Kimener, his wife. He was born at St. Athanase d'Iberville on Oct. 15, 1840. Mercier was educated at the Jesuit college of St. Mary, Montreal. Afterwards he was admitted to the bar of the province in April 1865. At the age of 22 he became the editor of the Conservative *Courrier de St. Hyacinthe*, in which he supported the policy of the Sicotte administration, which then represented the interests of Quebec, under the Act of Union (1840); but when Sicotte accepted a seat on the bench Mercier joined the Opposition, and contributed largely to the defeat of the Ministerial candidate. In 1864 he vigorously opposed the scheme of confederation, on the ground that it would prove fatal to the distinctive position held by the French Canadians. He resumed the editorship of the *Courrier* in 1866; but after a few months retired from journalism. In Aug. 1872 he was elected as member for the county of Rouville, and in May 1879 he became solicitor-general in the Joly Government, representing the county of St. Hyacinthe; and on the defeat of the ministry in October he passed, with his leader, into opposition. On the retirement of Joly from the leadership of the Liberal party in Quebec in 1883 Mercier was chosen as his successor. Mercier's attitude in the matter of the execution of Louis Riel, leader of the north-west rebellion brought adherents to the Liberal minority in the Legislative assembly, and at the general elections in Oct. 1886 the province was carried in the Liberal interest. In Jan. 1887 Mercier was sworn in as premier and attorney-general. He succeeded in passing without opposition the Jesuit Estates Act, a measure to compensate the order for the loss of property confiscated by the Crown. When Mercier appealed to the electorate in 1890, his policy was endorsed. Early in 1891 he negotiated a loan in Europe for the province, and whilst on a visit to Rome he was created a count of the Roman Empire by Leo XIII. For a few years he was the idol of the people of Quebec, but in 1891, it was alleged that subsidies voted for railways had been diverted to political use, and he was dismissed by the lieutenant-governor. At the elections held in March 1892, his party was hopelessly defeated. On the formation of a new Government he was brought to trial, and declared not guilty; his health, however, gave way.

See J.-O. Pelland, *Biographie, discours conférences, etc., de l'Hon. Honoré Mercier* (Montreal, 1893).

MERCIER, SEBASTIEN (1740–1814), French dramatist and miscellaneous writer, was born in Paris on June 6, 1740. He decried French tragedy as a caricature of antique and foreign customs in bombastic verse, and advocated the *comédie larmoyante* as understood by Diderot. To the *philosophes* he was entirely hostile. He denied that modern science had made any real advance; he even carried his conservatism so far as to maintain that the earth was a circular flat plain around which revolved the sun. Mercier wrote some 60 dramas, among which may be mentioned *Jean Hennuyer* (1772); *La Destruction de la ligue* (1782); *Jennéval* (1769); *Le Juge* (1774); *Natalie* (1775) and *La Brouette du vinaigrier* (1775). In politics he was a Moderate, and as a member of the Convention he voted against the death penalty for Louis XVI. During the Terror he was imprisoned, but was released after Robespierre's death. He died in Paris April 25, 1814.

See Léon Bechard, *Sebastien Mercier, sa vie, son oeuvre* (1903); R. Doumic in the *Revue des deux mondes* (July 15, 1903).

MERCK, JOHANN HEINRICH (1741–1791), German author and critic, was born at Darmstadt on April 11, 1741. He became paymaster at Darmstadt in 1768. Merck helped to found the *Frankfurter gelehrte Anzeigen* in 1772, and was one of the chief contributors to Nicolai's *Allgemeine Bibliothek*. In 1788 he was involved in serious financial difficulties, and although friends, notably Goethe, were ready to come to his assistance, his losses and the death of five of his children preyed upon his mind. He committed suicide on June 27, 1791. Merck influenced the *Sturm und Drang* movement by his acute criticisms, and was a mentor to the young poets of his day.

Merck's *Ausgewählte Schriften zur schönen Literatur und Kunst* were published by A. Stahr in 1840, with a biography. See *Briefe an J. H. Merck von Goethe, Herder, Wieland und andern bedeutenden Zeitgenossen* (1835), *Briefe an und von J. H. Merck* (1838) and *Briefe aus dem Freundeskreise von Goethe, Herder, Höpfner und Merck* (1847), all edited by K. Wagner. *Cf.* G. Zimmermann, *J. H. Merck, seine Umgebung und seine Zeit* (1871), and a selection of his writings and correspondence edited by K. Wolff in 1909 (2 vols.).

MERCOEUR, PHILIPPE EMMANUEL DE LORRAINE, DUC DE (1558–1602), French soldier, was born on Sept. 9, 1558, and married Marie de Luxemburg, duchesse de Penthièvre. In 1582 he was made governor of Brittany by Henry III., who had married his sister. Mercoeur put himself at the head of the League in Brittany, and had himself proclaimed protector of the Roman Catholic Church in the province in 1588. Invoking the hereditary rights of his wife, who was a descendant of the dukes of Brittany, he endeavoured to make himself independent in that province, and organized a Government at Nantes, calling his son "prince and duke of Brittany." With the aid of the Spaniards he defeated the duc de Montpensier, whom Henry IV. had sent against him, at Craon in 1592, but the royal troops, reinforced by English contingents, soon recovered the advantage. The king marched against Mercoeur in person, and received his submission at Angers on March 20, 1598. Mercoeur subsequently went to Hungary, where he entered the service of the emperor Rudolph II., and fought against the Turks, taking Stuhlweissenburg (Székes-Fehérvár) in 1599. Mercoeur died on Feb. 19, 1602.

See his *Correspondance* ed. by von de Carné (2 vols., 1899).

MERCUROCHROME is the trade name of the water-soluble disodium salt of dibrom-oxymercuri-fluorescein, $C_{20}H_9O_5Br_2$ (HgOH). Although the exact process of commercial manufacture is secret the general method of preparation is described in the *Journal of the American Chemical Society*, vol. xlii. (1920), page 2,355. It is claimed that Mercurochrome possesses many advantages over iodine. Like iodine, its stain (a deep cherry-red) gives a relatively permanent deposit of a bactericidal agent in the desired field and its visibility shows the extent of application. Mercurochrome does not burn, irritate or injure the body tissues, and it is not poisonous. It penetrates the tissues to a marked degree, preventing it from being washed away by body fluids or destroyed by other agents. Mercurochrome is frequently applied in the treatment of infectious diseases subject to local treatment, venereal diseases, infected and operative wounds, and is used successfully in the intravenous treatment of septicemias and local infections, such as pneumonia, erysipelas, scarlet fever and diphtheria. (F. J. G. DU.)

MERCURY (MERCURIUS, MIRQURIUS), the Italian god of merchandise (merx) and merchants. Rome frequently suffered from scarcity of grain during the unsettled times that followed the expulsion of the Tarquins. Various religious innovations were made to propitiate the gods, and, among other deities, in 495 the

Greek god Hermes was introduced into Rome under the Italian name of Mercurius (Livy ii. 21, 7; 27, 5). His temple on the Aventine became a sort of headquarters of the corn trade and of the merchants (*mercatores, mercuriales*) engaged in it, but he was soon worshipped by traders in general. His annual festival was on the 15th (the ides) of May, on which day his temple had been dedicated. May was chosen obviously because Maia (*q.v.*) was identified with her namesake the mother of Hermes; she was worshipped with Mercurius. His statues were in the business quarter (*e.g.* Festus, p. 157) and the water of his sacred spring near the Porta Capena was used by merchants for a lustral rite on May 15, see *Ovid*, Fast. v. 673ff.

In Roman art Mercury holds a caduceus and a purse (an element very rare in purely Hellenic representations).

See G. Wissowa, *Religion u Kultus*, 2nd ed. (1912), p. 304; Steuding in Roscher's *Lexikon, s.v.*

MERCURY (☿) is the smallest of the major planets, and has a diameter of only about 3,000 miles. It is also the nearest to the sun with a mean distance of 36,000,000 miles or 0·39 of the Earth's distance. But the eccentricity of its orbit, amounting to 0·206, is very much greater than that of any other major planet, and its perihelion and aphelion distances are respectively 28,500,000 and 43,350,000 miles or approximately in the ratio of 2 to 3. Its period of revolution in its orbit is 88 days, but its synodical period, *i.e.*, the interval between, say, successive superior conjunctions with the sun, is 116 days. At its most favourable elongations it recedes only about 28° from the sun. Its orbit has a greater inclination (7°) to the ecliptic than that of any other major planet. The albedo is low, but at a mean elongation its brightness is about equal to that of a star of zero magnitude; and

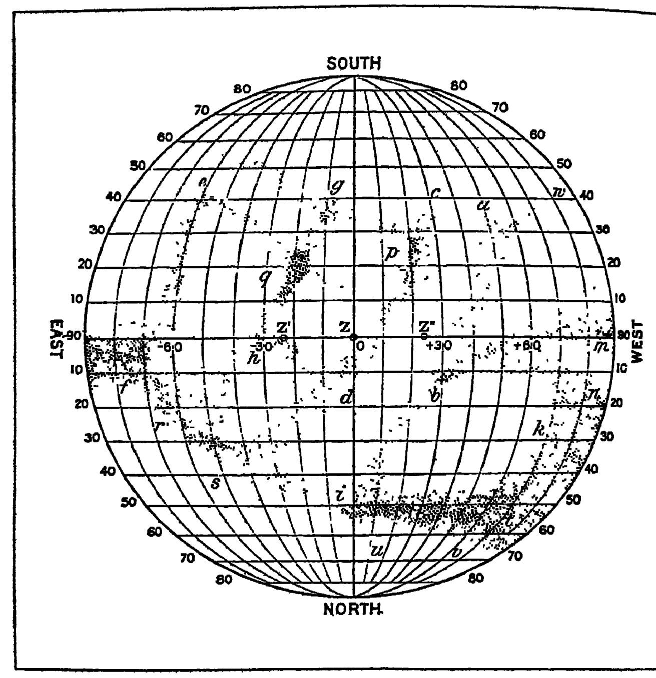
FIG. 1.—ANTONIADI'S CHART OF MERCURY SHOWING THE PORTION OF THE SURFACE TURNED TOWARDS THE SUN AT THE PLANET'S PERIHELION AND APHELION, I.E., AT THE POINTS ON THE ORBIT AT WHICH MERCURY IS NEAREST TO AND FARTHEST FROM THE SUN, Z' AND Z'' REPRESENTING EXTREME ZENITH POINTS OF THE SUN

although at a favourable elongation it can reach −1·2 magnitude, the planet is frequently dimmed or obscured by the haze and mists near the horizon. It can, however, be readily seen with a telescope in the daytime when high in the sky if the atmosphere is reasonably transparent.

As Mercury has no satellite it has been necessary to determine its mass from its attraction on Venus or some other body, and the result which has been deduced (about $\frac{1}{27}$ that of the earth) is somewhat uncertain. The density of the planet is apparently between that of Mars and the Moon.

Surface Features and Rotation.—As the angular diameter of Mercury varies from about 5″ to 13″ its phases are easily shown by quite a small telescope. But under the circumstances of observation it is far from easy to define the surface features with accuracy, and even the period of the planet's axial rotation was still regarded as uncertain until recently (1927). About the beginning of the 19th century Schroeter and Harding at Lilienthal



BY COURTESY OF DR. KOBOLD

FIG. 2.—SCHIAPARELLI'S CHART OF MERCURY SHOWING THE PORTION OF THE SURFACE TURNED TOWARDS THE SUN AT THE PLANET'S PERIHELION AND APHELION. Z, Z' AND Z'' INDICATE THE POINTS AT WHICH THE SUN IS IN THE ZENITH AT DIFFERENT TIMES IN MERCURY'S YEAR

recorded an occasional blunting of the S. cusp, and from the observations of this phenomenon and other features Bessel deduced a period of slightly more than 24 hours. Several other observers subsequently recorded light and dark patches and other features, but the conclusions drawn were somewhat discordant.

Between 1881 and 1889 Schiaparelli at Milan carried out a careful study of the planet, using at first a refractor of 8½ inches which was eventually replaced by one of 18 inches. His conclusion was that the periods of axial rotation and orbital revolution are identical, and that the axis of rotation is approximately normal to the orbit plane. Lowell at Flagstaff some years later came to a similar conclusion.

It would, of course, follow from such conditions that the planet always presents approximately the same face to the sun, as the Moon does to the Earth, though in consequence of the large eccentricity of the orbit, the effect of libration in longitude of the surface markings as seen from the sun would cause a displacement of nearly 24° on each side of a mean position. About 37% of the surface would be permanently sunlit; the same amount in perpetual night; and the remainder exposed alternately to sunlight and darkness with enormous changes of temperature during each revolution of the planet.

A fresh attack on the problem of Mercury's rotation was made by E. M. Antoniadi at Meudon with the help of the great 33-inch refractor of that observatory in 1927, and the result was to establish Schiaparelli's deductions. The markings were found to be somewhat variable in intensity, but—apart from the libration above mentioned—constant in position relatively to the terminator, thus indicating the identity of the periods of rotation and revolution. The charts of both Schiaparelli and Antoniadi are appended and it will be seen that many of the same features are presented in both, though Schiaparelli drew them as generally linear in character, whereas Antoniadi sees them rather as diffuse spots. Some of the objects shown by the latter can be also identified with features recorded at various times by Denning, Barnard,

Jarry-Desloges. Fournier, Danjon and other observers (see *L'Astronomie,* January 1928).

That Mercury has an atmosphere appears to be indicated by the varying intensity of the dark areas as observed at Meudon; but the visibility of the markings together with the planet's low albedo, and the absence of any appearance of an atmosphere as Mercury advances on or leaves the sun's disk on the occasions of its transit, would seem to show that it is scanty. This is what one would expect from a consideration of the smallness of the planet's mass and surface gravity. Radiometric observations at Mt. Wilson show that the temperature of the sunlit side is very far above the boiling point of water at the Earth's surface, but that of the opposite side may be not greatly removed from the absolute zero.

Transits.—Since the inclination of Mercury's orbit to the ecliptic is 7° it usually happens that at the time of inferior conjunction the planet passes N. or S. of the sun, but should conjunction occur when it is near one of its nodes it crosses the sun's disk and is seen during transit projected on it as a small black spot. As the earth passes the line of nodes about May 7 and November 9 transits can only take place near those dates. The November transits, however, which occur with Mercury in the neighbourhood of perihelion, and consequently more remote than usual from the earth, are very much more common than those in May when the conditions are reversed, the limits of distance from the node within which the planet must be for a transit to take place being 4° 45′ and 2° 40′ respectively.

The following table gives the dates and Greenwich Mean Astronomical Times of the middle of all the transits from 1677 (the date of the first one accurately observed) until the year 2003. The hours are in all cases reckoned from *noon.*

*Mercury grazes the sun's limb.

Motion of Perihelion.—What was for a long time a perplexing problem was presented by the motion of Mercury's perihelion, the line of apsides—or the longer axis of the orbit—showing a greater advance in the direction of the planet's motion than could be accounted for by the gravitational action of all the other planets. Leverrier in 1845 concluded that the excess of motion was 35″ per century—but this was increased by later investigations to over 40″ per century. It was accordingly concluded either that Mercury is disturbed by some unknown masses of matter or that Newton's law of gravitation is not rigidly true. Leverrier attributed the excess of motion to the action of a group of planets revolving inside the orbit of Mercury, and at first this explanation seemed to be confirmed by the occasional reports of dark objects seen in transit across the sun's face. But for very many years past the sun has been photographed almost daily at some observatory or other, such as Greenwich or the Cape, without any such objects being detected, and photographs of the sky in the neighbourhood of the sun during total eclipses have likewise failed to disclose anything of the sort. If, then, such intra-Mercurial bodies exist, they must be extremely small. It was at one time suggested that the minute particles which produce the Zodiacal light might be invoked to explain the observed motion, but the idea was shown on theoretical grounds to be untenable. The solution of the difficulty has since been supplied by Einstein's Theory of Generalized Relativity and the matter is now regarded as satisfactorily cleared up. (T. E. R. P.)

MERCURY, in chemistry, a metallic element which is easily distinguished from all others by its being liquid at even the lowest temperatures occurring in moderate climates (symbol Hg, atomic number 80, atomic weight, 200·6, numerous isotopes 197 to 204). This metal does not appear to have been known to the ancient Jews, nor is it mentioned by the earlier Greek writers. Theophrastus (about 300 B.C.) mentions it as prepared from cinnabar by treatment with copper and vinegar; Dioscorides obtained it from the same mineral with the aid of iron, using at the same time a primitive distillation apparatus. With the alchemists it was an important substance. When, about the beginning of the 16th century, chemistry and scientific medicine came to merge into one, this same mysterious element of "mercury" played a great part in the theories of pathology; and the metal, in the free as in certain combined states, was looked upon as a powerful medicinal agent.

Occurrence.—Mercury occurs in nature chiefly in the form of a red sulphide, HgS, called cinnabar (*q.v.*), which, as a rule, is accompanied by more or less of the reguline metal—the latter being probably derived from the former by some secondary reaction. The most important mercury mines in Europe are those of Almaden in Spain and of Carniola, Italy, and in America those of California and Texas. Deposits also occur in Russia, the Bavarian palatinate, in Hungary, Tuscany, Transylvania, Bohemia, Mexico, Peru and in some other countries.

Mercury occurs in formations of all ages from the Archean to the Quaternary, and it has been found in both sedimentary and eruptive rocks of the most varied character, *e.g.,* conglomerates, sandstones, shales, limestones, quartzites, slates, serpentines, crystalline schists, and eruptive rocks from the most acid to the most basic.

In former times quicksilver deposits were supposed to be formed by sublimation, but from a careful study of the California occurrences S. B. Christy was convinced as early as 1875 that this was unlikely, and that deposition from hot alkaline sulphide solutions was more probable. By treating the black mercuric sulphide with such solutions, hot and under pressure, he succeeded in producing artificial cinnabar and metacinnabarite. He also showed that the mineral water at the New Almaden mines, when charged with sulphydric acid and heated under pressure, was capable of effecting the same change, and that this method of production agreed better with all the facts than the sublimation theory. (*See* "Genesis of Cinnabar Deposits," *Amer. Jour. Science,* xvii., 453.) The investigations of Dr. G. F. Becker on the "Quicksilver Deposits of the Pacific" (U.S. Geol. Survey, *Mon.* xiii., 1888) established the correctness of these views beyond doubt.

Properties.—Pure mercury is a coherent, mobile liquid, which does not wet glass or objects placed in it; it is silvery white with a metallic lustre; in very thin layers it transmits a bluish-violet light. It freezes at about −39° C with contraction, and the formation of a white, very ductile and malleable mass (sp. gravity 14·193 at m.p.) easily cut with a knife, and exhibiting crystals belonging to the cubic system. When heated the metal expands very uniformly, and vaporizes at about 360° (b.p. 357·01°/760 mm.); the volatility is generally increased by the presence of impurities; its high expansion and the wide range of temperature over which it is liquid render it especially valuable as a thermometric fluid. (*See* THERMOMETRY.) The vapour is colourless, and its density points to the conclusion that the molecules are monatomic. The specific gravity of liquid mercury at 0° is 13·5959 and 13·690 at its m.p. Mercury is about half as heavy again as copper volume for volume, a quarter as heavy again as lead, and nearly twice as heavy as zinc; this property is turned to account in the construction of barometers and air-pumps. Its specific heat is about 0·0333 (*see* CALORIMETRY); its electrical

conductivity is involved in the definition of the ohm (*see* CONDUCTIVITY); and its thermal conductivity is about two-thirds that of silver.

Pure mercury remains unchanged in dry air, oxygen, nitrous oxide, carbon dioxide, ammonia and some other gases at ordinary temperatures; hence its application for collecting and measuring gases. In damp air it slowly becomes coated with a film of mercurous oxide; and when heated for some time in air or oxygen it becomes transformed into the red mercuric oxide, which decomposes into mercury and oxygen when heated to a higher temperature; this reaction is of great historical importance, since it led to the discovery of oxygen at the hands of Priestley. The halogens and sulphur combine directly with the metal. Mercury is unattacked by dilute sulphuric acid; the strong acid, however, dissolves it on heating with the formation of sulphur dioxide and mercurous or mercuric sulphate according as mercury is in excess or not. Hydrochloric acid when concentrated has only very slight action. Dilute nitric acid readily attacks it, mercurous nitrate being formed in the cold with excess of mercury, mercuric nitrate with excess of acid, or with strong acid, in the warm. The metal dissolves in solutions containing chlorine or bromine, and consequently in aqua regia.

Mercury dissolves many metals to form compounds termed amalgams, of considerable importance to the arts.

COMPOUNDS OF MERCURY

Mercury forms two well-defined series of salts—the mercurous salts derived from the oxide Hg_2O, and the mercuric salts from the oxide HgO. Like mercurous oxide the mercurous salts are generally formulated as containing two mercury atoms in each molecule. According to H. B. Baker vaporized mercurous chloride or calomel (*q.v.*) has the formula Hg_2Cl_2.

Mercurous Oxide, Hg_2O, is an unstable dark-brown powder formed when caustic potash acts on calomel; it is decomposed by light or on trituration into mercury and mercuric oxide. *Mercuric oxide,* HgO, occurs in two forms: it is obtained as a bright-red crystalline powder (also known as "red precipitate," or as *mercurius praecipitatus per se*) by heating the metal in air, or by calcining the nitrate, and as an orange-yellow powder by precipitating a solution of a mercuric salt with potash; the difference is probably one of subdivision. The yellow form is the most reactive and is transformed into the red when heated to 400°. If the red oxide be heated it becomes black, regaining its colour on cooling, and on further heating to 630° it decomposes into mercury and oxygen. It is slightly soluble in water, to which it imparts an alkaline reaction and strongly metallic taste. A peroxide is obtained as a brown solid from mercury and slightly acid 30% hydrogen peroxide at low temperatures.

Mercurous and mercuric chlorides, known respectively as calomel (*q.v.*) and corrosive sublimate (*q.v.*), are two of the most important salts of mercury. *Mercurous bromide,* Hg_2Br_2, is a yellowish-white powder, insoluble in water. *Mercuric bromide,* $HgBr_2$, forms white crystals, sparingly soluble in cold water, readily in hot, and prepared by the direct union of its components *Mercurous iodide,* Hg_2I_2, is a yellowish-green powder obtained by heating its components to about 250°, or by triturating them with a little alcohol; it is also obtained by precipitating a solution of mercurous nitrate with potassium iodide. It is blackened by exposure to light. *Mercuric iodide,* HgI_2, exists in two crystalline forms. By mixing solutions of mercuric chloride and potassium iodide under a microscope, yellow rhombic plates are seen to be formed which are transformed very quickly into scarlet quadratic octahedra. On heating to about 126° the red form is transformed into the yellow modification; on cooling the reverse gradually occurs, and immediately if the yellow iodide be touched. When cooled to the temperature of liquid air red mercuric iodide assumes a pale yellow colour. Mercuric iodide is insoluble in water, but soluble in absolute alcohol; and also in potassium iodide solution, with the formation of K_2HgI_4, which may be obtained in lemon-yellow crystals. A strongly alkaline solution of this salt known as Nessler's reagent is specially used for determining traces of ammonia. (*See* below.) Mercuric iodide dissolves in other iodide solutions to form similar compounds; these solutions are characterized by their exceptionally high specific gravity, and hence are employed in density determinations. (*See* DENSITY.) It also forms many other double salts. Oxidation with strong nitric acid gives the *iodate,* $Hg(IO_3)_2$.

Mercurous Nitrite is obtained in yellow needles by the action of cold dilute nitric acid on mercury. Prolonged action of this acid transforms the salt into *mercurous nitrate*

$$Hg_2(NO_3)_2,2H_2O,$$

a white crystalline salt soluble in water. If the metal be in excess basic salts are obtained. By adding ammonia to a solution of mercurous nitrate a black precipitate of variable composition, known in pharmacy as *mercurius solubilis Hahnemanni,* is obtained.

Mercuric Nitrate.—By dissolving mercuric oxide in strong nitric acid there is obtained a heavy liquid which on the addition of more strong nitric acid gives a white precipitate of

$$2Hg(NO_3)_2,H_2O.$$

Water decomposes it to basic salts. By dissolving the oxide in dilute nitric acid, the crystalline basic salt

$$Hg(NO_3)_2 \cdot HgO \cdot H_2O$$

is obtained.

When mercurous or mercuric nitrate is treated with aqueous ethylene thiourea (etu) a stable neutral complex nitrate $[Hg,3etu](NO_3)_2$ is produced in rhombic plates which dissolve in water to a neutral solution and resemble the nitrates of the alkaline earths.

Mercuric Sulphide is the principal ore of mercury occurring in nature as the mineral cinnabar (*q.v.*), and is extensively used as a pigment, vermilion (*q.v.*). It is obtained as a black powder by triturating mercury with sulphur, the compound thus formed being known in pharmacy as *Aethiops mineralis,* and also by precipitating a mercuric salt with sulphuretted hydrogen. There are three crystalline forms of mercuric sulphide:—the light red form αHgS corresponding with cinnabar or vermilion; the black cubic variety α'HgS corresponding with metacinnabarite; a deep red hexagonal form βHgS not occurring in nature. Mercuric sulphide is only slightly acted upon by nitric acid; it dissolves in aqua regia; chlorine gives a yellow compound, $2HgS \cdot HgCl_2$; and it dissolves in potassium sulphide solutions to form double sulphides.

Mercurous Sulphate, Hg_2SO_4, is a white, sparingly soluble, crystalline substance obtained by adding sodium sulphate to a solution of mercurous nitrate. *Mercuric sulphate,* $HgSO_4$, is a white, soluble salt obtained by dissolving mercury in hot strong sulphuric acid; on digestion with water, it decomposes into an insoluble basic salt, $HgSO_4 \cdot 2HgO$, known as *turbith* or *turpeth mineral,* and into a soluble acid salt, $HgSO_4 \cdot 2SO_3$.

Mercury Phosphide, Hg_3P_2, is obtained as brilliant red, hexagonal crystals by heating mercury with phosphorus iodide to 300° and removing the mercuric iodide simultaneously formed by means of potassium iodide solution. *Mercurous phosphate,* Hg_3PO_4, and *mercuric phosphate,* $Hg_3(PO_4)_2$, are obtained as white precipitates by adding sodium phosphate to solutions of mercurous and mercuric nitrates respectively.

Mercurammonium Compounds.—With ammonia and ammonium salts, mercury compounds yield a number of substances, many of which have long been used in medicine. By the action of dry ammonia on calomel mercuroso-ammonium chloride, NH_3HgCl, is obtained; aqueous ammonia on calomel gives dimercuroso-ammonium chloride, NH_2Hg_2Cl. By adding ammonia to a solution of mercuric chloride, mercurammonium chloride, known in pharmacy as "infusible white precipitate," NH_2HgCl, is obtained; "fusible white precipitate" is mercuro-diammonium chloride, $Hg(NH_3Cl)_2$, and is obtained by adding a solution of mercuric chloride to hot solutions of ammonium chloride and ammonia so long as the precipitate first formed redissolves; the substance separates out on cooling. With ammonia and a strongly alkaline solution of mercuric iodide in potassium iodide (Nessler's solution) there is obtained a yellow precipitate of $HO \cdot Hg \cdot NH \cdot HgI$; this reaction is the most delicate test for ammonia, a yellow color-

ation being given by minute traces. By passing dry ammonia over precipitated mercuric oxide at 130°, a nitride, N_2Hg_3, is obtained. The oxide and ammonia solution gives the stable and basic mercurhydroxylamine, NHg_2OH.

Analysis.—Mercury compounds, when heated in a closed tube with sodium carbonate, yield a grey to black sublimate of metallic mercury, which readily unites to form visible globules. The metal is precipitated from solutions on to bright copper-foil; the mercury coating becomes silvery on rubbing and disappears when the quicksilvered copper is heated in a sublimation tube.

Solutions of mercurous salts with hydrochloric acid give a white precipitate of calomel, which becomes jet-black on treatment with ammonia. Stannous chloride, in its twofold capacity as a chloride and a reducing agent, precipitates both mercurous and mercuric solutions, at first as calomel, and on addition of an excess of reagent the precipitate becomes grey through conversion into finely-divided quicksilver. Sulphuretted hydrogen, when added very gradually to an acid mercuric solution, gives at first an almost white precipitate, which, on addition of more and more reagent, assumes successively a yellow, orange and at last jet-black colour. The black precipitate is HgS, identified by its great heaviness, and insolubility in boiling nitric or hydrochloric acid. Aqua regia (*q.v.*) dissolves it as chloride.

"Mercurous" mercury is quantitatively estimated by precipitating as calomel and weighing the precipitate on a tared filter at 100°. The metal may also be estimated by distillation in a closed tube with lime, the metal being collected and weighed, or by precipitation as sulphide with excess of sulphuretted hydrogen, the precipitate being collected on a tared filter or Gooch crucible, washed with carbon disulphide, dried and weighed.

PHARMACOLOGY AND THERAPEUTICS

The British Pharmacopeia contains some twenty-five mercurial preparations, including those of calomel (*q.v.*). Only the useful preparations will be mentioned here. Free mercury is contained in Hydrargyrum cum Creta, or "grey powder," which consists of one part of mercury to two of prepared chalk. The dose is 1–5 gr., and the preparation is usually employed for children. The Pilula Hydrargyri, or "blue pill," contains one part of mercury in three, and the dose is 4–8 gr. It is usually employed for adults. There are also five preparations of free mercury for external use. Of these the most useful is the Unguentum Hydrargyri, "or blue ointment," which contains one part of mercury in two. Weaker ointments are also prepared from the red and the yellow forms of mercuric oxide. The perchloride of mercury or corrosive sublimate is therapeutically the most important salt of mercury. The dose is $\frac{1}{32}-\frac{1}{16}$ gr. It is incompatible with alkalis, alkaline carbonates, potassium iodide, albumin and many other substances, and should therefore be prescribed alone. It is decomposed by impure water, and distilled water is therefore used in making the Liquor Hydrargyri Perchloridi, in which form it is usually prescribed. This contains half a grain of the perchloride to the fluid ounce and its dose is 30–60 minims. The perchloride is also compounded with lime-water to form the Lotio Hydrargyri Flava, or "yellow wash," which contains two grains of the salt to the fluid ounce. Mercuric iodide is an equally potent salt and has come into wide use. It has the same dose as the perchloride and is largely prescribed in the Liquor Arsenii et Hydrargyri Iodidi, or Donovan's solution, which contains 1% of arsenious iodide and 1% of mercuric iodide, the dose being 5–20 minims. An ointment widely used is prepared from the mercur-ammonium chloride (Unguentum Hydrargyri ammoniatum) of which it contains one part in ten. It is known as "white precipitate ointment."

In discussing the pharmacology of mercury and its compounds, it is of the first importance to observe that metallic mercury is inert as such, and that the same may practically be said of mercurous salts generally. Both mercury itself and mercurous salts tend to be converted in the body into mercuric salts, to which the action is due. When metallic mercury is triturated or exposed to air it is partly oxidized, the first stage of its transformation to an active condition being thus reached.

Metallic mercury can be absorbed by the skin, passing in minute globules through the ducts of the sweat-glands. The mercury contained in "blue ointment" is certainly thus absorbed, actually circulating in the blood in a very different form, as described below. There is no local action on the skin. The mercuric salts, and especially the chloride and iodide, are probably the most powerful of all known antiseptics. One part of the perchloride in 500,000 will prevent the growth of anthrax bacilli, and one part in 2,000—the strength commonly employed in surgery—kills all known bacteria. The action is apparently specific and not due to the fact that perchloride of mercury precipitates albumin, including the albuminous bodies of bacteria, for the iodide is still more powerful as a germicide, though it does not coagulate albumin. These salts cannot be employed for sterilizing metallic instruments, which they tarnish. As these drugs are essentially poisons they must be used with the greatest care in surgical practice, and as they are particularly deleterious to the secreting structure of the kidney they must not be employed as antiseptics in diseases where renal inflammation is already present or probable. They are therefore contra-indicated for application to the throat in scarlet-fever or to the uterus in eclampsia. The stronger mercurial ointments kill cutaneous parasites and also possess some degree of antipruritic action, especially when the cause of the itching is somewhat obscure. Mercuric salts, when in strong solution, are caustic. It is important to observe that the volatility of metallic mercury and many of its compounds causes their absorption by the lungs even when no such effect is intended to follow their external application. This fact explains the occurrence of chronic mercurial poisoning in certain trades.

Single doses of mercury or its compounds have no action upon the mouth, the characteristic salivation being produced only after many doses. Their typical action on the bowel is purgative, the effect varying with the state of the mercury. So relatively inert is metallic mercury that a pound of it has been given without ill effects in cases of intestinal obstruction, which it was hoped to relieve by the mere weight of the metal. Half a grain of the perchloride, on the other hand, is a highly toxic dose. The action of mercurials on the bowel is mostly exerted on the duodenum and jejunum, though the lower part of the bowel is slightly affected. Hence a dose of mercury usually needs a saline aperient to complete its action, as in the "blue pill and black draught" of former days. Mercurials do not cause, in therapeutic doses, much increase in the intestinal secretion, the action being mainly exerted on the muscular wall of the bowel. The bile is rapidly removed from the duodenum, before any re-absorption can occur, and the bacterial action which decomposes the bile-pigment is arrested by the antiseptic power of the drug, so that the excreta are of a very dark colour. The classical experiments of William Rutherford (1839–1899), of Edinburgh, showed that calomel does not increase the amount of bile formed by the liver. Corrosive sublimate does, however, stimulate the liver to a slight degree. In large doses mercurials somewhat diminish the secretion of bile. The greater part of the mercury administered by the mouth, in whatever form, is excreted as mercuric sulphide. Prior to this decomposition the mercury exists as a complex soluble compound with sodium, chlorine and albumen. When perchloride of mercury is injected subcutaneously the sodium chloride in the blood similarly prevents the precipitation of the albuminate of mercury, and it is therefore desirable to add a little sodium chloride to the solution for injection of mercuric chloride.

Mercury is largely used in affections of the alimentary canal, and has an obscure but unquestionable value in many cases of heart-disease and arterial degeneration. But its value in syphilis (*see* VENEREAL DISEASES) far outweighs all its other uses.

Toxicology.—Acute poisoning by mercurials usually occurs in the case of corrosive sublimate. There is intense gastro-intestinal inflammation, with vomiting, frequent "rice-water" stools and extreme collapse. The treatment, except when the case is seen at once, is very difficult, but white-of-egg or other form of albumin is the antidote, forming an insoluble compound with the perchloride.

Chronic poisoning (hydrargyrism or mercurialism) is of great importance, since any indication of its symptoms must be closely

watched for in patients who are under mercurial treatment. Usually the first symptom is slight tenderness of the teeth whilst eating, and some foetor of the breath. These symptoms become more marked and the gums become the seat of severe inflammation, being spongy, vascular and prone to bleed. The salivary glands are swollen and tender, and the saliva pours from the mouth, and may amount to pints in the course of a day. The teeth become quite loose and may fall out. The symptoms are aggravated until the tongue and mouth ulcerate, the jaw-bone necroses, haemorrhages occur in various parts of the body, and the patient dies of anaemia, septic inflammation or exhaustion. The treatment consists, besides stopping the intake of poison and relieving the symptoms, in the administration of potassium iodide in small, often repeated doses.

Mercuro Zinc Cyanide, $Zn_3Hg(CN)_8$ (Lister's antiseptic), was suggested in the early days of antiseptics (1886) by W. Martindale. In the form of "cyanide gauze" and "cyanide wool," this dressing has been largely used, both in general surgery and for the requirements of war.

Mercurochrome "220" (di-sodium hydro-oxy-mercury dibromo fluorescein) has been advocated through the work of various authorities in the United States for a variety of affections. This compound has an English equivalent *mercurome*, which is identical chemically. The drug is deemed of very great service as an antiseptic for vesical injections in cystitis, pyelitis, etc., and as a skin antiseptic it is highly recommended. Considerable strides have been made with the intravenous injection of this compound, *e.g.*, in puerperal fever, typhoid and grave bacterial infections in general, and it has been suggested for use intravenously in plague. As the limits of dosage are not as yet completely determined, mercurochrome is to be used with caution. At the same time, the remarkable fact remains that this compound, containing approximately 23% of mercury in a non-ionised form has been injected in the massive dose of 3 grains (0·2 gram) in contrast with an ordinary intravenous dose of mercuric chloride of about $\frac{1}{30}$ to $\frac{1}{16}$ grain (0·001 to 0·002 gram).

MERCURY, FULMINATE OF. A highly explosive compound used in percussion caps and detonators. Substances which fulminate on heating or gentle percussion have been known for a long time, but the first of which we have any definite chemical knowledge was mercury fulminate, a substance first made by E. C. Howard in 1799. J. von Liebig, who is stated to have become acquainted with the substance when he was a boy, succeeded in isolating fulminic acid whilst working in Gay Lussac's laboratory in 1823. Previous attempts appear to have been made to utilize the explosive property of fulminate for igniting gunpowder and led to many inventions.

Mercury fulminate is retained for two military purposes: (1) as an igniter in so-called cap-compositions; and (2) as a detonator, in which case it may be used alone or mixed with a nitro-derivative, such as trinitrotoluene, where it can act as "starter" of a more powerful detonator.

Being too rapid in action, pure mercury fulminate will not ignite gunpowder, the grains being merely scattered. The application of fulminate as a cap-composition for setting fire to gunpowder, while being itself fired by percussion, has been reached by methods of "taming" or slowing down the detonating action by addition of diluents. These diluents, which could be ignited by the fulminate, burned at a sufficiently slow rate to set fire to the gunpowder or other propellant. The slowing down or taming mixture consists, generally, of sulphide of antimony, Sb_2S_3, and potassium chlorate, $KClO_3$, both in very fine powder, the fulminate being used in small crystals as made, for it cannot be ground or powdered. A silver fulminate was made by L. G. Brougnatelli in 1798, who dissolved silver in nitric acid and added this solution to spirits of wine. The white powder obtained is extremely sensitive to friction, percussion or heat and apparently unsuited to any practical application. Other fulminating substances obtained before this date by the action of ammonia on solutions of gold or silver are similarly unsuitable.

Manufacture.—Clean mercury, one part, and nitric acid of sp.gr. 1·36, about ten parts, are placed in a glass flask and, after the mercury has dissolved, allowed to cool to about 15° to 20° C. Ten to twelve parts of 90% alcohol are placed in a capacious flask and the mercury solution is added. A reaction commences in a few minutes with formation of copious white fumes followed after a short time by red gases. The action may require regulating by outward application of cold water, but generally after the temperature has risen to 80°–90° C it settles down quietly. The reaction mixture is poured into cold water; the sparingly soluble mercury salt is precipitated, and is washed with cold water until free from acid. Mercury fulminate is a grey, sandy, crystalline powder, is extremely poisonous, and has a sp.gr. of about 4·4, varying a little with the conditions of formation.

Many chemists, since Liebig, have suggested constitutional formulae for fulminic acid (*q.v.*); it may not be quite settled even now, but the formula $(CNO)_2Hg$ is almost certainly correct for mercury fulminate. Since the discovery of hydrazoic acid, N_3H, some of its salts, such as the azides of lead or silver, have for special purposes become rivals of fulminate (*see* LEAD AZIDE).

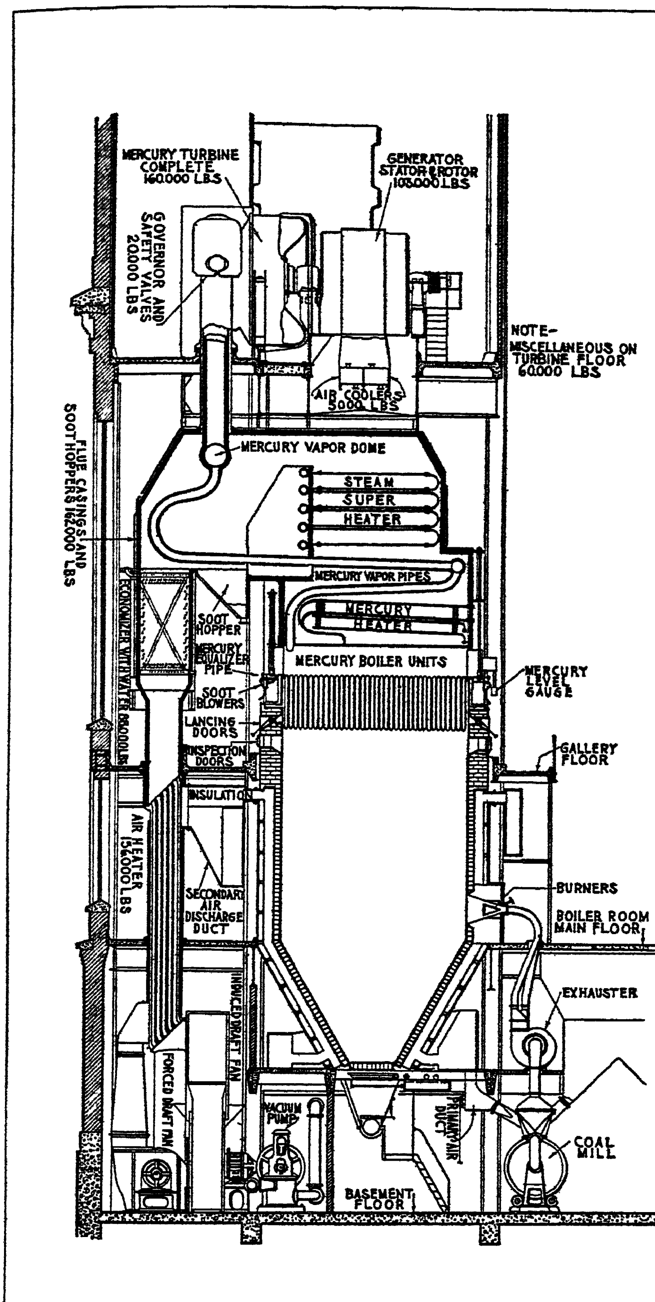
MERCURY-VAPOUR BOILER, a process of power generation which uses mercury instead of water in a boiler. The boiling point of mercury as compared with water is given below. It will be seen that with mercury saturated vapour can be obtained with low pressures and with much higher temperatures than is possible with water steam.

Pressures	Boiling Point	
	Mercury	Water
100 lb. gauge	928° F	338° F
80 „ „	899	324
60 „ „	866	307·6
40 „ „	824·6	287·1
20 „ „	769	259·3
10 „ „	730·4	240·1
	674·5	212
20 in. vacuum (atm.)	576	161·50
25 „ „ „	520	133·78
28 „ „ „	456·8	101·7
29 „ „ „	414	79·06

The highest pressure at which saturated water vapour can exist is 3,200 lb. pressure per square inch, and at that pressure the temperature is only 706° F. In the mercury cycle, mercury is boiled in a specially designed boiler at whatever pressure is desirable. In the Hartford, Conn., installation this pressure has been chosen at 70 lb. gauge. The vapour is then carried through a turbine where it does useful work. The exhaust pressure is kept at whatever vacuum is desirable to obtain the proper steam pressure. In Hartford the steam is generated at 350 lb. pressure, which means a mercury vacuum of about 28 inches.

In the mercury cycle all the latent heat of the mercury vapour is turned into steam at any steam pressure desirable, and this steam can be used either for power as in Hartford or for heating purposes. The mercury cycle can thus be considered as a steam producer, where a large amount of power can be obtained from the mercury vapour at practically theoretical rate, and the amount of steam produced is only slightly less than that produced by a steam boiler for the same amount of fuel.

A Typical Installation.—Figs. 1 and 2 give side and end elevation of the 10,000 kw. mercury turbine installation at Hartford, Conn., by the Hartford Electric Lighting Company, and a description of the same will give a clear view of the great gain in efficiency obtained by this installation. The equipment is de-



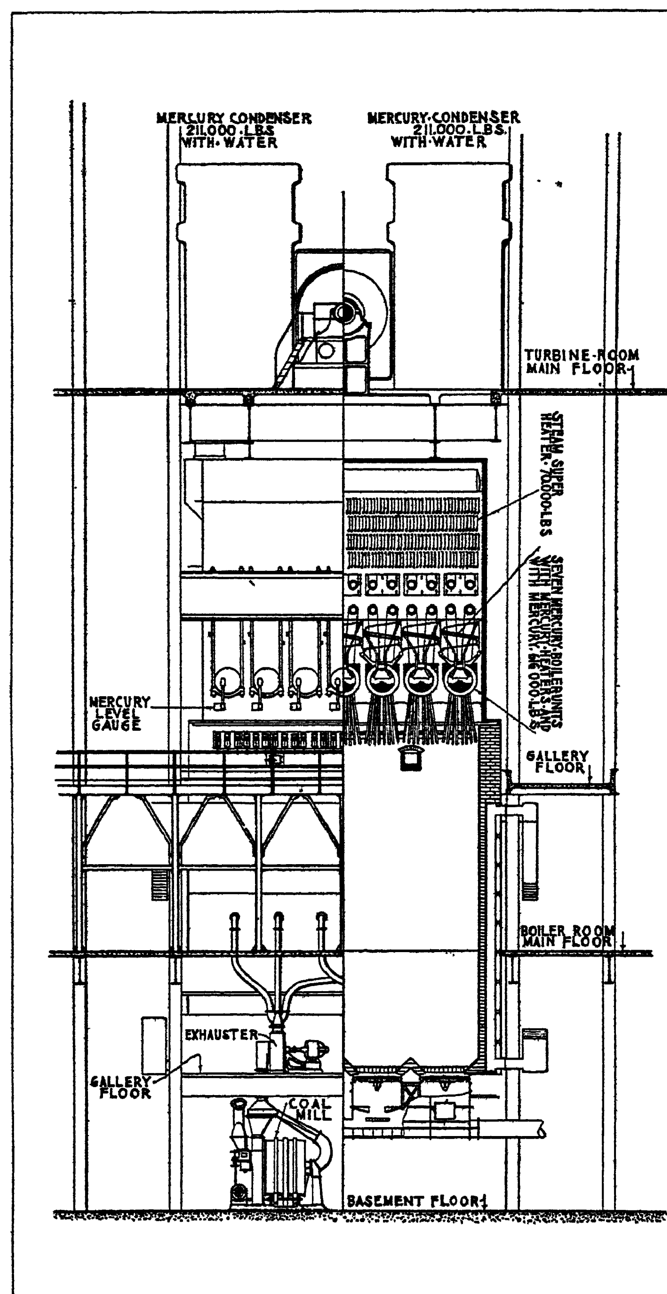
BY COURTESY OF THE GENERAL ELECTRIC COMPANY

FIG. 1.—ARRANGEMENT FOR MERCURY-VAPOUR BOILER AND TURBINE EQUIPMENT, SIDE ELEVATION

signed for the following results: Full-load output of mercury turbine, 10,000 kw.; coal burned per hour, 14,500 lb.; steam produced per hour, 350 lb. gauge, 700° F, 125,000 pounds. The fuel is burned in the furnace, as in a steam boiler, and the products of combustion pass successively through a mercury boiler, a mercury liquid heater, a steam superheater, a feed water heating economizer and an air preheater. The first two of these give heat to the mercury. The others give it to the steam or return it to the furnace.

The mercury vapour made in the boiler passes first through a turbine driving at 10,000 kw. generator at 720 r.p.m. and then exhausts into a pair of surface condensers. The tubes of these condensers contain water, so that the heat delivered to them by the condensation of the exhaust mercury vapour causes them to make steam which collects in drums above the tubes at which point it is available for use. In the equipment being described, this steam passes from these drums through the superheater mentioned. The condensed mercury is drained through a cleaning sump and then runs by gravity through the liquid heater and into the boiler. By mounting the condenser high enough above the boiler, the weight of the descending column of mercury overcomes the boiler pressure so that no feed pump is required.

Basis of Design.—The following list gives data as to designed conditions for the 10,000 kw. unit and its substantial accuracy is fully established by experience with apparatus now operating: Output of mercury turbine, 10,000 kw.; speed of mercury turbine, 720 r.p.m.; steam produced per hour, 125,000 lb.; steam pressure, 350 lb. gauge; steam temperature, 700° F; mercury vapourized per hour, 1,150,000 lb.; temperature mercury vapour, 884° F; pressure vapour at mercury turbine, 70 lb. gauge; vacuum in mercury condenser, 28 in.; temperature mercury exhaust, 458° F; gas temperature beyond mercury liquid heater, 950° F; gas temperature beyond steam superheater, 650° F; gas temperature beyond water economizer, 480° F; gas temperature to stack, 280° F; air temperature entering furnace, 390° F; coal burned per hour, 14,500 lb.; heat in coal per pound 14,500 B.T.U. It will thus be seen that when 14,500 lb. of coal (with a heat value of 14,500 B.T.U. per pound) is burned under the mercury boiler



BY COURTESY OF THE GENERAL ELECTRIC COMPANY

FIG. 2.—ARRANGEMENT FOR MERCURY-VAPOUR BOILER AND TURBINE EQUIPMENT, END ELEVATION

per hour, 10,000 kw. are generated by the mercury boiler and 125,000 lb. of steam are generated at 350 lb. gauge pressure and with a temperature of 700° F (264° F superheat).

What this amount of steam can accomplish in combination with the mercury turbine in existing power plants is shown by the table below:

Fuel Rates in B.T.U. per Kilowatt Hour

	Steam alone	Steam with mercury	Per cent gain
A . . .	14,000	9,400	33
B . . .	17,000	10,500	38
C . . .	22,000	11,600	47
D . . .	35,000	13,800	60·5

Case *A* represents the best development of modern plants with 350 lb. pressure, high superheat and the most effective auxiliary and feed heating arrangements. Case *B* represents a station that was considered very good a short time ago with about 200 lb. steam pressure, less perfect firing and auxiliary arrangements and less superheat. Case *C* represents a station in which conditions of size, load factor or efficiency are even less favourable. Case *D* represents what might be done in a good non-condensing station. The ratios here shown are not much affected by the usual causes of relative inefficiency such as load factor, turbine efficiency or condensing facilities.

The mercury cycle lends itself particularly to the increasing of station capacity of existing plants. By burning approximately 20% more fuel, the same amount of steam as before can be produced, the power from the mercury turbine will be almost equal that produced by the steam turbines, the fuel rate of the mercury turbine will be at approximately 4,000 B.T.U. per kilowatt hour, and the fuel rate of the steam turbine will remain as before. If this rate was 17,000 B.T.U. per kilowatt hour, the combined rate would be at about 10,500 B.T.U.—a gain of 38%.

Heating Plants.—From the figures that have been given, it will be seen that the gain in economy is incident to the production of steam by a method which gives a valuable by-product in the form of power. A very striking case of profitable use is found in a city heating plant. If, in such a plant, this unit were used in connection with a suitable steam turbine unit which would take steam at 350 lb. gauge pressure, superheated and exhausted into the street mains at 100 lb. per square inch and saturated, the results with the best coal burned efficiently would be about as follows: Fuel burned per hour, 14,500 lb.; steam delivered per hour, 125,000 lb.; power produced by mercury turbine, 10,000 kw.; power produced by steam, 3,400 kw.; total power produced, 13,400 kilowatts. From these figures it will be seen that the power is produced at a rate of about 16,000 B.T.U. in fuel per kilowatt hour, which is comparable with very good condensing steam stations, and that all this 100 lb. heating steam is produced in addition.

A careful investigation in regard to the probable mercury supply of the world indicates that it is sufficient to take care of this process for practically an indefinite time. The present mercury mines in operation could easily double their output which would take care of 1,000,000 kw. per year, in addition to the present uses of mercury.

MERCY, FRANZ, FREIHERR VON, lord of Mandre and Collenburg (d. 1645), German general in the Thirty Years' War, who came of a noble family of Lorraine, was born at Longwy between 1590 and 1598. From 1606 to 1630 he was engaged in the imperial service. After distinguishing himself at the first battle of Breitenfeld (1631) he commanded a regiment of foot on the Rhine and defended Rheinfelden against the Swedes with the utmost bravery, surrendering only after enduring a five-months' siege He now became a general officer of cavalry, and in 1635, 1636 and 1637 took part in further campaigns on the Rhine and Doubs. In September 1638 he was made master-general of ordnance in the army of Bavaria, then the second largest army in Germany. In the next campaign he was practically commander-in-chief of the Bavarians, and at times also of an allied army of Imperialists and Bavarians. He was made general field marshal in 1643, when he won his great victory over the French marshal Rantzau at Tuttlingen (Nov. 24–25), capturing the marshal and seven thousand men. In the following year Mercy opposed the French armies, now under Enghien (afterwards the great Condé) and Turenne. He fought, and in the end lost, the desperate battle of Freiburg, but revenged himself next year by inflicting upon Turenne the defeat of Mergentheim (Marienthal). Later in 1645, fighting once more against Enghien and Turenne, Mercy was killed at the battle of Nördlingen (or Allerheim) as the crisis of the engagement, which, even without Mercy's guiding hand, was almost a drawn battle. He died on Aug. 3, 1645. On the spot where he fell, Enghien erected a memorial, with the inscription *Sta viator, heroem calcas.*

CLAUDIUS FLORIMOND, COUNT MERCY DE VILLETS (1666–1734), Imperial field marshal, was born in Lorraine, and entered the Austrian army as a volunteer in 1682. After seven years of service in Hungary and five years in Italy, he displayed great daring in the first campaigns of the Spanish Succession War in Italy, twice fell into the hands of the enemy in fights at close quarters and for his conduct at the surprise of Cremona (Jan. 31, 1702) received the emperor's thanks. With this he took part in the Rhine campaign of 1703, and the battle of Friedlingen, and his success as an intrepid leader of raids and forays became well known to friend and foe. He was on that account selected early in 1704 to harry the elector of Bavaria's dominions. His resolute leadership was conspicuous at the battle of Peterwardein (1716) and he was soon afterwards made commander of the Banat of Temesvár. At the battle of Belgrade (1717) he led the second line of left wing cavalry in a brilliant and decisive charge which drove the Turks to their trenches. After the peace he resumed the administration of the Banat, which after more than 150 years of Turkish rule needed a humane and capable governor. But he was called away to southern Italy, where he fought the battle of Francavilla (June 20, 1719), took Messina and besieged Palermo. For eleven years more he administered the Banat, reorganizing the country as a prosperous and civilized community. In 1734 he was made a field marshal, but on June 29, was killed at the battle of Parma while personally leading his troops. He left no children, and his name passed to the Mercy-Argenteau family.

MERCY, compassion, pardon, pity, or forgiveness. The Latin word *merces* was used in the early Christian ages for the reward that is given in heaven to those who have shown kindness without hope of return. In the mediaeval Church there were seven "corporeal" and seven "spiritual works of mercy" (*opera misericordiae*). The order of the Sisters of Mercy is a religious sisterhood of the Roman Church, founded in 1827.

MERCY-ARGENTEAU, FLORIMOND CLAUDE, COMTE DE (1727–1794), Austrian diplomatist, son of Antoine, comte de Mercy-Argenteau, entered the diplomatic service of Austria, going to Paris in the train of Prince Kaunitz. He became Austrian minister at Turin, at St. Petersburg, and in 1766 at Paris, where his first work was to strengthen the alliance between France and Austria, which was cemented in 1770 by the marriage of the dauphin, afterwards Louis XVI., with Marie Antoinette, daughter of the empress Maria Theresa. Mercy-Argenteau was in Paris during the years which heralded the Revolution, and supported first Loménie de Brienne, and then Necker. In 1792 he became Austrian governor-general of the Belgian provinces. In July 1794 he was appointed Austrian ambassador to Great Britain, but he died a few days after his arrival in London.

See T. Juste, *Le Comte de Mercy-Argenteau* (Brussels, 1863); A. von Arneth and A. Geoffroy, *Correspondances secrètes de Marie Thérèse avec le comte de Mercy* (1874); and A. von Arneth and J. Flammermont, *Correspondance secrète de Mercy avec Joseph II. et Kaunitz* (1889–91). Mercy-Argenteau's *Correspondances secrètes de Marie Thérèse* has been condensed and translated into English by Lilian Smythe as *A Guardian of Marie Antoinette* (2 vols., 1902).

MER DE GLACE. A glacier 16 sq.m. in area on the northern slope of Mt. Blanc, near Chamonix. During the summer months the rate of flow is estimated at two feet a day. It is a favourite tourist resort.

MERE. (1) An adjective primarily indicating something pure and unmixed (Lat. *merus*, pure).

(2) An arm of the sea, or estuary; a lake or any shallow stretch of inland water. In the Fen countries "mere" is applied to marshland, *cf.* Lat. *mare*, Fr. *mer*, Ger. *meer*.

(3) A landmark or boundary; an object indicating the extent of a property without actually enclosing it; a road which forms a dividing line between two places (O.E. *maere*, Lat. *murus*, a wall). A "meresman" is an official appointed by parochial authorities to ascertain the boundaries of a parish and to report upon the roads, bridges, waterways, etc. In the mining districts of Derbyshire a mere is a certain measurement of land in which lead-ore is found.

MEREDITH, GEORGE (1828–1909), British novelist and poet, was born at Portsmouth, Hants., on Feb. 12, 1828. About his early life little is recorded, but there is a good deal of quasi-autobiography, derived apparently from early associations and possibly antipathies, in some of his own novels, notably *Evan Harrington* and *Harry Richmond*. He had, as he said, both Welsh (from his father) and Irish blood (from his mother) in his veins. His father, Augustus Armstrong Meredith, was a naval outfitter at Portsmouth (mentioned as such in Marryat's *Peter Simple*); and his grandfather, Melchisedek Meredith, clearly suggested the "Old Mel" of *Evan Harrington*. Melchisedek was 35 when, in 1796, he was initiated as a freemason at Portsmouth; and he appears to have been known locally as "the count," because of a romantic story as to an adventure at Bath; he was church warden in 1801 and 1804; and some of the church plate bears his name.

Meredith's mother died when he was three years old, and he was made a ward in chancery. He was sent to school at Neuwied on the Rhine, and remained in Germany till he was 16. During these impressionable years he imbibed a good deal of the German spirit; and German influence, especially through the media of poetry and music, can often be traced in the cast of his thought and sentiment, as well as in some of the intricacies of his literary style. Returning to England he was at first articled to a solicitor in London, but he had little inclination for the law, and soon abandoned it for the more congenial sphere of letters, of which he had become an eager student. At the age of 21 he began to contribute poetry to the magazines, and he eked out a livelihood for some years by journalism, on the *Daily News* and other London papers, and for the *Ipswich Journal*, for which he wrote leaders; a certain number of his more characteristic fugitive writings are collected in the memorial edition of his works (1909–11). In London he became one of the leading spirits in the group of young philosophical and positivistic Radicals, among whom were John (afterwards Lord) Morley, Frederic Harrison, Cotter Morison and Admiral Maxse. But during the years when he was producing his finest novels he was practically unknown to the public. In 1849 he married Mrs. Nicholls, daughter of Thomas Love Peacock, the novelist, a widow, eight years his senior, whose husband had been accidentally drowned a few months after her first marriage (1844), and who had one child, a daughter; but their married life was broken by separation; she died in 1861, and in 1864 Meredith married Miss Vulliamy, by whom he had a son and daughter. His second wife died in 1885. Up to that time there is little to record in the incidents of his life; he had not been "discovered" except by an "honourable minority" of readers and critics. It must suffice to note that during the Austro-Italian War of 1866 he acted as special correspondent for the *Morning Post*; and though he saw no actual fighting, he enjoyed, particularly at Venice, opportunities for a study of the Italian people which he turned to account in several of his novels. Towards the close of 1867, when his friend John Morley paid a visit to America, Meredith undertook in his absence the editorship of the *Fortnightly Review* for Messrs. Chapman and Hall. They were not only the publishers of his books, but he acted for many years as their literary adviser, in which capacity he left a reputation for being not only eminently wise in his selection of the books to be published, but both critical and encouraging to authors of promise whose works he found himself obliged to reject. Thomas Hardy and George Gissing were among those who expressed their grateful sense of his assistance. He was indeed one of the last of the old school of "publishers' readers." In his early married life he lived near Weybridge, and later at Copsham between Esher and Leatherhead, while soon after his second marriage he settled at Flint cottage, Mickleham, near Dorking, where he remained for the rest of his life.

EARLY WORK

Meredith's first appearance in print was in the character of a poet, and his first published poem "Chillian Wallah," may be found in *Chambers's Journal* for July 7, 1849. Two years later he put forth a small volume of *Poems* (1851), which was at least fortunate in eliciting the praise of two judges whose opinion was of the first importance to a beginner. Tennyson was at once struck by the individual flavour of the verse, and declared of one poem, "Love in the Valley," that he could not get the lines out of his head. Charles Kingsley's eulogy was at once more public and more particular. In *Fraser's Magazine* he subjected the volume to careful consideration, praising it for richness and quaintness of tone that reminded him of Herrick, for completeness and coherence in each separate poem, and for the animating sweetness and health of the general atmosphere. At the same time he censured the laxity of rhythm, the occasional lack of polish, and the tendency to overload the description with objective details to the confusion of the principal effect. No doubt as a result of Kingsley's introduction, two poems by Meredith appeared in *Fraser's Magazine* shortly afterwards; but apart from these, and a sonnet in the *Leader*, he published nothing for five years.

In the meanwhile he was busy upon his first essay in prose fiction. It was on Dec. 19, 1855, that the *Shaving of Shagpat*, a work of singular imagination, humour and romance, made its appearance. Modelled upon the stories of the *Arabian Nights*, it catches with wonderful ardour the magical atmosphere of Orientalism, and in this genre it remains a unique triumph in modern letters. Though unappreciated by the multitude, its genius was at once recognized by such contemporaries as George Eliot and Dante Gabriel Rossetti, the latter of whom was one of Meredith's intimate friends. For his next story it occurred to Meredith to turn his familiarity with the life and legendary tradition of the Rhinelander into a sort of imitation of the grotesquerie of the German romanticists, and in 1857 he put forth *Farina, a Legend of Cologne*, which sought to transfer to English sympathies the spirit of German romance in the same way that *Shagpat* had handled oriental fairy-lore. The result was less successful. The plot of *Farina* lacks fibre, its motive is insufficient, and the diverse elements of humour, serious narrative, and romance scarcely stand in proportion to one another. But the *Ordeal of Richard Feverel*, which followed in 1859, transferred Meredith at once to a new sphere and to the altitude of his accomplishment. With this novel Meredith deserted the realm of fancy for that of the philosophical and psychological study of human nature, and *Richard Feverel* was the first, as it is perhaps the favourite, of those wonderful studies of motive and action which placed him among the literary demigods. It depicts the abortive attempt of an opinionated father to bring up his son to a perfect state of manhood through a "system" which controls his circumstances and represses the natural instincts of adolescence. The love scenes in *Richard Feverel* are gloriously natural and the book marked a revolution in the English treatment of manly passion. Certain chapters were omitted from later editions. In the following year Meredith contributed to *Once a Week*, and published in America (1860; 1st English edition 1861) as a book the second of his novels of modern life, *Evan Harrington*, originally with the subtitle "He Would be a Gentleman"—in allusion to the hero being the son of "Old Mel," the tailor—which contains a richly humorous—in its unrevised form, splendidly farcical—plot, with some magnificent studies of character. Afterwards revised, a certain amount of the farcical element was cut out, with the result

that, considered as comedy, it has weak spots; but the countess de Saldar remains a genuine creation. In 1862 he produced his finest volume of poems, entitled *Modern Love, and Poems of the English Roadside, with Poems and Ballads*. An attack upon the dramatic poem which gives the volume its title appeared in the *Spectator*, and is memorable for the fact that Meredith's friend, the poet Swinburne, with one of his characteristically generous impulses, replied (*Spectator*, June 7, 1862), in a spirit of fervent eulogy. Some of the "sonnets" (of 16 lines) into which *Modern Love* is divided rank with the most subtle and intense poetic work of the 19th century.

Returning to fiction, Meredith next published *Emilia in England* (1864), afterwards renamed *Sandra Belloni* (1886). His powerful story *Rhoda Fleming* (1865) followed soon afterwards. *Vittoria*, published in the *Fortnightly Review* in 1866, and in book form in 1867, is a sequel to *Emilia in England*. Four years later appeared *The Adventures of Harry Richmond* in the pages of *Cornhill* (1870–71). Its successor was *Beauchamp's Career* (*Fortnightly Review*, 1874–75), the novel which Meredith usually described as his own favourite. Its hero's character is supposed to have been founded upon that of Admiral Maxse. *Sandra Belloni*, *Rhoda Fleming*, *Vittoria* and *Beauchamp* are all masterpieces of his finest period, rich in incident, character and workmanship. "The House on the Beach" and "The Case of General Opie and Lady Camper" (*New Quarterly Magazine*, 1877) were slight but glittering exercises in comedy; the next important novel was *The Egoist* (1879), which shows an increase in Meredith's twistedness of literary style and is admittedly hard to read for those who merely want a "story," but which for concentrated analysis and the real drama of the human spirit is an astounding production. In an interesting series of lectures which Meredith delivered at the London Institution in 1877, his main thesis was that a man without a sense of comedy is dead to the finer issues of the spirit, and the conception of Sir Willoughby Patterne, the central figure of *The Egoist*, is an embodiment of this idea in the flesh. *The Tragic Comedians* (1880), the next of Meredith's novels, slighter in texture than his others, combines the spirits of comedy and tragedy in the story of the life of Ferdinand Lassalle, the German Socialist. The appearance of *Diana of the Crossways* (1885), a brilliant book, full of his ripest character-drawing, though here and there tormenting the casual reader by the novelist's mannerisms of expression, marks an epoch in Meredith's career, since it was the first of his stories to strike the general public. Its heroine was popularly identified with Sheridan's granddaughter, Mrs. Norton, and the use made in it of the contemporary story of that lady's communication to *The Times* of the cabinet secret of Peel's conversion to Free Trade had the effect of producing explicit evidence of its inaccuracy from Lord Dufferin and others. As a matter of historical fact it was Lord Aberdeen who himself gave Delane the information.

Meanwhile further instalments of poems—*Poems and Lyrics of the Joy of Earth* (1883)—had struck anew the full, rich note of natural realism which is Meredith's chief poetic characteristic. "The Woods of Westermain," in particular, has that sense of the mysterious communion of man with nature which is found in the poetry of Wordsworth and Shelley. *Ballads and Poems of Tragic Life* (1887) and *A Reading of Earth* (1888) gave further evidence of the wealth of thought and vigour of expression which Meredith brought to the making of verse. His readers, of the verse even more than of the prose, must be prepared to meet him on a common intellectual footing. When once that is granted, however, the music and magic of such poems as "Seed-time," "Hard Weather," "The Thrush in February," "The South-Wester," "The Lark Ascending," "Love in the Valley," "Melampus," "A Faith on Trial," are very real, amid all their occasional obscurities of diction.

Meredith had now completed his 60th year, and with his advancing years the angles of his individuality began to grow sharper, while the difficulties of his style became accentuated. The increase in mannerism was marked in *One of Our Conquerors* (1891), otherwise a magnificent rendering of a theme full of both tragedy and comedy, in the poem of "The Empty Purse" (1892) and in *Lord Ormont and His Aminta* (1894). In *The Amazing Marriage* (1895) he seemed to catch an afterglow of genius. In 1898 appeared his *Odes in Contribution to the Song of French History*, consisting of one ode ("France, Dec. 1870") reprinted from *Ballads and Poems* (1871), and three other previously unpublished; a fine example of his lofty thought, and magnificent—if often difficult—and individual diction. In 1901 another volume of verse, *A Reading of Life*, appeared. In later years, too, he contributed occasional poems to newspapers and reviews and similar publications, which were collected after his death (*Last Poems*, 1910). His comedy, *The Sentimentalists*, was performed on March 1, 1910; his early but unfinished novel, *Celt and Saxon*, was also posthumously published in that summer.

Now famous, Meredith was chosen to succeed Tennyson as president of the Authors' Society; on his 70th birthday (1898) he was presented with a congratulatory address by 30 prominent men of letters; he received the Order of Merit; and new editions of his books (both prose and verse), for which there had long been but scanty demand, were called for. One of the results was that Meredith, with very doubtful wisdom, recast some of his earlier novels; and in the sumptuous "authorized edition" of 1897 (published by the firm of Constable, of which his son, William Maxse Meredith, was a member) very large alterations are made in some of them. It meant the excision in old age of some of the most virile passages of books that were written in the full glow and vigour of his prime. In Constable's memorial edition (1910) of his complete works the excisions were published separately.

HIS STYLE AND PHILOSOPHY

Meredith's literary quality must always be considered in the light of the Celtic side of his temperament and the peculiarities of his mental equipment. His nature was intuitive rather than ratiocinative; his mental processes were abrupt and far-reaching; and the suppression of connecting associations frequently gives his language, as it gave Browning's, but even to a greater extent, the air of an impenetrably nebulous obscurity. This criticism applies mainly to his verse, but is also true of his prose in many places, though there is much exaggeration about the difficulties of his novels. When once, however, his manner has been properly understood, it is seen to be inseparable from his method of intellection, and to add to the narrative of description both vividness of delineation and intensity of realization. But when Meredith is at his best he is only involved with the involution of his subject; the aphorisms that decorate his style are simple when the idea they convey is simple, elaborate only in its elaboration. Pregnant, vividly graphic, capable of infinite shades and gradations, his style is a much finer and subtler instrument than at first appears, and must be judged finally by what it conveys to the mind, and not by its superficial sound upon the conventional ear. It owes something to Jean Paul Richter; something, too, to Carlyle, with whose methods of narrative and indebtedness to the apparatus of German metaphysics it has a good deal in common. To the novelist Richardson, too, a careful reader will find that Meredith, both in manner and matter (notably in *The Egoist* and in *Richard Feverel*), owes a good deal; in "Mrs. Grandison" in *Richard Feverel* he even recalls "Sir Charles Grandison" by name; and nobody can doubt that Sir Willoughby Patterne, both in idea and often in expression, was modelled on Richardson's creation. Careful students of the early 19th century English novel will find curious echoes again in Meredith of Bulwer-Lytton's (Baron Lytton's) literary manner and romantic outlook.

The philosophy which represents Meredith's "criticism of life," is broadly speaking a belief in the rightness and wholesomeness of Nature, when Nature—"Sacred Reality"—is lovingly and faithfully and trustfully sought and known by the pure use of reason. Man must be "obedient to Nature, not her slave." Mystical as this philosophy occasionally becomes, it is yet an inspiring one, clean, austere and practical; and it is always dominated by the categorical imperative of self-knowledge and the striving after honesty of purpose and thought. A strong vein of political Radicalism runs through Meredith's creed. It is, how-

ever, a Radicalism allied to that of the French *philosophes*, rather than to the contemporary developments of British party politics, though in later life he gave his open support to the Liberal Party. In spite of his German upbringing Meredith was always strongly French in his sympathies, and his appreciation of French character at its best and at its worst is finely shown in his Napoleon odes.

Meredith died at Flint cottage, Box hill, Surrey, on May 18, 1909. A strong feeling existed that he should be buried in Westminster Abbey, and a petition to that effect, which was approved by the prime minister, H. H. Asquith, was signed by a large number of men of letters. But this was not to be. A memorial service was held in the abbey, but Meredith's own remains, after cremation, were interred at Dorking by the grave of his second wife. He died just after his old friend Swinburne.

(H. C.)

Bibliography.—The first edition of Meredith's collected works was published by Messrs. Chapman and Hall (1885–95); other editions are the edition de luxe (39 vols., 1896–1912), the library edition (18 vols., 1897–1910), the memorial edition (27 vols., 1909–11), and the standard edition (1914, etc.), all published by Messrs. Constable. *The Poetical Works of George Meredith* were published with notes by G. M. Trevelyan (1912). *See* M. B. Forman, *Bibliography of the Writings in Prose and Verse of George Meredith* (1922) and *Meredithiana* (1924). *The Letters of George Meredith* have been collected and edited by his son, W. M. Meredith (2 vols., 1912); *see* also *Letters to Edward Clodd and Clement K. Shorter* (1913); *Letters to Richard Henry Horne* (Cape Town, 1919); *Letters to Swinburne and Watts-Dunton* (Cape Town, 1922); *Letters to Various Correspondents* (Pretoria, 1924); *Letters to Alice Meynell, . . . 1896–1907* (Nonesuch Press, 1923). For biography and criticism *see* R. Le Gallienne, *George Meredith: Some Characteristics* (1890), which includes a bibliography by John Lane; M. Sturge Henderson, *George Meredith, Novelist, Poet, Reformer* (1907); G. M. Trevelyan, *The Poetry and Philosophy of George Meredith* (1912); C. Photiades, *George Meredith sa vie* (1910, Eng. trans. 1913); Lady Alice M. Butcher, *Memories of George Meredith* (1919); R. Galland, *George Meredith and British Criticism* (1923); J. B. Priestly, *George Meredith* (1926); Robert E. Sencourt, *The Life of George Meredith* (1929).

MERES, FRANCIS (1565–1647), English divine and author, was born at Kirton in the Holland division of Lincolnshire in 1565. He was educated at Pembroke college, Cambridge. His kinsman, John Meres, was high sheriff of Lincolnshire in 1596, and apparently helped him in the early part of his career. In 1602 he became rector of Wing in Rutland, where he had a school. He died on Jan. 29, 1647. Meres rendered immense service to the history of Elizabethan literature by the publication of his *Palladis Tamia, Wits Treasury* (1598). The *Palladis Tamia* contained moral and critical reflections borrowed from various sources, and embraced sections on books, on philosophy, on music and painting, and a famous "Comparative Discourse of our English poets with the Greeke, Latin and Italian poets." This chapter enumerates the English poets from Chaucer to Meres's own day, and in each case a comparison with some classical author is instituted. The book was issued in 1634 as a school book, and has been partially reprinted in the *Ancient Critical Essays* (1811–15) of Joseph Haslewood, Prof. E. Arber's *English Garner*, and Gregory Smith's *Elizabethan Critical Essays* (1904).

MEREZHKOVSKY, DMITRI SERGEIEVICH (1865–), Russian novelist and critic, was born in St. Petersburg (Leningrad) on Aug. 2, 1865, the son of a court official, and graduated from St. Petersburg university. He married Zinaida Hippius, the poet (*q.v.*). His first volume of poetry, published in 1888, was followed by more poetry, *Vera, Sakya Muni, Avakum, Black Angel*, etc., by translations from Euripides and other Greek classics, by literary essays on Russian and foreign writers, *Eternal Companions* (1897), and by a trilogy of historical romances collectively entitled *Christ and Antichrist* and consisting of *Smert Bogov* (1895, Eng. trans. *The Death of the Gods*, 1901, popular ed. 1926), the central figure of which is Julian the Apostate; *Voskresenie Bogi* (1902, Eng. trans. *The Forerunner*, 1902; repr. 1924), which described the life and times of Leonardo da Vinci; and *Antikhrist: Pëtr i Aleksyey* (1905, Eng. trans. *Peter and Alexis*, 1905), based on the story of the relations between Peter the Great and his son. After the "trilogy" came the novels *Alexander I.* (1911, French trans. 5th ed. 1922), *December 14* (1920, Eng. trans. 1923), and in connection with the Tutankhamun excavations, *The Birth of the Gods* (Eng. trans. 1925), followed by *Akhnaton* (Eng. trans. 1927).

About 1900–02 Merezhkovsky evolved a mystic, neo-Christian or apocalyptic teaching, based on the equal sanctity of flesh and spirit as opposed to the cult of the flesh as represented by paganism, and the cult of the spirit as revealed by ecclesiastical Christianity. The influence of Sienkiewicz can be traced in many of Merezhkovsky's writings, which include critical studies such as *Tolstoï and Dostoïevsky* (2 vols., 1901–02). He also wrote on religious, political and social questions, and published several plays, including *Paul I.* (1908) and *Carewicz Aleksy* (Warsaw, 1921), a tragedy in five acts. After the revolution he left Russia and went to live in Paris, where he continued to write.

Merezhkovsky's collected works were published in 24 vols. in 1914. *See* also J. Chuzeville, *Dmitri Merezhkovsky* (1922).

MERGANSER, the name applied to a group of fish-eating ducks forming the subfamily *Merginae* of the *Anatidae*. Mergansers have long, narrow beaks, with a small hook at the tip and the edges beset with denticulations. There is a crest on the head, and the legs are set far back on the body. The birds have great diving power.

The largest species is the goosander (*Mergus merganser*), found throughout the northern parts of the world. In breeding plumage the male is a very beautiful bird. *M. serrator*, the red-breasted merganser, has the same range as the last but is smaller. In both the bill and feet are orange. *M. albellus*, the smew, is smaller still and confined to the old world. The feet are dull grey and the breeding plumage predominantly white. *M. cucullatus*, intermediate in size between the last two, is the hooded merganser of N. America. Other species inhabit S. America and the Antarctic.

Differing in possessing spiny tails and spurred wings are the S. American torrent-ducks (*Merganetta*).

MERGENTHEIM, a town of Germany, in the republic of Württemberg, situated in the valley of the Tauber, 7 m. S. from Lauda by rail. Pop. (1925) 5,430. Mergentheim (*Mariae domus*) is mentioned in chronicles as early as 1058, as the residence of the counts of Hohenlohe, who early in the 13th century assigned the greater part of their estates in and around Mergentheim to the Teutonic Order. On the secularization of the Order in Prussia in 1525, Mergentheim became the residence of the grand master, and remained so until the final dissolution of the Order in 1809. The town contains a castle with a natural history collection and the archives of the Teutonic Order. The industries include tanning, the manufacture of agricultural machinery and brewing.

MERGER, in law, the sinking or "drowning" of a lesser estate in a greater, when the two coalesce in one and the same person without any intervening estate, as, *e.g.*, when the tenant for life becomes owner of the absolute freehold. The term is also used for the extinguishment of any right, contract, etc., by absorption in another, *e.g.*, the acceptance of a higher security for a lower, or the embodying of a simple contract in a deed.

Merger in Industry.—The term merger is one that is used in the United States to denote the large industrial or commercial concern which results from a "merging" of previously independent and probably competing concerns in the same line of business. It corresponds almost exactly with the British term "combine" and, like "combine," enjoys the peculiarity of being a term in widespread use which is seldom, if ever, found in the registered title of the type of organization to which it is applied. Prominent among the objects for which firms are "merged" is the suppression of competition between them and its replacement by a unified control which, in cases where the merger gathers into one consolidated interest the bulk of the output of an industry, becomes a control over the price at which the product shall be sold. The merger is one of the several forms of monopolistic organization which has come into being as the result of the persistent movement from competition to combination. (*See* Amalgamation; Combination; Fusion; Monopoly; Trusts and Cartel.)

MERGUI, the southernmost district of Burma, in the Tenasserim division, bounded on the west by the Andaman sea of the

Bay of Bengal and on the east by Siam. Area 9,789 sq.m. Two principal ranges cross the district from north to south, running almost parallel to each other for a considerable distance, with the Tenasserim river winding between them till it turns south and flows through a narrow rocky gorge in the westernmost range to the sea. The whole district, from the water's edge to the loftiest mountain on the eastern boundary, may be regarded as almost unbroken forest. The timber trees found towards the interior, and on the higher elevations, are of great size and beauty, the most valuable being the teak (*Tectona grandis*) of the drier, sheltered valleys only, *thin-gan* (*Hopea odorata*), *ka-gnyeng* (*Dipterocarpus laevis*), etc. The coast-line of the district, off which lies an archipelago of two hundred and seven islands, is much broken, and for several miles inland is very little raised above sea-level, and is drained by numerous muddy tidal creeks. Southwards of Mergui town it consists chiefly of low mangrove swamps alternating with small fertile rice plains. After passing the mangrove limits, the ground to the east gradually rises till it becomes mountainous, even to the banks of the rivers, and finally culminates in the grand natural barrier dividing Burma from Siam. The four principal rivers are the Tenasserim, Le-nya, Pakchan and Palauk, the first three being navigable for a considerable distance. Coal is found on the banks of the Tenasserim and its tributaries, but is little worked. Gold, copper, iron and manganese are also found in various parts of the district, and there are tin mines at Maliwun and elsewhere, but the tin mines are less important than in the Tavoy district to the north.

From the notices of early travellers it appears that Mergui, when under Siamese rule, before it passed to the Burmese, was a rich and densely peopled country. On its occupation by the British in 1824–1825 it was found to be almost depopulated—the result of border warfare and of the cruelties exercised by the Burmese conquerors. At that time the entire inhabitants numbered only 10,000. Pop. (1921), 135,465, showing an increase of 24,091 in the decade and giving a density of 14 inhabitants to the square mile. Mergui carries on a flourishing trade with Rangoon and the Straits Settlements. The chief exports consist of rubber, tin ore, rice, rattans, dried fish, areca-nuts and edible birds' nests. The staple imports are piece goods, tobacco, cotton, earthenware, tea and sugar. The climate is remarkably healthy, the heat due to its tropical situation being moderated by land and sea breezes. The rainfall is very heavy and usually exceeds 150 inches, the dry season is short, so that these two factors combined have led to the development of rubber planting.

Mergui town has risen into prominence in recent years as the centre of the rubber and tin ore exporting trade, which has eclipsed its earlier importance as the centre of the pearling trade in the neighbouring archipelago. Pop. (1921), 17,297.

MERGUI ARCHIPELAGO, a cluster of islands in the Andaman sea, near the southern coast of Lower Burma. They are chiefly noted for their picturesque beauty, some of them rising to 3,000 feet. They are only sparsely inhabited by the island race of Selungs and by Burmans.

MERIAN, MATTHEW (1593–1650), Swiss engraver, was born in Basle on Sept. 25, 1593. In 1609 he was placed under Dietrich Meyer, a painter and engraver of Zürich, and in 1613 went to Nancy, where he worked at copper-engraving. After studying in Paris, Stuttgart (1616), and the Low Countries, he came to Frankfurt, where in 1618 he married the eldest daughter of J. T. de Bry, publisher, bookseller, and engraver. After working for some time with his father-in-law at Oppenheim, Merian returned to Basle, but came back to Frankfurt after Bry's death (1623), to take over his business. This remained in his family till 1726, when a great fire wiped it out of existence. In 1625 Merian became a burgher of Frankfurt, then the great centre of the book trade in Germany. He lived there till his death on June 22, 1650. He published a series of *Topographia*, with text by Martin Zeiller, an Austrian; and copper-plate illustrations furnished chiefly by Merian. The first volume, dealing with Switzerland, the Grisons, and the Valais contains the earliest known view of the glaciers of Grindelwald. He published a series of illustrations to the Bible (1625–30), and a *Dance of Death* (1649); and began (1635) the series *Theatrum Europaeum*.

See Life by H. Eckardt (Basle, 1887).

MÉRIDA, a city of Mexico and capital of the State of Yucatan, 23 m. by rail S. of Progreso, its port on the Gulf of Mexico. Pop. (1921) 79,225, the Maya element being predominant. Mérida is the centre of an isolated railway system, connected with the ports of Progreso and Campeche, and having short lines (chiefly narrow gauge, private lines) radiating in all directions to Peto, Valladolid and Izamal. It stands on a broad plain situated near the northern border of the peninsula, where the thin loose soil covering a limestone foundation permits the rapid percolation of the rainfall, and as a natural consequence supports a comparatively scanty vegetation. It is highly favourable to maguey cultivation, however, and Mérida is the centre of the henequén, or sisal fibre industry. There is an imposing 16th-century cathedral facing upon the principal plaza, a Franciscan convent, dating from 1547, and also an old university, with schools of law, medicine and pharmacy, an episcopal seminary and a number of other educational institutions. The exports are sisal, hides, sugar, rum, chicle and indigo. Mérida was founded in 1542 by the younger Francisco de Montejo on the site of a native city called Tihoo, or Thó, whose stone pyramids furnished building material in abundance for the invaders.

MÉRIDA (anc. *Augusta Emerita,* capital of Lusitania), a town of western Spain, in the province of Badajoz, on the right bank of the river Guadiana, 30 m. E. of Badajoz. Pop. (1920) 15,502. Mérida is an important railway junction, for here the Madrid-Badajoz railway meets the lines from Seville, Huelva and Cáceres. Augusta Emerita was founded in 25 B.C. As the capital of Lusitania it soon became one of the most splendid cities in Iberia, and was large enough to contain a garrison of 90,000 men. In 1129 its archbishopric was formally transferred to Santiago de Compostela, and in 1228, when Alphonso IX. of Leon expelled the Moors, Mérida was entrusted to the order of Santiago, in whose keeping it soon sank into decadence. Chief among the Roman remains is the bridge, constructed of granite under Trajan, or Augustus, and restored by the Visigoths in 686 and by Philip III. in 1610. It comprised 81 arches, 17 of which were destroyed during the siege of Badajoz (1812), and measured 2,575 ft. in length. There are a few remnants of Roman temples and of the colossal wall which encircled the city, besides a Roman triumphal arch, commonly called the Arco de Santiago, and a second Roman bridge, by which the road to Salamanca was carried across the small river Albarregas (*Alba Regia*). The Moorish *alcázar* or citadel was originally the chief Roman fort. From the Lago de Proserpina, or Charca de la Albuera, a large Roman reservoir, 3 m. N., water was conveyed to Mérida by an aqueduct, of which there are extensive remains. The massive Roman theatre is in good preservation; there are also a few vestiges of an amphitheatre and of a circus which measured 485 yd. by 120. Other Roman remains are exhibited in the archaeological museum.

MERIDEN, a city of New Haven county, Connecticut, U.S.A., midway between New Haven and Hartford, on Federal highway 5 and the New York, New Haven and Hartford Railroad. The population was 29,867 in 1920 (26% foreign-born white) and was 38,481 in 1930 by the Federal census. The city occupies 16·4 sq.m. and is traversed by the Quinnipiac river and Harbor Brook. West Peak State Park, with hills 700 ft. above sea-level, is on its north-west border. It is the seat of the Connecticut school for boys and of a State tuberculosis sanatorium. The assessed valuation in 1927 was $48,931,165. Meriden has a great variety of manufacturing industries, with an output in 1925 valued at $37,627,656, and is especially noted for its silverware, both sterling and plated. Samuel Yale began the manufacture of pewter and Britannia ware here in 1794. In 1847 the Rogers Brothers invented a process of depositing silver on other metals by electricity, and shortly afterward united with the Meriden Britannia Company to found the house which still operates under their name. The town of Meriden was separated from Wallingford and incorporated in 1806; the city was chartered in 1867; and in 1922 town and city were consolidated. The oldest building in the city is the Goffe House (1711).

MERIDIAN, a city of eastern Mississippi, U.S.A., county seat of Lauderdale county; 140 m. S.W. of Birmingham (Alabama). It is on Federal highways 11, 45 and 80, and is served by the Gulf, Mobile and Northern, the Illinois Central, the Mobile and Ohio and the Southern railways. In 1920 it was the largest city of the State; population then was 23,399 (36% negroes); in 1930 it was 31,954 by Federal census. The city lies in a valley of wooded hills, streams and lakes, in a lumbering and agricultural region of diversified products, including cotton, bright-leaf tobacco, corn, oats, strawberries, peaches, grapes, figs, hogs, dairy cattle and poultry. It has 15 wholesale houses, the only stock-yards in the State, and a retail trade territory with a 75 m. radius. There are large railway shops, cotton gins and compresses, cottonseed-oil mills, lumber mills, brick plants, canneries and knitting mills. The factory output in 1925 was valued at $8,630-636. Hydro-electric power is available. The city has an assessed valuation of $22,836,623 (1927). Meridian was laid out in 1854, and chartered as a city in 1860. On Feb. 14, 1864, General Sherman entered the city and within a week destroyed most of it. The "Meridian riot" of 1871 was a prominent episode of the Reconstruction period. On March 2, 1906, a cyclone caused great loss of life and property. A commission form of government was adopted in 1913.

MERIDIAN, in general a direction towards the south or towards the position of the sun at mid-day. Geographical meridians are the great circles drawn on the earth's surface which pass through the Poles, and thus pass through all places having the same longitude. The meridian of Greenwich (the great circle passing through Greenwich Observatory and the two Poles) is the zero from which terrestrial longitudes are reckoned. In astronomy the meridian is the great circle through the Pole and the zenith; it intersects the horizon in the north and south points.

MERIDIAN HIGHWAY, an American highway which, as its name implies, extends north and south from Canada to Mexico about midway between the Atlantic and Pacific oceans. It is gravelled, hard or paved its entire length of 1,769 miles. Winnipeg, Canada, is its northern terminus, whence it passes through Fargo, N.D., Watertown, S.D., Norfolk, Neb., Wichita, Kan., Chickasha, Okla. and Fort Worth and Austin to Laredo, Tex.

MERIKANTO, OSKAR (1868–1924), Finnish composer, was born at Helsingfors on Aug. 5, 1868. He received his musical education in Leipzig and Berlin. Returning to Finland he began to write operas, drawing his subjects from the legends of his country. In 1911 he was appointed conductor of the opera at Helsingfors. Outside Finland he is best known for his very beautiful Finnish songs. Besides the three operas, *Daughter of Pohja, The death of Elina, Queen of Emmeritz,* he wrote organ music and some choral works. He died at Helsingfors on Feb. 17, 1924.

MÉRIMÉE, PROSPER (1803–1870), French novelist, archaeologist, essayist, and in all these capacities one of the greatest masters of French style during the 19th century, was born at Paris on Sept. 28, 1803. His grandfather, of Norman extraction, had been a lawyer and steward to the maréchal de Broglie. His father, Jean François Léonor Mérimée (1757–1836), was a painter of repute. Mérimée had English blood in his veins on the mother's side, and had English proclivities in many ways. He was educated for the bar, but entered the public service instead. A young man at the time of the Romantic movement, he felt its influence strongly, though his peculiar temperament prevented him from joining any of the coteries of the period. Nothing was more prominent among the romantics than the fancy, as Mérimée himself puts it, for "local colour," the more unfamiliar the better. He exhibited this in an unusual way. In 1825 he published what purported to be the dramatic works of a Spanish lady, Clara Gazul, with a preface stating circumstantially how the supposed translator, one Joseph L'Estrange, had met the gifted poetess at Gibraltar. This was followed by a still more audacious and still more successful *supercherie.* In 1827 appeared a small book entitled *la Guzla* (the anagram of Gazul), and giving itself out as translated from the Illyrian of Hyacinthe Maglanovich.

This book, which has greater formal merit than *Clara Gazul,* is said to have taken in Sir John Bowring, a competent Slav scholar, and the Russian poet Pushkin, but, as Mérimée declares, a few words of Illyrian and a book or two of travels and topography were the author's only materials. In the next year appeared a short dramatic romance, *La Jacquerie,* in which is visible Mérimée's faculty of local and historical colour. This was followed by the *Chronique de Charles IX.* (1829).

He had already obtained a considerable position in the civil service, and after the revolution of July he was *chef de cabinet* to two different ministers. He was then appointed to the more congenial post of inspector-general of historical monuments. He did not, however, neglect novel writing during this period, and numerous short tales appeared, chiefly in the *Revue de Paris.* The best of all, *Colomba,* a Corsican story of extraordinary power, appeared in 1840. He travelled a good deal; and in one of his journeys to Spain, about the middle of Louis Philippe's reign, he made an acquaintance destined to influence his future life not a little—that of Mme. de Montijo, mother of the future empress Eugénie.

Mérimée, though in manner and language the most cynical of men, was a devoted friend, and shortly before the accession of Napoleon III. he had occasion to show this. His friend, Libri Carucci dalla Sommaja, was accused of having stolen valuable manuscripts and books from French libraries, and Mérimée took his part so warmly that he was actually sentenced too, and underwent fine and imprisonment. Between 1840 and 1850 he wrote more tales, the chief of which were *Arsène Guillot* and *Carmen* (1847), this last, on a Spanish subject, hardly ranking below *Colomba.*

The marriage of Napoleon III. with the daughter of Mme. de Montijo at once enlisted what was always strongest with Mérimée—the sympathy of personal friendship—on the emperor's side. He was made a senator, but his most important rôle was that of a constant and valued private friend of both the "master and mistress of the house," as he calls the emperor and empress in his letters. He was occasionally charged with a kind of irregular diplomacy, and once, in the matter of the emperor's *Caesar,* he had to give literary assistance to Napoleon.

At this time he wrote the letters which have been published as *Lettres à une inconnue,* and also the letters addressed to Sir Anthony Panizzi, librarian of the British Museum. After various conjectures it seems that the *inconnue* just mentioned was a certain Mlle. Jenny Daqin of Boulogne. The acquaintance extended over many years.

Both series, and others since published, abound in gossip, in amusing anecdotes, in sharp literary criticism, while both contain evidences of a cynical and Rabelaisian or Swiftian humour which was very strong in Mérimée. This characteristic is said to be so prominent in a correspondence with another friend, which now lies in the library at Avignon, that there is but little chance of its ever being printed. A fourth collection of letters, of much inferior extent and interest, has been printed by Blaze de Bury under the title of *Lettres à une autre inconnue* (1873), and others still by d'Haussonville (1888), and in the *Revue des Deux Mondes* (1896). In the latter years of his life Mérimée suffered very much from ill-health. He died at Cannes September 23, 1870.

Mérimée's character was a peculiar and in some respects an unfortunate one, but by no means unintelligible. Partly by temperament, partly it is said owing to some childish experience, when he discovered that he had been duped and determined never to be so again, not least owing to the example of Henri Beyle (Stendhal), who was a friend of his family, Mérimée appears at an early age to have imposed upon himself as a duty the maintenance of an attitude of sceptical indifference and sarcastic criticism.

All his literary work has the Renaissance character. It is tolerably extensive, amounting to some seventeen or eighteen volumes, but its bulk is not great for a life which was not short, and which was occupied, at least nominally, in little else. About a third of it consists of the letters already mentioned. Rather more than another third consists of the official work which has been already alluded to—reports, essays, short historical sketches, the chief of which latter is a history of Pedro the Cruel (1843),

and another of the curious pretender known in Russian story as the false Demetrius (1852). Some of the literary essays, such as those on Beyle, on Turgeniev, etc., where a personal element enters, are excellent. Against others and against the larger historical sketches—admirable as they are—Taine's criticism that they want life has some force. In purely archaeological matters his *Description des peintures de Saint-Savin* is noteworthy.

It is, however, in the remaining third of his work, consisting entirely of tales either in narrative or in dramatic form, and especially in the former, that his full power is perceived. He translated a certain number of things (chiefly from the Russian); but his fame does not rest on these, on his already-mentioned youthful *supercheries*, or on his later semi-dramatic works. There remain about a score of tales, extending in point of composition over exactly forty years and in length from that of *Colomba*, the longest, which fills about one hundred and fifty pages, to that of *l'Enlèvement de la redoute* (1829), which fills just half a dozen. They are unquestionably the best things of their kind written during the century, the only *nouvelles* that can challenge comparison with them being the very best of Gautier, and one or two of Balzac. The motives are sufficiently different. In *Colomba* and *Mateo Falcone* (1829), the Corsican point of honour is drawn on; in *Carmen* (written apparently after reading Borrow's Spanish books), the gipsy character; in *la Venus d'Ille* (1837) and *Lokis* (two of the finest of all), certain grisly superstitions.

Arsène Guillot is a singular satire, full of sarcastic pathos, on popular morality and religion; *la Chambre bleue*, an 18th-century *conte*, worthy of C. P. J. Crébillon for grace and wit, and superior to him in delicacy; *The Capture of the Redoubt* just mentioned is a perfect piece of description; *l'Abbé Aubain* is again satirical; *la Double méprise* (the authorship of which raised objections to Mérimée when he was elected to the Academy) is an exercise in analysis strongly impregnated with the spirit of Stendhal, but better written than anything of that writer's. These stories, with his letters, assure Mérimée's place in literature at the very head of the French prose writers of the century. He had undertaken an edition of Brantôme for the Bibliothèque Elzévirienne, but it was never completed. (G. SA.)

MERINO. The Spanish name for a breed of sheep, and hence applied to a woollen fabric. The merino is a white, short-wool sheep, the male having spiral horns, the ewes being generally hornless. It is bred chiefly for its wool, because, though an excellent grazer and very adaptable, it matures slowly and its mutton is not of the best quality. The wool is close and wavy in staple, reaching four inches in length, and surpasses that of all other sheep in fineness; it is so abundant that little but the muzzle, which should be of an orange tint, and hoofs are left uncovered. The best wool is produced on light, sandy soils.

The merino is little known in Great Britain, the climatic moisture of which does not favour the growth of the finest wools, but it predominates in all regions where sheep are bred for their wool rather than their mutton, as in the western United States, Cape Colony, Australia, New Zealand and Argentina. In Australasia, especially in New Zealand, the merino has been crossed with Lincolns, Leicesters, Shropshires and other breeds, with the result of improving the quality of the mutton while sacrificing to some extent that of the wool.

The merino sheep appears to have originated in Africa, whence it was brought by the Moors to Spain and thence spread over Europe, especially to Austria-Hungary, Germany and France. The best-known breeds are the Rambouillet, a large merino named after the village near Paris to which it was imported towards the end of the 18th century, and the Negretti, which stands in closer relationship to the old Spanish stock and has shorter wool but a more wrinkled fleece. Importations to America began about the beginning of the 19th century. The so-called American merino, the Delaine, the Vermont and the Rambouillet, are well-known breeds in the United States.

The term "merino" is widely employed in the textile industries with very varied meanings. Originally it was restricted to denote the wool of the merino sheep reared in Spain, but owing to the superiority of the wools grown on merino sheep and shipped from Botany bay the name as applied to wool was replaced by the term "botany." In the dress-goods and knitting trades the term "merino" still implies an article made from the very best soft wool. The term "cashmere," however, is frequently confused with it, although cashmere goods should be made from true cashmere and not, as is often the case, from the finest botany wool. In the hosiery and re-manufactured materials trades the term "merino" is applied to fibre-mixtures of cotton and wool in contradistinction to "all wool" goods.

MERIONETH (Welsh *Meirionydd*), a county of North Wales bounded north by Carnarvon and Denbigh, east by Denbigh and Montgomery, south-east by Montgomery, south by the Dovey estuary, dividing it from Cardigan, and west by Cardigan bay. It is nearly triangular, its greatest length from north-east to south-west being about 45 m., and its greatest breadth about 30 miles. Area, 422,372 acres. Pop. (1931), 43,198 (administrative county).

Geology.—The outstanding geological feature is the Harlech dome—a mountain tract about 15 m. from north to south by 10 m. from east to west, from the coast inland. It is roughly oval, with Barmouth and Dolgelly, Harlech and Maentwrog around its edges. It is of Cambrian age and composed of grits, quartzites and slates, forming a large anticline. Its central portion is occupied mainly by Harlech grits and Menevian beds. Around the dome on the north, east and south, from Towyn around to Carnarvonshire, great volcanic masses, mostly greenstone, stand out in a sweeping curve. The igneous material is intruded into Lingula, Tremadoc and Arenig beds. This belt of high ground surrounding the dome includes Rhobell Fawr (2,313 ft.), composed of andesitic rock, while in the Arenig beds (interstratified with and overlaid by accumulations of volcanic ashes, felspathic traps or lava flows) are the rugged heights of Cader Idris (*q.v.*), Aran Fawddwy (2,970 ft.) and Arenig Fawr (2,600 ft.). The rough grits of the Harlech dome are separated from the grits and lavas further east by the valley of the Eden and Mawddach. The Ordovician volcanic rocks are, in turn, overlaid by the Llandeilo and Bala beds, the latter including the Bala limestone. South of Rhobell Fawr the great ring of volcanic mountains is broken across by the deep straight Bala cleft—one of the sharpest geological fault lines in Britain. The line of depression marking the fault runs from the sea near Towyn through the long and narrow Dysynni valley to Tal-y-llyn, and over the low hump of the Cross Foxes to the elongated Bala lake, the source of the Dee. The great fault line has many branches; the Mawddach estuary line, with its beautiful sands, represents a section which has sunk seawards.

Here and there along the eastern boundary of the county, Llandovery and Wenlock strata are included. The structure of the Silurian tract is synclinal; in the Berwyn mountains the Ordovician rocks again appear with associated andesitic and felsitic lavas and tuffs. West of Llangar, near Corwen, is a small patch of Carboniferous limestone. Glacial drift with boulder clay is a prominent feature in the valleys and on the mountain sides, while a good deal of blown sand fringes the coast north and south of Harlech.

The southern section of the county is bordered in some parts by the river Dyfi (Dovey), which rises in a small lake near Aran Fawddwy, passes Machynlleth and expands into an estuary on Cardigan bay, the origin of which is probably associated with

the Llyfnant fault zone of northern Cardiganshire and southern Montgomeryshire.

History and Early Settlement.—The Ardudwy coast between Barmouth and Harlech seems to have been important in Megalithic times, while finds of flat axes of bronze to the north-east of Bala lake indicate early attempts to reach the coast from England by way of the Bala cleft. The finds of gold and Late Bronze age hoards on the north-west coast near Harlech indicate contact with Ireland. The upper Dee valley, as well as other strategic sites in the county have hilltop camps of Romano-British age. A Roman trackway ran from the military site at Pennal, in the south of the county, northwards to Tomen y Mur and hence to Segontium and Kanovium in the north. Somewhere to the east of Dolgelly this trackway was met by another following the Bala cleft from Caergai. In the post-Roman centuries, the remoteness and isolation of the county became more pronounced. Shut off by hills on all sides, it experienced little Saxon; Scandinavian or early Norman influence. In this respect it bears a striking contrast to the neighbouring county of Montgomery, which had easier connections with England. In Saxon times the county was under the princes of Gwynedd, although some parts of what later became Merionethshire were under the princes of Powys. A Norman attempt to enter the county was repulsed in 1096. During the next 300 years there were many fights in the neighbourhood of Corwen, which commanded the entrance to the county via the Bala cleft. Here Owain Gwynedd was posted to repel Henry II., and hither Owain Glyn Dwr retired before Henry IV. The remoteness of the region made it a gathering ground of the Welsh resistance to the English, and in the county and over its borders, at Dolgelly and Machynlleth, there are traditions of Owain Glyn Dwr's parliaments. In this sheep-rearing county the Cistercian abbey of Cymmer (Y Fanner), near Dolgelly, was founded about 1200. It was dissolved by Henry VIII., though some interesting ruins remain. The county was still inaccessible in Elizabethan times, and its remoteness is mentioned by Churchyard (1587). About this time may be traced the beginnings of the slate industry, though it did not come into prominence until the 18th century. There were quarries in the 19th century at Festiniog, Corris, Aberllefeni, Pennal, Abergynolwyn and Arthog, though the depression in the slate industry since 1914 has seriously diminished the output. There are records of gold mines in the Mawddach valley from early times, and copper has been mined in the Ardudwy, and lead in the Dyfi valleys. The flannel and woollen industries were important in the county until recently. In the 18th century Dolgelly was famous for its production of a Welsh tweed cloth, and Bala made stockings and woollen caps. The coming of steam-driven machinery seriously diminished these trades and the county is now almost entirely a region of pastoral farming, exporting young men and women to the large cities.

Of recent years, however, with the advent of better roads and the motor car, the coastal towns, particularly Aberdovey, Barmouth and Harlech, have many summer visitors.

Communications, Travel and Government.—The climate varies much with the elevation. Grain crops cover a small area only; barley and oats are the most important crops. Potatoes, turnips and swedes are also grown, but there is very little cultivation of fruit. While the soil is generally thin, there are fertile tracts in the valleys, and there is some reclaimed land. The small hardy ponies (known as of Llanbedr, Conway valley) are now almost restricted to this county and Montgomeryshire. The Great Western railway skirts the coast from Portmadoc to Aberdyfi. At Barmouth junction a branch crosses to Dolgelly. Bala and Festiniog are also united by the G.W. railway, and Festiniog is further joined with Llandudno junction by the L.M.S. railway, and with Portmadoc by a narrow-gauge line. The coast is almost unnavigable, owing to sand-banks, and the only havens are Barmouth and Aberdyfi.

The county returns one member to parliament, and has neither parliamentary nor municipal borough. The urban districts are: Bala, Barmouth, Dolgelly, Festiniog, Mallwyd and Towyn. The shire is in the north-west circuit, and assizes are held at Dolgelly. It is partly in the diocese of St. Asaph, partly in Bangor.

MERISTEM, a botanical term for tissue which has the power of developing new forms of tissue, such as the cambium from which new wood is developed or the tissue at the apex which is responsible for the growth in length of the stem or root.

MERIVALE, CHARLES (1808–1893), English historian and dean of Ely, the second son of John Herman Merivale was born on March 8, 1808. He was at Harrow (1818–24) and St. John's college, Cambridge (1826), where he was elected fellow in 1833. He declined the professorship of modern history at Cambridge in 1869, but in the same year accepted from Gladstone the deanery of Ely, which he held until his death on Dec. 27, 1893. His principal work was *A History of the Romans under the Empire* (7 vols., 1850–62); but he wrote several smaller historical works, and published sermons, lectures and Latin verses.

See *Autobiography of Dean Merivale,* with selections from his correspondence, edited by his daughter, Judith A. Merivale (1899); and *Family Memorials,* by Anna W. Merivale (1884).

MERKARA: *see* MERCARA.

MERLE, a name sometimes applied to the European blackbird (*Turdus merula*), especially in association with the word mavis in Scottish poetry. *See* BLACKBIRD.

MERLIN, ANTOINE CHRISTOPHE (1762–1833), French revolutionary, called "of Thionville," was born at Thionville on Sept. 13, 1762. After studying theology, he devoted himself to law. In 1790 he was sent by the department of Moselle to the Legislative assembly. On Oct. 23, 1791 he moved and carried the institution of a committee of surveillance, and it was he who proposed the law sequestrating the property of the *émigrés.* He was elected deputy to the Convention, and pressed for the execution of Louis XVI. He took part in the reaction which followed the fall of Robespierre, sat in the council of the Five Hundred, and at the *coup d'état* of the 18th Fructidor (Sept. 4, 1797) demanded the deportation of certain republican members. In 1798 he was appointed director-general of posts, being sent subsequently to organize the army of Italy. He lived in retirement under the consulate and the empire. He died in Paris on Sept. 14, 1833.

See J. Reynaud, *Vie et correspondance de Merlin de Thionville* (Paris, 1860).

MERLIN, PHILIPPE ANTOINE, COUNT (1754–1838), French politician and lawyer, known as Merlin "of Douai," was born at Arleux (Nord) on Oct. 30, 1754, and was called to the Flemish bar in 1775. As deputy for Douai in the Constituent Assembly he carried important legislation abolishing the feudal and seignorial rights. On the dissolution of the Assembly he became judge of the criminal court at Douai. As a member of the council of legislation he presented to the Convention on Sept. 17, 1793 the law permitting the detention of *suspects.* He was closely allied with his namesake Merlin "of Thionville," and, after the counter-revolution which brought about the fall of Robespierre, he became president of the Convention and a member of the Committee of Public Safety. He persuaded the Committee of Safety to close the Jacobin club. He recommended the readmission of the survivors of the Girondin party to the Convention, and drew up a law limiting the right of insurrection. With Cambacérès he had been commissioned in April 1794 to report on the civil and criminal legislation of France, and produced his *Rapport et projet de code des délits et des peines* (10 Vendémiaire, an. IV.). Merlin's code abolished confiscation, branding and imprisonment for life. He was made minister of justice (Oct. 30, 1795) under the Directory. After the *coup d'état* of the 18th Fructidor he became (Sept. 5, 1797) one of the five directors, and, being accused of the various failures of the government, retired into private life on June 18, 1799. Under the consulate he became procureur-général in the court of cassation, and did more than any other lawyer to fix the interpretation of the Napoleonic Code. He became a member of the council of state, count of the empire, and grand officer of the Legion of Honour; but was banished on the second restoration. The years of his exile were devoted to his *Répertoire de jurisprudence* (5th ed., 18 vols., 1827–1828) and to his *Recueil alphabétique des questions de droit* (4th ed., 8 vols., 1827–28). At the revolution of 1830 he returned to France, and

re-entered the Institute of France. He died in Paris on Dec. 26, 1838.

See M. Mignet, *Portraits et notices historiques* (1852), vol i.

MERLIN, the famous bard of Welsh tradition, enchanter and counsellor of Arthurian romance. The personality of Merlin, on one side of demoniac, on the other of human, parentage, is now generally recognized as a combination of diverse traditions. Geoffrey of Monmouth, to whom we owe the conception of the romantic Merlin, probably knew more than one tradition, Nennius' story of the boy Ambrosius, "child without a father," who revealed to Vortigern the secret of the insecure foundations of his tower, being the starting point of his combination. Into this framework were introduced elements derived from the much older story of the demon Asmodeus (Aschmedai), who acted as familiar spirit to Solomon—the feats of divination with which the boy astonishes the messengers of the king, derive directly from this source. Later on a *Vita Merlini,* long attributed to Geoffrey—an attribution on which modern scholarship has thrown doubts—incorporated features from the Scotch tradition of a certain Lailoken, a "wild man of the woods," gifted with powers of divination. This led to the idea that there had been two Merlins, Merlin-Ambrosius and Merlin-Sylvestris, a view now very generally rejected. The second part of Robert de Borron's trilogy, which was the starting point of the Arthurian cyclic development, dealt with the birth of the seer and his relations with Uther Pendragon. This, originally in verse form, was later worked over in prose, and expanded, first with additions dealing with the wars incident to the opening of Arthur's reign, then with a medley of romantic incidents connected with Arthur's court. The two elements are combined in a unique ms., No. 337 (*Fonds Français*) of the Bibliothèque Nationale. Finally, a fantastic romance, entitled *Les Prophécies de Merlin,* belonging to a late period of Arthurian evolution, completed the cycle. Merlin is a strange and interesting personality, and his story may quite possibly have been inspired by popular tradition connected with an actual Welsh bard and sooth sayer.

BIBLIOGRAPHY.—For the life of Merlin *see* Geoffrey of Monmouth's *Historia* and the *Vita Merlini* (ed. J. J. Parry, University of Illinois, *Studies in Language and Literature,* vol. x. 1925). For the romantic Merlin see *Merlin,* ed. H. O. Sommer (1894) and vol. ii. of Sommer's *Vulgate Version of the Arthurian Romances* (1908–16); *Merlin,* ed. G. Paris and J. Ulrich (*Société des anc. textes fr.* 1886), an edition of the unique Huth ms., the version contained in which was utilized by Malory; *Les Prophécies de Merlin,* ed. L. A. Paton (1926–27). *See* also F. Lot, *Annales de Bretagne,* vol. xv. For the Oriental parallels *see* M. Gaster, *The Exempla of the Rabbis* (1925) and E. Seymour, *Tales of King Solomon* (1925). J. D. Bruce, *The Evolution of Arthurian Romance,* vol. ii. (1923), gives a bibliography of the scattered *Merlin* studies. (J. L. W.)

MERLIN, the name given to members of a group of small falcons (*Falco*) and especially to the European merlin (*F. aesalon*). This is a bold little bird, steel-blue above and red-brown below in the male, the female being brown. It nests on the ground, usually in heather. Scarcely to be distinguished is the N. American pigeon-hawk (*F. columbanus*), while other larger species occur in India and Africa. *See* FALCON.

MERLINO COCCAJA: *see* FOLENGO, TELEOFILO.

MERLON, the raised, solid portion of a battlement parapet, sometimes pierced by loop-holes (*see* BATTLEMENT).

MERMAIDS AND MERMEN, in the folk-lore of England and Scotland, semi-human beings who dwell in the sea, but can live on land and enter into social relations with humans.

The typical mermaid has the head and body of a lovely woman, but below the waist is fashioned like a fish, with scales and fins. For a time a mermaid may become to all appearance an ordinary human being; an Irish legend ("The Overflowing of Lough Neagh and Liban the Mermaid," in Joyce's *Old Celtic Romances*) represents the reverse case.

The mermaid legends of all countries may be grouped as follows: (*a*) "A mermaid or mermaids either voluntarily or under compulsion reveal things that are about to happen." Thus in the *Nibelungenlied.* (*See* also *Kong Fredericks den andens Krönike,* Copenhagen, 1680, p. 302.) (*b*) "A mermaid imparts supernatural powers to a human being." (*See* "The Old Man of Cury," in Hunt's *Popular Romances of the West of England,* 1871.) (*c*) "A mermaid has some one under her protection and for wrong done to her ward exacts a terrible penalty." (*See* the "Mermaid's Vengeance" in Hunt's book already quoted.) (*d*) "A mermaid falls in love with a human being, lives with him as his lawful wife for a time, and then, some compact being unwittingly or intentionally broken by him, departs to her true home in the sea." Here the typical legend is that of *Mélusine* (*q.v.*), made the subject of a romance by Jean d'Arras. (*e*) "A mermaid falls in love with a man, and entices him to go to live with her below the sea; or a merman wins the affection or captures the person of an earthborn maiden." This form of legend is very common, and has been a favourite with poets. Danish ballads are full of the theme; as "Agnete and the Merman," an antecedent of Matthew Arnold's "Forsaken Merman"; the "Deceitful Merman, or Marstig's Daughter"; and the story of Rosmer Hafmand (No. 49 in Grimm). The mermaid has generally to be bribed or compelled to utter her prophecy or bestow her gifts, and whether as wife or paramour brings disaster in her train. The fish-tail is really of secondary importance, for the true Teutonic mermaid—probably a remnant of the great cult of the Vanir—had no fish-tail. The Tritons, the Sirens of classical antiquity, the Phoenician Dagon, and the Chaldaean Oannes are well-known examples. (*See* also Jones, *Traditions of the North American Indians,* 1830; Dennis, *Folklore of China,* 1875.)

Quasi-historical instances of the appearance or capture of mermaids are common enough, and serve, with the frequent use of the figure on signboards and coat of arms, to show how thoroughly the myth had taken hold of the popular imagination.

The best account of the mermaid-myth is in Baring-Gould's *Myths of the Middle Ages. See* also Pontoppidan, who has collected much matter to prove the existence of mermaids; Maillet, *Telliamed* (Hague, 1755); Grimm, *Deutsche Mythologie,* i. 404, and *Altdän. Heldenlieder* (1811); Waldron's *Description of the Isle of Man.*

MEROBAUDES, FLAVIUS (5th century A.D.), Latin rhetorician and poet, probably a native of Baetica in Spain. He was the official laureate of Valentinian III. and Aëtius. Till the beginning of the 19th century he was known only from the notice of him in the *Chronicle* (year 443) of his contemporary Idacius, where he is praised as a poet and orator, and mention is made of statues set up in his honour. In 1813 the base of a statue was discovered at Rome, with a long inscription belonging to the year 435 (*C.I.L.* vi. 1724) upon Flavius Merobaudes, celebrating his merits as warrior and poet. Ten years later, Niebuhr discovered some Latin verses on a palimpsest in the monastery of St. Gall, the authorship of which was traced to Merobaudes, owing to the great similarity of the language in the prose preface to that of the inscription.

His "Panegyric" and minor poems have been edited by B. G. Niebuhr (1824); by I. Bekker in the Bonn *Corpus scriptorum hist. Byz.* (1836); his "De Christo" in T. Birt's *Claudian* (1892), where the authorship of Merobaudes is upheld; *see* also A. Ebert, *Geschichte der Literatur des Mittelalters im Abendlande* (1889).

MEROE, the southern capital of the Ethiopian kings of Napata, 700–300 B.C., becoming eventually the sole capital of the Meroitic kingdom which lasted till about A.D. 350; now an extensive field of ruins, found on the east bank of the Nile near Kabushia railway station in the Egyptian Sudan, lat. 15° 30′ N. The whole site was surveyed by Lepsius in 1844. A quarter of a mile from the river is an enclosure containing royal palaces and other important buildings, reaching back to Aspaluta, *c.* 590 B.C., in the lower levels. Here was found a bronze head of Augustus now in the British Museum, and many remnants of building and sculpture of Netekaman, *c.* A.D. 100, who built a temple of Ammon outside, backed against the east face of the enclosure. Baths were attached to the later palaces. Northwards from the enclosure was a little temple of Isis (*temp.* Akinirar, etc.); eastwards was another, rather earlier, of the lion god Apiremak with stelae down to Taqeriramane, A.D. 250, and a kilometre beyond a larger temple of the sun (?), containing a monument of Aspaluta but mostly built by Teriteqas, Candace and Akinirar, a trio of *c.* 30 B.C. All the above temples face the east; but southwards about 2m. was a shrine facing westwards, with great stelae at the

entrance of Candace and Akinirar containing a reference to Augustus. The nearest necropolis eastwards is Meroitic at the north end, post-Meroitic towards the south end, the latter part with burials on wooden beds and remarkable pottery. Our knowledge up to this point is due to Garstang's excavations, 1909–14; the more distant cemeteries and the pyramids were completely excavated by Reisner in 1921–23. On the hills about 2m. away are two groups of pyramids. In the southern group were buried three kings of the early part of the 3rd century B.C. surrounded by various tombs of the 8th to the 3rd century; the northern group was almost entirely royal with pyramids of 30 later kings and queens, the earliest being that of Ergamenes in the early part of the 3rd century B.C. Westwards of these and about 1m. from the city was a great cemetery of nobles and others of the Ethiopian and Meroitic periods. A fragment of the Greek inscription of a heathen invader from Axum was picked up by Sayce, and an Axumite graffito exists in one of the pyramid shrines.

See J. Garstang, *Meroë* (1911), and *reports* in "Annals of Archaeology and Anthropology," vols. iii.–vii. (Liverpool, 1910–14); G. A. Reisner, *articles* in "Boston Museum of Fine Arts Bulletin" xx., xxi., xxiii., and "The Journal of Egyptian Archaeology," vol. ix.
(F. Ll. G.)

MEROITIC LANGUAGE AND WRITING. The Ethiopian kings of Napata, and afterwards of Meroe, employed the Egyptian language in hieroglyphic writing for their formal inscriptions and presumably for other records; but dating from the first century B.C. to near the end of the third century A.D. there are found in Nubia monumental records, tombstones, funerary altars, and graffiti inscribed in a native language and in a special script which is called Meroitic, since Nubia was then ruled from Meroe. The same writing is found also on potsherds, and the use of it on prepared skins and writing tablets of wood can be certified from small fragments. For the decoration of temples, etc., there were employed the original hieroglyphic (pictorial) forms of the Meroitic writing symbols, but debased hieroglyphic Egyptian was also used for the same purpose.

The symbols of Meroitic writing were modelled on debased Egyptian, but were employed on an entirely different system. Like Egyptian, the Meroitic writing was from right to left; the signs, unlike Egyptian, face backwards. The elaborate Egyptian writing does not express vowels, whereas the simple Meroitic system aimed at recording syllables each consisting of a consonant followed by a vowel. The Meroitic alphabet consisted of seventeen consonantal signs and four rather vague vowel signs together with two syllabics *te* and *tē* or *tō*, making twenty-three characters in all. Besides the alphabet there were special symbols for numerals and perhaps in rare cases resort could be had to special picture signs to symbolize special words. The words were usually separated by double points so that the writing was admirably clear except in regard to the distinction of vowel sounds and the probability that a certain kind of vowel (*a*?) was not marked and had to be surmised from the context.

Meroitic writing was deciphered in 1910 after the discovery of a large number of new inscriptions in Lower Nubia and at Meroe; the language, however, is still almost entirely a sealed book, though names of persons, deities and places, also certain titles borrowed from Egyptian and Meroitic titles which occur in Egyptian demotic, are readily found. It can only be stated as yet that the Meroitic language shows agglutinative formation, absence of gender, and some degree of connection with Nubian.

See F. Ll. Griffith, *Karanòg, The Meroitic Inscriptions of Shablûl and Karanòg* (University of Pennsylvania, Eckley B. Coxe, Jr., Expedition to Nubia, vol. vi., 1911) and articles in *The Journal of Egyptian Archaeology*, vols. iii., iv. and xi. (F. Ll. G.)

MEROPE, name of: (1) The daughter of Cypselus, king of Arcadia, and wife of Cresphontes, ruler of Messenia. Cresphontes and two of his sons were murdered and the throne seized by Polyphontes, who forced Merope to marry him. A third son, Aepytus escaped; he returned later, killed Polyphontes and recovered the kingdom. (Apollodorus ii. 180; Pausanias iv. 3, 6.)

(2) The daughter of Atlas and wife of Sisyphus. She was one of the seven Pleiades, but remained invisible, hiding her light for shame at having become the wife of a mortal (Apollodorus i. 85; iii. 10, 1; Ovid., *Fasti*, iv. 175).

MEROVINGIANS, the name given to the first dynasty which reigned over the kingdom of the Franks. The name is taken from Merovech, an early king of the Salian Franks, who succeeded to Clodio in the middle of the 5th century, and soon became a legendary figure. At the great battle of Mauriac (the Catalaunian fields), in which Aetius checked the invasion of the Huns (451), there were present in the Roman army a number of Frankish *foederati*, and a later authority states that Merovech (Merovaeus) was their leader. Merovech was the father of Childeric I. (457–481), and grandfather of Clovis (481–511). *See* France: *History*.

(Leipzig, 1894); *Urgeschichte der germanischen und romanischen Völker*, iii. (1883); W. Schultze, *Deutsche Geschichte von der Urzeit bis zu den Karolingern*, ii. (Stuttgart, 1896). For the Merovingian legend *see* G. Kurth, *Hist. poét. des Mérovingiens* (1893).

MERRIAM, CLINTON HART (1855–), American biologist, born in New York on Dec. 5, 1855, was educated at Yale and Columbia universities. In 1872 he accompanied the Hayden surveys in Utah, Idaho, Montana and Wyoming as naturalist; in 1875 he was assistant to the U.S. fish commission at Woods Hole, Mass.; in 1876 he collected marine invertebrates in the Bay of Fundy; in 1881 he visited the Bermudas; in 1881 and 1882 he studied the life of the St. Lawrence river; and in 1883 he sailed to the Arctic seal fisheries as surgeon on the ship "Proteus." In 1885 he took charge of the newly-established division of ornithology and mammalogy in the U.S. Department of Agriculture, later called the U.S. biological survey in 1896. He had charge of the Death Valley expedition in 1890–91 and served as Bering sea commissioner to investigate seal fisheries off the Pribilof islands in 1891. In 1910 he became a research associate of the Smithsonian institution and conducted biological and ethnological investigations under the E. H. Harriman trust fund. He was also chairman of the U.S. geographic board, 1917–25. In later years he devoted himself to the distribution, linguistics and mythology of Pacific coast Indians. He first described many genera and species of North American mammals and plants and has published over 400 scientific papers.

Among his books are: *Birds of Connecticut* (1877); *Mammals of the Adirondacks* (1882–84); *Biological Survey of San Francisco Mountain Region and Desert of the Little Colorado, Arizona* (1890); *Biological Reconnaissance of Idaho* (1891); *Geographic Distribution of Life in North America* (1892); *Distribution of Trees and Shrubs in the Deserts and Desert Ranges* (1893); *Laws of Temperate Controls of the Geographic Distribution of Terrestrial Animals and Plants* (1894); *Monographic Revision of the Pocket Gophers* (1895); *Revision of the American Shrews* (1895); *Life Zones and Crop Zones of the United States* (1898); *Biological Survey of Mt. Shasta* (1899); *Indian Population of California* (1905); *Totemism in California* (1908); *The Dawn of the World* (1910); *Review of the Grizzly and Brown Bears of America* (1917); *Baird the Naturalist* (1924); *William Healey Dall* (1927).

MERRIAM, JOHN CAMPBELL (1869–), American palaeontologist, was born in Hopkinton, Ia., on Oct. 20, 1869. Educated at Lenox College, Ia., the university of California, and Munich, he taught palaeontology and historical geology at the University of California. He was chairman of the National Research Council, and has been president of the Carnegie Institution of Washington, Washington, D.C., since 1920. He is the author of the following: *The Thalattosauria, a Group of Marine Reptiles from the Triassic of California* (1905); *Cave Exploration* (1905); *Triassic Ichthyosauria* (with special reference to the American forms, 1908); *The Occurrence of Twisted Horned Antelopes in the Tertiary of Northwestern Nevada* (1909); *The Fauna of Rancho La Brea*, Part 1, *Occurrence* (1911); *Discovery of Human Remains in an Asphalt Deposit at Rancho La Brea* (1914); *Extinct Faunas of the Mojave Desert* (their significance in a study of the origin and evolution of life in America, 1915); *Relationships of Pliocene Mammalian Faunas from the Pacific Coast and Great Basin Provinces of North America* (1917); *The Function of Educational Institutions in Development of Research* (1920); *Earth Sciences as the Background of History* (1920); *Common Aims of Culture and Research in the University* (1922); also numerous other papers.

MERRICK, LEONARD (1864–), English novelist and dramatist, was born on Feb. 21, 1864, in London, the son of William Miller, and was educated at Brighton. He changed his name to Merrick by deed poll. A collected edition of his works was issued in 1918.

His numerous novels include:—*Conrad in Quest of his Youth* (1903); *When Love Flies out of the Window* (1906); *The Quaint Companions* (1903); *The House of Lynch* (1907); *While Paris Laughed* (1918). His plays are *The Free Pardon* (with F. C. Philips); *When the Lamps are Lighted; My Innocent Boy; The Elixir of Youth; A Woman in the Case* (with G. R. Sims).

MERRILL, a city of north-central Wisconsin, U.S.A., on the Wisconsin river, at an altitude of 1,270 ft., 185 m. N.W. of Milwaukee; the county seat of Lincoln county. It is on Federal highway 51 and is served by the Chicago, Milwaukee, St. Paul and Pacific railroad. Pop. (1920) 8,068, and in 1930, 8,458. In the picturesque environs, brook trout and game of various kinds (including deer) still abound. Lumber is the leading industry. Merrill was settled in 1875, incorporated as a village in 1880, and chartered as a city in 1883.

MERRIMAC, a river of the United States, rising in the White Mountains of New Hampshire, and flowing through Massachusetts into the Atlantic ocean. With its largest branch it has an extreme length of about 183m. and drains a region 4,553 sq.m. in extent. The Merrimac proper is formed at Franklin (N.H.), by the junction of the Pemigewasset and Winnepesaukee rivers. The river falls 269ft. in 110m. from Franklin, yielding water-power to Lowell and Lawrence in Massachusetts, and Manchester and Concord in New Hampshire. For 17½ miles (including Newburyport and Haverhill) the river is navigable.

MERRIMAN, HENRY SETON (d. 1903), the pen-name of Hugh Stowell Scott, English novelist. He was a member of the firm of Henry Scott and Sons, and was for some years an underwriter at Lloyd's. His literary career began in 1889 with *The Phantom Future,* and he made his first decided hit with his Russian story, *The Sowers* (1896), which was followed by many other well-constructed novels. He was an enthusiastic traveller, many of his journeys being undertaken with his friend Stanley Weyman. He was about 40 when he died near Ipswich, on Nov. 19, 1903.

Among his most successful books were *Roden's Corner* (1898); *The Isle of Unrest* (1899); *In Kedar's Tents* (1897); *The Velvet Glove* (1901); *The Vultures* (1902); *Barlasch of the Guard* (1903); and *The Last Hope* (1904).

MERRIMAN, JOHN XAVIER (1841–1926), South African statesman, was born on March 15, 1841 at Street, Somerset, England, the son of a clergyman who afterwards became bishop of Grahamstown, South Africa. His family moved to South Africa in 1849, and he was educated at the Diocesan College, Rondebosch, and later at Radley College, England, returning to the Cape in 1861. He entered politics in 1869. In 1875 he joined the Molteno Ministry as commissioner of public works, and was virtually Secretary for War during the Galeka war of 1877. In the Scanlen Ministry (1881–4) he was commissioner of public works. The Afrikander Bond caused the fall of the Scanlen administration because the Ministry opposed the attempt of the Transvaal Boers to seize Bechuanaland; and when Rhodes formed a Ministry in 1890 Merriman, alienated by the extreme policy of the Bond, joined it as treasurer-general. Meanwhile the Bond had adopted a constitutional programme, and 1890 saw a drawing together of the Dutch and British elements at the Cape. But the Uitlander troubles in the Transvaal became acute, and in 1893 Merriman resigned. He was chairman of the Cape parliamentary committee which inquired into the Jameson raid of 1895, and drew up its report. The general election in Cape Colony in 1898 gave the Bond a very narrow victory, and W. P. Schreiner became Prime Minister, with Merriman treasurer-general again, though he was not a member of the Bond. Merriman was among the ministers who in 1900 opposed the measure to disfranchise the Cape rebels, causing the cabinet to resign. At the general election of 1904 Merriman was defeated, but was returned shortly afterwards at a by-election. In Jan. 1908 he succeeded Dr. Jameson as Prime Minister and treasurer-general (*see* SOUTH AFRICA: *History*). Merriman was now head of the Afrikander Bond party, renamed the South African party. He was a member of the national convention which hammered out the new constitution. He supported the unitary as against the federal principle in South African policy. It was expected in some quarters that Merriman would be the first prime minister of the Union. The position fell to Botha. Merriman remained outside the ministry, though he gave the government steady support. He opposed the disruptive policy of Hertzog as strongly as he had formerly supported the independence of the Boer republics. He died Aug. 2, 1926.

MERRITT, WESLEY (1836–1910), American soldier, was born in New York city on June 16, 1836, graduating at West Point. He won distinction in the Virginian campaigns of 1864–65 and in Sheridan's Shenandoah valley campaign, and in 1895, he became major-general. He was superintendent at West Point (1882–87), and commanded the military department of Missouri (1887–95) and that of the Atlantic (1897–98). In May 1898 he commanded the U.S. forces sent to the Philippines after Admiral Dewey's victory; stormed Manila on Aug. 13, and was military governor of the islands until Aug. 30. At Paris, he was on the peace commission. He died at Natural Bridge (Va.) on Dec. 3, 1910.

MERRY DEL VAL, RAPHAEL (1865–1930), Spanish ecclesiastic and diplomat, was born on Oct. 10, 1865 in London, where his father was secretary to the Spanish legation. Educated at Baylis House, near Slough, and at Ushaw college, near Durham he took up diplomacy at the Vatican and in 1892 became Master of the Robes and acting private chamberlain to Pope Leo XIII., of whom he was a great favourite. In 1897 he was sent to Canada to report on the difficult Manitoba schools question, and in 1900 he became archbishop of Nicea. He was secretary of the Sacred College of Cardinals during the election of Pius X. (July 1903) under whom he became cardinal and secretary of state. On Jan. 12, 1913 he succeeded Cardinal Rampolla as archpriest of the Vatican Basilica; in the following October he was appointed secretary of the Holy Office, and in Dec. 1920 he became camarlengo of the Holy Roman Church. Cardinal Merry del Val died in Vatican City on Feb. 26, 1930.

MERSEBURG, in Saxony, on the river Saale. Pop. (1925) 25,703. From 968 until the Reformation, it was the seat of a bishop, also the residence of the margraves of Meissen, and a favourite residence of the German kings. Fifteen diets were held here, when its fairs enjoyed an importance anticipating Leipzig. From 1657 to 1738 it was the residence of the dukes of Saxe-Merseburg. It consists of an irregularly built old town, a new quarter and two suburbs, Altenburg and Neumarkt. The cathedral, restored in 1884–86, has a choir, a crypt and two towers of the 11th, a transept of the 13th and a late Gothic nave of the 16th century. It contains a great organ dating from the 17th century. The Gothic palace, formerly the residence of the bishops of Merseburg, is now used as public offices. The industries include machinery and paper, metal founding, tanning and brewing.

MERSEN (MEERSSEN), **TREATY OF,** concluded on Aug. 8, 870 at Mersen, in Holland, between Charles the Bald and his half-brother, Louis the German, by which the kingdom of their nephew, Lothair II. (d. 869) was divided between them. Charles received a portion of the kingdom of Lothair, afterwards called Lorraine, extending from the mouths of the Rhine to Toul, together with the town of Besançon, the Lyonnais, the Viennais, the Vivarais and the Uzège, while Louis had the cities of Cologne, Trier and Metz, together with Alsace, the Escuens and the Varais, *i.e.*, the greater part of the diocese of Besançon. The boundary between the two realms was marked approximately by the valleys of the Meuse and Moselle and by the Jura.

MERSENNE, MARIN (1588–1648), mathematician, was born of peasant parents near Oizé (Sarthe) on Sept. 8, 1588, and died in Paris on Sept. 1, 1648. He was educated at the Jesuit college of La Flèche, where he was a fellow-pupil of Descartes. In 1611 he joined the Minim Friars, and in 1620 he settled in Paris at the convent of L'Annonciade. In 1623 he published *Quaestiones celeberrimae in Genesim; L'Impiété des déistes* (1624); *La Vérité des sciences* (1624). Submitting Descartes' *Meditations* to John

Locke (*q.v.*), he defended him with enthusiasm against clerical critics. In later life he turned to scientific research, especially in mathematics, physics and astronomy. His *Harmonie universelle* (1636) deals with the theory of music and musical instruments.

See Hilarion de Coste, *La vie du rév. père Marin Mersenne* (1649); new ed. with unpublished letters, by B. T. de Larroque (1892); M. Frischeisen-Köhler in *Arch. für Gesch. der Philos.*, vol. xv. (1902).

MERSEY, JOHN CHARLES BIGHAM, 1ST VISCOUNT (1840–1929), was born on Aug. 3, 1840, and educated at the Liverpool institute, and in Berlin and Paris. He was called to the bar in 1870, and became Q.C. in 1883. In 1895 he was elected Unionist M.P. for a division of Liverpool, and kept his seat until 1897, serving on the South African committee of the House of Commons in 1896–97. In 1897 he was made judge of the king's bench division of the High Court of Justice and in 1909–10 was president of the probate divorce and admiralty division. He served on several Government commissions and from 1904 to 1910 was chief judge in bankruptcy. He was made a privy councillor in 1909, received a barony in 1910, and a viscountcy in 1916. He died in Sussex on Sept. 3, 1929.

MERSEY, a river in Cheshire, England, 70 miles long, formed by the Goyt which rises in Axe Edge, south-west of Buxton, and the Etherow between Penistone and Glossop, watering the narrow Longdendale in which are reservoirs for Manchester. The Mersey drains a large part of the Peak district of Derbyshire. At Stockport the river Tame joins from the north. The Bollin joins from the south-east near Heatley, and the main river expands into an estuary which narrows to less than ¾ m. at Liverpool and forms an important harbour. (*See* LIVERPOOL and BIRKENHEAD.) The Manchester Ship canal (*q.v.*) joins the estuary through Eastham locks, skirts its southern shore up to Runcorn, and crosses the river several times.

MERSINA, a seaport of Asia Minor, and in the vilayet of Adana. Pop. (1927) 46,831. Its existence began with the silting up of Tarsus and Pompeiopolis, east and west, in the early middle ages; but it grew with the Egyptian occupation of Cilicia (1832). It is the busiest port on the south coast, being the terminus of the railway from Adana and Tarsus, by which (but still more by road) the produce of the rich "Aleian" plain comes down. The anchorage is good, but the bay shoals for a long way out, and is exposed to swell from south-west and south. The low coastal section has a bad summer climate.

MERSWIN, RULMAN (1307–1382), German mystic, was born at Strasbourg in 1307, and became a banker. At the age of 40, he came into touch with Tauler and the group of 14th century mystics known as the Friends of God. In Merswin's *Story of the First Four Years of a New Life*, he writes: "Of all the wonderful works which God had wrought in me I was not allowed to tell a single word to anybody until the time when it should please God to reveal to a man in the Oberland to come to me. When he came to me God gave me the power to tell him everything." Merswin claimed that certain books were written by this "Friend of God," who has been identified with various people by different scholars, and that other books were written by himself. As all the writings bear the marks of a single authorship it has been assumed, especially by Denifle, that "the Friend of God" is a literary creation of Merswin just as William Langland in England about the same time drew the figure of Piers Plowman.

Karl Rieder (*Der Gottesfreund von Oberland,* Innsbruck, 1905) attributes the authorship to Merswin's secretary and associate Nicholas of Löwen, head of the House of St. John at Grünenwörth.

See besides the works cited Karl Schmidt, *Nicolaus von Basel* (Vienna, 1866); Denifle, *Der Gottesfreund im Oberland und Nikolaus von Basel* (1870); Rufus M. Jones, *Studies in Mystical Religion,* ch. xiii. (1909).

MERTENSIA, a genus of perennial herbs of the family Boraginaceae (*q.v.*) comprising about 40 species found in cool regions of the northern hemisphere and especially abundant in western North America. Many are very smooth plants, of pleasing habit, with brightly coloured usually blue or white flowers. Well known representatives are the sea lungwort and the Virginia cowslip (*q.v.*), which is not to be confused with the yellow cowslip of Europe.

MERTHYR TYDFIL or **MERTHYR TYDVIL,** municipal, county and parliamentary borough, of Glamorganshire, S. Wales, situated on the river Taff and the Glamorganshire Canal, and served by the G.W.R. and L.M.S.R., 2 m. N.W. of Cardiff. Pop. (1931) 71,099. It is said to have derived its name from the martyrdom of St. Tydfil, daughter of Brychan, put to death by Saxons in the 5th century. Three miles to the north on a limestone rock rising 470 ft. are the ruins of Morlais Castle, built about 1286 by Gilbert de Clare on the northern limits of his lordship of Glamorgan. The town is irregularly built and owed its early industrial prosperity to the abundant ironstone of the district. Four great iron works were established here between 1759 and 1782. With the earliest, that of Dowlais, the Guest family were associated. In 1765, Cyfarthfa was started by Anthony Bacon and sold in 1794 to Richard Crawshay. The Plymouth works were started soon after Cyfarthfa, by Wilkinson and Guest. They were closed down in 1882, but the collieries belonging to them continued to be worked. The fourth great ironworks were those of Pen-y-darran which were carried on from 1782 to 1859. It was at Dowlais (in 1856) that Bessemer steel was first rolled into rails, but the use of puddled iron was not wholly abandoned at the works till 1882. The use of the local coal for smelting gave a great impetus to the iron industry. The Dowlais Company work collieries and have since 1891 a branch steel and iron works on the coast near Cardiff. Industrial depression after the World War seriously affected the coal, iron and steel trades. Cyfarthfa was converted into steel works in 1883. The iron ore used latterly has been mainly imported from Spain. Merthyr Vale is mainly dependent on coal-mining. In 1850, the town had a local board of health; in 1894, an urban district council; in 1905, a corporation; in 1898, a county borough. In 1832, it was given one member and a second in 1867.

MERV, MERU or **MAUR,** an ancient and once famous oasis and town of Asiatic Russia in the Turkmen S.S.R. The oasis has an area of 134,400 sq.km., and a population (1926) of 253,049, mainly Turkmens of the Tekke tribe. The great chain of mountains which, under the names of Paropamisus and Hindu-Kush, extends from the Caspian to the Pamirs, is interrupted some 180 m. S. of Merv. Through or near this gap flow northwards in parallel courses the rivers Heri-rud (Tejend) and Murghab, until they lose themselves in the desert of Kara-kum, and the loess oasis of Merv depends on irrigation from the Murghab for its life. In 1895 the Russians completed further irrigation works bringing 436 sq.m. under cultivation, and in 1927 the Soviet Government began the construction of an electric power station. Cereals, cotton, fruits and vine are cultivated; cotton production is markedly increasing to supply the textile industry of European Russia. The railway from Krasnovodsk on the Caspian, linking with the Orenburg-Tashkent lines, passes through the town of Merv, from which there is a branch line southwards to Russia. The town of Merv, population (1926) 19,099, has cotton and wool cleaning factories, a flour-milling and brewing industry. The horses are famous throughout central Asia.

After the 1917 revolution, a period of disorder set in which markedly diminished cultivation and stock-raising, and resulted in the disorganization of the irrigation system. In 1926 new laws regulating the distribution of water were enforced, extensive repairs were carried out, and production has now almost reached the 1913 level, while as regards cotton production, it has markedly surpassed it. Native crafts include silver work, the making of armour, carpet weaving and the making of felt and woollen goods. Summer heat is oppressive, 97° F, and the least wind raises clouds of dust which darken the air and make respiration difficult. In winter the temperature is 19° F, but snow rarely falls and never lies; the rainfall is about 5 in. per annum, June to October being usually rainless months.

History.—In the Hindu (the *Puranas*), Parsi, and Arab tradition Merv is looked upon as the ancient Paradise, the cradle of the Aryan families of mankind, and so of the human race. Under the name of Mouru this place is mentioned with Bakhdi (Balkh) in the geography of the *Zend-Avesta* (*Vendidad,* ed.

Spiegel, 1852–63), which dates probably from at least 1200 B.C. Under the name of Margu it occurs in the cuneiform (Behistun) inscriptions of the Persian monarch Darius Hystaspis, where it is referred to as forming part of one of the satrapies of the ancient Persian empire. It afterwards became a province (Margiana) of the Graeco-Syrian, Parthian, and Persian kingdoms. On the Margus—the Epardus of Arrian and now the Murghab—stood the capital of the district, Antiochia Margiana, so called after Antiochus Soter, who rebuilt the city founded by Alexander the Great.

About the 5th century, during the rule of the Persian Sassanian dynasty, Merv was the seat of a Christian archbishopric of the Nestorian Church. The town was occupied (A.D. 646) by the lieutenants of the caliph Othman, and was constituted the capital of Khorasan. From this city as their base the Arabs, under Kotaiba (Qotaiba) ibn Moslim, early in the 8th century brought under subjection Balkh, Bokhara, Ferghana, and Kashgaria, and penetrated into China as far as the province of Kan-suh. In the latter part of the 8th century Merv became obnoxious to Islam as the centre of heretical propaganda preached by Mokanna (*q.v.*). In 874 Arab rule in Central Asia came to an end. During their dominion Merv, like Samarkand and Bokhara, was one of the great schools of learning, and the celebrated historian Yaqut studied in its libraries. In 1040 the Seljuk Turks crossed the Oxus from the north, and having defeated Masud, sultan of Ghazni, raised Toghrul Beg, grandson of Seljuk, to the throne of Persia, founding the Seljukian dynasty, with its capital at Nishapur. A younger brother of Toghrul, Daud, took possession of Merv and Herat (*q.v.*). Toghrul was succeeded by his nephew Alp Arslan (the Great Lion), who was buried at Merv. It was about that time that Merv reached the zenith of her glory. During the reign of Sultan Sanjar or Sinjar of the same house, in the middle of the 11th century, Merv was overrun by the Turkish tribes of the Ghuzz from beyond the Oxus. It eventually passed under the sway of the rulers of Khwarizm (Khiva).

Merv was conquered in 1221 by Tule (*see* MONGOLS), most of the inhabitants were massacred, and from that time the city began to decay. It was the seat of a Christian Archbishopric in the early 14th century and in 1380 was included in the possessions of Timur (*q.v.*). In 1505 the city was invested by the Usbegs, who were expelled (1510) by Ismail Khan of Persia. It remained in Persian hands until 1787 when the Emir of Bokhara captured it. In 1794 the Bokharians burned it to the ground and made the whole district a waste. When Sir Alexander Burnes traversed the country in 1832, the Khivans were the rulers of Merv. About this time the Tekke Turkomans, then living on the Heri-rud, were forced by the Persians to migrate northward. The Khivans contested the advance of the Tekkes, but ultimately, about 1856, the latter became the sovereign power in the country, and remained so until the Russians occupied the oasis in 1883.

NEW MERV, the present chief town of the oasis, founded in the first quarter of the 19th century, is on the Transcaspian railway, 380m. by rail south-west from Samarkand. It stands on both banks of the Murghab, 820ft. above the Caspian. In 1926 the population was about 12,000, including Russians, Armenians, Turkomans, Persians, and Jews. It has a meteorological observatory. Corn, raw cotton, hides, wool, nuts, and dried fruit are exported.

See C. Marvin, *Merv* (1880); E. O'Donovan, *The Merv Oasis* (1882); and H. Lansdell, *The Russians at Merv and Herat* (1883). (*See* TURKESTAN.)

MERX, ADALBERT (1838–1909), German theologian and orientalist, was born at Bleicherode, Prussian Saxony, on Nov. 2, 1838, and became (1875) professor of theology of Heidelberg. He elucidated the Sinaitic palimpsest discovered in 1892 by Mrs. Agnes Smith Lewis (*see* BIBLE), the results being embodied in *Die vier kanonischen Evangelien nach ihrem ältesten bekannten Texte* (1897–1905). He died at Heidelberg on Aug. 6, 1909.

MÉRYON, CHARLES (1821–1868), French etcher, was born in Paris on Nov. 24, 1821. His father was an English physician, his mother a French dancer. Méryon's childhood was spent with his mother, but she died when he was still young, and he entered the French navy, and in the corvette "Le Rhin" made the voyage round the world. He was already a draughtsman, for on the coast of New Zealand he made pencil drawings which he was able to employ, years afterwards, as studies for etchings of the landscape of those regions. Méryon left the navy as a lieutenant. Finding that he was colour-blind, he determined to devote himself to etching. He entered the work studio of one Bléry, from whom he learnt something of technical matters, and to whom he always remained grateful. Méryon was by this time poor. It is understood that he might have had assistance from his kindred, but he was too proud to ask it, and had to earn his living by irksome mechanical work. For the sake of practice he made some studies after the Dutch etchers, such as Zeeman and Adrian van de Velde. He then began the series of etchings called "Eaux-fortes sur Paris." These plates, executed from 1850 to 1854, are never to be met with as a set; neither were they published as such; but to Méryon they constituted a series.

Besides these twenty-two etchings "sur Paris," Méryon did seventy-two others, all of them being catalogued in Wedmore's *Méryon and Méryon's Paris*. This list includes, however, the works of his apprenticeship and of his decline, adroit copies and more or less dull portraits. Among the dozen outside his professed series which are worthy of special mention are three or four beautiful etchings of Paris and two or three of Bourges. Although a master of his craft, he was appreciated only by a few artists, critics and connoisseurs, and when he sold his etchings, it was for a few pence only. Disappointment told upon him, and, frugal as was his way of life, his poverty must have depressed him. He became subject to hallucinations, and a few years after the completion of his Paris series he was lodged in the madhouse of Charenton. A partial cure was effected, but in 1867 he returned to the asylum, where he died in 1868.

Of the twenty-two pieces in the *Eaux-fortes sur Paris*, ten were destined as headpiece, tailpiece, or running commentary on some more important plate. But each has its value, and certain of the smaller pieces throw great light on the aim of the entire set. Thus, one little plate—not a picture at all—consists of verses by Méryon describing the darker side of Paris life. His etchings are spoken of as views of Paris but they are likewise the visions of a poet and the compositions of an artist who had set himself to create an epic of the city. The Abside de Notre Dame, a general favourite, is commonly held to be Méryon's masterpiece. Light and shade play wonderfully over the great fabric of the church, as seen over the spaces of the river. Méryon was at home with every style of architecture, and in this respect it is interesting to contrast him with Turner, who, in drawing Gothic, often drew it with want of appreciation. It is evident that architecture must enter largely into any representation of a city, however much such representation may be a vision and not merely a chronicle. Generally speaking, Méryon's figures are those of a landscape painter; but sometimes, as in the case of *La Morgue*, it is they who tell the story of the picture, or, in the case of *La Rue des Mauvais Garçons*, with the two passing women conversing secretly, at least suggest it. In *L'Arche du Pont Notre Dame*, again, it is the figures which give vitality and animation to the scene.

Méryon was little called upon by the character of his subjects to deal with Nature. He drew trees and foliage badly, both in detail and in mass. But it was necessary that he should know how to portray a certain kind of water—river-water, mostly sluggish—and a certain kind of sky—the grey, obscured and lowering sky that broods over a world of roof and chimney. Of such water and such skies Méryon was past master.

Sir Seymour Haden has called Méryon a great original engraver rather than an etcher, and certainly he does not display those virtues of the etcher defined by Hamerton—"selection" and "abstraction." But he was an excellent draughtsman.

MESA, in geomorphology, a high table-land capped with harder rock, being the remnant of a plateau (Span. *mesa*, from Lat. *mensa*, a table), built up of horizontal or very gently inclined strata. During denudation the hard rock acts as a flat protective cap for those portions situated between places, such as stream valleys, where erosion is especially active. This results in land-forms resembling "table-mountains" or "fortress-hills." Many examples are found in the Colorado regions of North America. The term "butte" is generally employed for a "mesa" of small extent. (*See* also Marsh.)

MESATICEPHALIC or **MESOCEPHALIC,** a term applied by anthropologists to those skulls which exhibit a cephalic index intermediate between the dolichocephalic and brachycephalic crania (*see* Craniometry). Taking the longer diameter of a skull, *i.e.*, from front to back, as 100, mesocephalic skulls are those of which the transverse diameter varies between 75 to 80.

MESDAG, HENDRIK WILLEM (1831–1915), Dutch marine painter, was born at Groningen on Feb. 23, 1831. He entered the family banking firm of Mesdag, but about 1866, owing to the influence of Josef Israels, took up the study of art. His sea pieces became famous and earned him the gold medal of the Paris Salon, among them being "Effet du soir à Scheveningen" (1872); "Apres l'Orage" (1895); "Rentrée des bateaux de pêche" (1900) and "Une Soirée sur la plage de Scheveningen" (1911). He presented his fine collection of pictures and *objets d'art* to the nation, and they are housed in the Mesdag museum at The Hague. He died at The Hague on July 7, 1915.

MESEMBRIA, a town of Bulgaria, situated on a narrow promontory in the Black sea, connected by a causeway with the land, 20 m. N. of Burgas (*q.v.*). Coasting steamers from Varna and Burgas touch here, and there is a motor-bus service by land to Anhialo. Mesembria was founded as a colony of Megara in the 7th century B.C., and remained Greek ever after till 1925, when it was settled with Bulgarians under the exchange of populations. In the early middle ages it was very rich, and frequently visited by the Byzantine emperors, and the remains of over 40 Byzantine churches can be traced in its small area, showing examples of every style of Bulgarian ecclesiastical architecture. A few of these (St. John of the Sea, the new cathedral, St. John) are still in fair repair. The whole forms a collection of unique interest. Fine works of Greek art have been discovered here.

MESHCHERYAKS or Meshchers, a people inhabiting eastern Russia. Some of the Mordvinians (of Finnish origin) call themselves Meshchers. The town Meshchersk, now Meshchovsk, has maintained their name. After the conquest of the Kazan empire by Russia, part of them migrated north-eastwards. The western branch became Russified, and the eastern branch has fused with the Bashkirs.

MESHED (properly *Mash-had*, the place of martyrdom), capital of Khurasan in Persia, is situated at an elevation of 3,197 ft., in the valley of the Ab-i-Meshed or Kashaf Rud, a tributary of the Hari Rud. The town, in 37° 16′ N., 59° 36′ E. is 460 m. crowfly from Tehran (566 m. by road), 200 m. from Herat, and 472 m. by road from Duzdab near the frontier of India. The population is estimated at 60,000–80,000 of which about 10,000 are pilgrims. Meshed Jews number about 4,000 and inhabit a quarter near one of the gates. The climate is fairly healthy with an average maximum temperature of 90·9° Fahr. in July and minimum of 22·3° in January. The average rainfall over a period of 17 years was 9·37 inches. The town, irregular of shape, is about 6 m. in circumference and surrounded by a mud wall with towers. In the north-west stands the Ark, or citadel, which serves also as the residence of the Governor, and in front of this is the *maidan*, an open square about ¼ m. in extent. There are unusually large numbers of caravanserais. The city has five gates from one of which, the Bala Khiaban gate, the main street forms a fine avenue planted with plane and mulberry trees and having a stream running down the centre. Meshed has grown up around the tomb of the Imam Riza and has supplanted Tus, the ancient capital, now in ruins, about 15 m. to the north-west. It is visited annually by some 100,000 pilgrims. Riza (770–819) was the eighth of the twelve Imams in line of succession after Mohammed's cousin and son-in-law Ali, whose particular followers—as Shiahs—the Persians are. To the Shiahs, Imam Riza is a martyr, being believed to have been poisoned by the Caliph Mamun. The buildings of the shrine—"the Glory of the Shiah World"—together with a space extending to about one hundred yards beyond the gates of the shrine on each side, is *bast, i.e.*, sanctuary.

Meshed is very important politically as well as commercially and the British and Russian Governments maintain consulates-general there. The transit trade of Meshed to Central Asia is not so great as before the construction of the Trans-Caspian railway. It is the centre of the northern wool trade and of an important rug industry. It is a nucleus of trunk roads, being joined with Tehran (566 m.) by a partly metalled road passable for carts at all times and by light motors in summer. It is joined also with Ashgabad on the Trans-Caspian railway by a good carriage road; and southward there is at Duzdab (600 m.) the road to railhead of the Indian system, which was made passable by motor cars during the World War. The total value of the trade passing through Meshed in 1925–6 was 38,339,080 krans (£ St.=45 krans) exports about balancing imports. The chief items of export were carpets (5,669,-965 krans), hides and skins (5,550,213 krans), opium (4,351,600 krans), timber, and cotton tissues; the imports were sugar, skins and hides, cotton stuffs, carpets, minerals and metals.

(P. Z. C.)

MESHREBIYA (drinking places), the Arabic term given to projecting oriel windows enclosed with lattice-work, so-called from the small semicircular bows, in which porous water-bottles are placed to cool.

MESMER, FRIEDRICH (or Franz) **ANTON** (1733–1815), Austrian doctor, from whose name the word "Mesmerism" was coined (*see* Hypnotism), was born at Weil, near Constance, on May 23, 1733. He studied medicine at Vienna. Interested in astrology, he imagined that the stars exerted an influence on beings living on the earth. He identified the supposed force first with electricity, and then with magnetism; and it was but a short step to suppose that stroking diseased bodies with magnets might effect a cure. He published his first work (*De planetarum influxu*) in 1766. Ten years later, on meeting with J. J. Gassner in Switzerland, he observed that the priest effected cures by manipulation alone. This led Mesmer to discard the magnets, and to suppose that some kind of occult force resided in himself by which he could influence others. He held that this force permeated the universe, and more especially affected the nervous systems of men. He began to hold séances in Vienna, but the police interfered and ordered him to leave the city within 48 hours. He then went to Spa. He removed to Paris in 1778, and in a short time Mesmer's consultations became the fashion. The medical faculty of Paris stigmatized him as a charlatan; still the people crowded to him. The government appointed a commission of physicians and members of the academy of sciences to investigate the phenomena observed in the séances. Franklin and Baillie were members of this commission, and drew up an elaborate report admitting many of the facts, but contesting Mesmer's theory that there was an agent called animal magnetism, and attributing the effects to physiological causes. Mesmer himself was undoubtedly a mystic; and, although the excitement of the time led him to indulge in mummery, he was honest in his beliefs. However he was

denounced as an imposter. He left Paris and died at Meersburg in Switzerland on March 5, 1815. The most distinguished of his disciples was the marquis de Puységur.

MESNE, middle or intermediate, an adjective used in several legal phrases. A mesne lord is one who has tenants holding under him, while himself holding of a superior lord. Mesne process was such process as intervened between the beginning and end of a suit (*see* PROCESS). Mesne profits are profits derived from land whilst in wrongful possession, and may be claimed in damages for trespass in a separate action or joined with an action for the recovery of the land. The plaintiff must prove that he is entitled to re-enter into possession, his title during the period for which he claims, the fact that the defendant has been in possession during that period, and the amount of the mesne profits. The amount recovered as mesne profits need not be limited to the rental value of the land but may cover deterioration or reasonable costs of getting possession, etc.

MESOLITHIC: *see* ARCHAEOLOGY: *Iron Age.*

MESOMEDES of Crete, Greek lyric poet, who lived during the 2nd century A.D. He was a freedman of the emperor Hadrian, on whose favourite Antinous he is said to have written a panegyric. Two epigrams by him in the Greek anthology (*Anthol. pal.* xiv., xvi.) and a hymn to Nemesis are extant. The hymn is of special interest as preserving the ancient musical notation written over the text. Two other hymns—to the muse Calliope and to the sun—formerly assigned to Dionysius of Alexandria, have also been attributed to him.

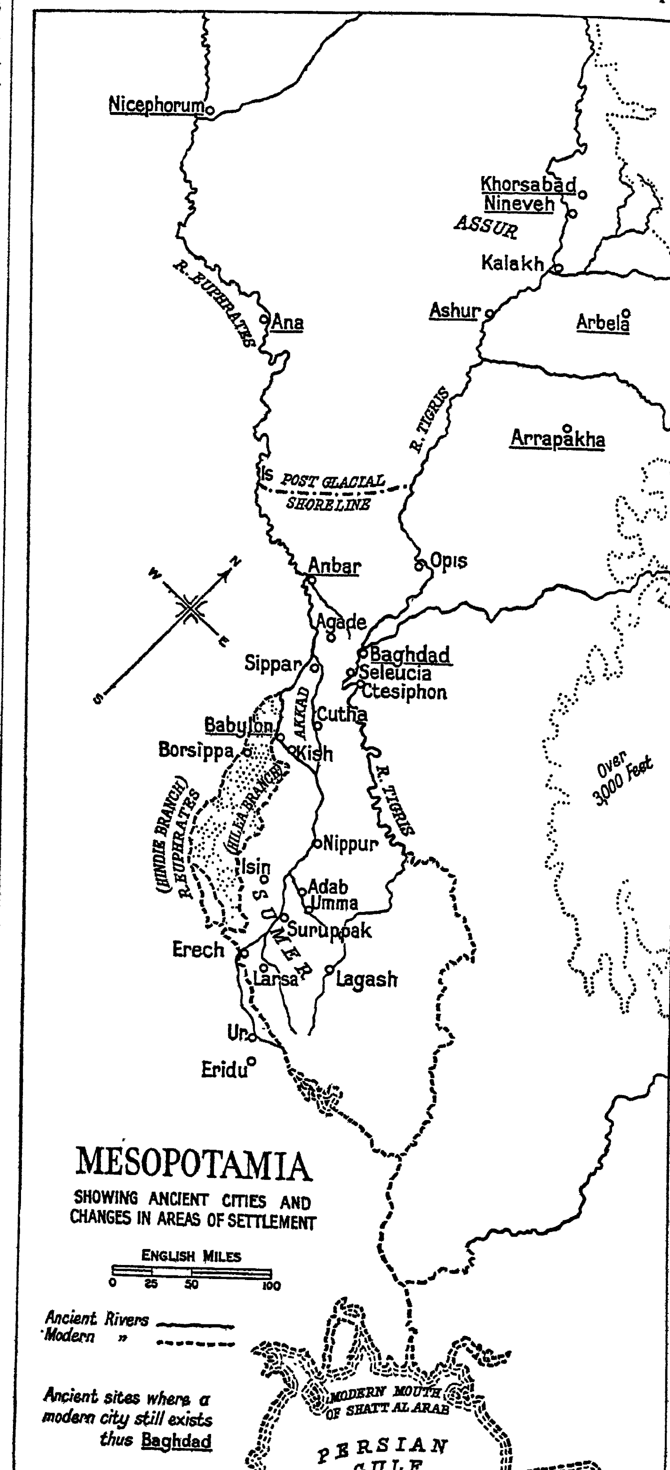
See J. F. Bellermann, *Die Hymnen des Dionysius und Mesomedes* (1840); C. de Jan, *Musici scriptores graeci* (1899); S. Reinach in *Revue des études grecques,* ix. (1896); Suidas, *s.v.*

MESONERO ROMANOS, RAMÓN DE (1803–1882), Spanish prose-writer, who was born in Madrid and died there, wrote the *Panorama matritense* (1835–36), a collection of interesting pen-pictures of old-time Madrid, and an autobiography, *Memorias de un setentón, natural y vecino de Madrid* (1880).

MESOPOTAMIA. Although the boundaries of the modern kingdom of 'Iraq, which occupies the land of ancient Mesopotamia, have recently been clearly defined the term Mesopotamia has been loosely used. In this article the area included is the great depression shut in between the escarpment of the Arabian desert and the mountains, which form the western boundary of the plateau of Iran on the west and east respectively, and bounded on the north by the mountains of Armenia and Asia Minor, and on the south by the Persian gulf. In the north there is a belt of stony country varying between 40 and 100 miles broad which extends as far as Hit, which stands on the site of the old coast line before the formation of the alluvial plain of the twin rivers, the Tigris and the Euphrates. This alluvial plain extends southwards, falling nearly 100 feet between Baghdad and Basra, and forms the fertile basin in which grew up the ancient civilizations of Sumer and Akkad. The plain is everywhere extremely flat and has a transverse slope away from the rivers and from the Persian hills to the Tigris. This flatness and the form of the slope combined to allow perennial irrigation on a large scale and so made the ancient civilizations possible. The alluvial plain itself is of comparatively small extent, about 35 thousand square miles, rather over a sixth of the whole area of Mesopotamia.

Geology.—South of the Eurasiatic massif there are three great plateaux, the remains of a tropical continent. Between these plateaux, India, Arabia and Africa south of the Atlas there are a series of basins, Mesopotamia itself forming the basin between the plateau of Arabia and the fold mountains of Persia. The latter parallel ranges, which bound it on the east are of many different ages. The south-western boundary is the Archaean rocks of the Arabian plateau. This contrast between the eastern and western boundaries is enhanced by the difference of climates. The rainfall of the Persian mountains has been accompanied by rapid rock decay and numerous canyons have carried down to the plain a rich and fertile alluvium, but the valley bottom lacking the rainfall of the Indo-Gangetic plain, to which it corresponds physiographically, has not been able to support the dense population of the latter area. On the west the plateau is arid, streams are few, and the denudation has been of the desert type, contributing but little to the plain.

The history of this condition seems to be as follows. The earliest direct information on the geological history of upper Mesopotamia is found at Ana on the Euphrates where upper



MESOPOTAMIA
SHOWING ANCIENT CITIES AND CHANGES IN AREAS OF SETTLEMENT

Cretaceous limestones were formed at a time when upper Mesopotamia was all submerged. A volcanic period in Oman seems to have occurred at the beginning of Cenozoic times, when most of Arabia and Persia were dry land, and coal seams were forming in Mesopotamia. The lower Eocene sea covered parts of the Persian gulf, and during the middle Eocene there was another advance of the sea. At this time there was a deposition of a nummulitic limestone, which is succeeded in upper Mesopotamia by beds which contain fish teeth and marine shells of the Upper

Eocene. This period is not widely developed, and in the succeeding Oligocene there was a land period of which at present only a few fossil remains have been discovered. During the Miocene the sea extended from northwest India to Asia Minor. A further advance appears to have followed which resulted in the deposition of red clays, which are interbedded with rocksalt, oil beds and gypsum. The deposition of these beds was interrupted by an uplift which eventually converted the whole area into a continuous land surface. This uplift was associated with foldings of the greatest significance. Previous foldings had already built the ranges of northern Persia and to a certain extent the Zagros range, but the main folding, which built up the mountain boundary to the northeast of Mesopotamia is probably Pliocene.

As a result of this folding a weak belt was formed along the outer edge of the folded zone. This belt formed the Mesopotamian depression. It has been estimated that the displacement on the Persian side was as much as 9,000 feet, due to the combination of faulting and monoclinal folding. On the west the displacement due to simple faulting alone was slight.

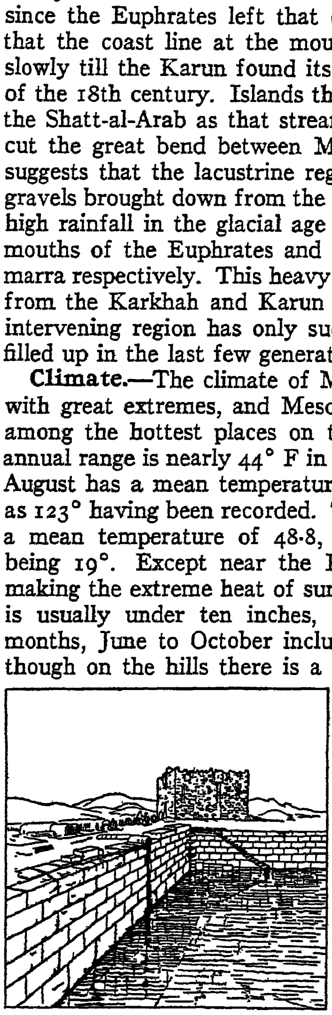
Upper Mesopotamia (Jezirah) contrasts strongly in formation with the lower alluvial valley. The mountain border of the Jezirah begins with the gently folded beds of sandstones, gypsum and conglomerates of Jebel Hamr. There are hills of a similar composition near Mosul on the southwest bank of the Tigris. At this point the river flows along the fault plane between lower Miocene on the southwest and Pliocene Conglomerate on the northwest. Farther to the northwest the range of hills is capped by basalt. Its continuation Jebel Sinjar also consists of basalt, overlying Miocene rocks, and the basalts have further a wide extension along the Tigris to the northeast of the Sinjar hills. Further to the west lies the Jebel Abd al-Aziz and still further north of a line drawn from Mardin to Urfah the land rises into the foothills of the Taurus which is composed chiefly of Cretaceous, Eocene and Miocene beds, although there are some basaltic lavas from the old volcano Qara Dagh. In the northwesterly corner of the Mesopotamian depression between Diarbekr and Mardin gault ammonites have been found but most of the country near Diarbekr consists of volcanic rocks through which the Tigris has cut a 300-ft. canyon. The Cretaceous beds to the northwest of Ana are Senonian but below this town they are partly Turonian. Above this belt of Cretaceous rocks along the great western bend of the Euphrates past Birijik and near Samsat there are Miocene beds. To the north they are succeeded by volcanic rocks, through which on both sides of the Taurus the Euphrates has cut a magnificent gorge.

Although lower Mesopotamia consists mainly of alluvium there are extensive outcrops of older formations. There are conglomerates at Beled on the Tigris, 84 miles from Baghdad by river, and a few miles above Beled at Qadisiyeh and also from Zobeir near Basra to the Euphrates at Suq esh Shuyukh. At Beled the conglomerates rest on a bed of clay.

Conglomerate is however exceptional on the great flood plain and in most of the region the tracts of marshy alluvium are only interrupted by areas of sandy and stony desert. These probably are found where Miocene beds outcrop as low plateaux of gypsiferous marls and are of great interest to students of human history as they probably formed ancient islands, which may have been inhabited in pre-Sumerian times. One of these plateaux forms a ridge about a mile wide between Museyib and Baghdad. Miocene outcrops also occur west of Basra.

The most interesting question however in the geology of the alluvial plain, in relation both to the ancient history of Mesopotamia and certain modern problems, is the growth of the deltaic region. While it seems probable that the old shore line was in glacial times near Hit the position of the sea coast in Sumerian times is open to considerable conjecture. Langdon in his map in the *Cambridge Ancient History* puts the site of ancient Eridu actually at the head of the gulf (Eridu lies a few miles southeast of Ur), a position fully justified by the explicit statements of ancient texts. Campbell Thompson however in his excavations on this site found fresh water mussels, and suggests that although there is no reason to doubt that Eridu was on the edge of the "sea" that sea was a fresh water lake and not the actual gulf itself but as he also found marine shells it is possible that the fresh water shells were used for food. Sir A. T. Wilson suggests that in ancient times there was a great lake or chain of lakes, all of which except that fed by the Jarrahi poured their waters as at present through the Shatt-al-Arab. He believes that at the beginning of the Christian era the coast coincided from Bubiyan island with the present shore, curving thence inwards to somewhere near Abadan, and joining the present coast near Qubban. He suggests further that 90% of the silt deposited in the lakes and therefore never reached the gulf. The size of Bubiyan island shows that in prehistoric times the Euphrates carried great deposits of silt, while the Tigris was less active. Under these circumstances the rapid extension of land at Fao, according to Rawlinson as much as 53 metres per annum between the years 1793 and 1833 is no indication of a stable coast line. There does not appear to be any reason to think that the coast east of Bahmishir has advanced since the Karun abandoned it, nor that the coast at Bubiyan has advanced at all in the past twenty centuries, that is since the Euphrates left that channel. Wilson's conclusions are that the coast line at the mouth of the Shatt-al-Arab advanced slowly till the Karun found its way into that channel at the end of the 18th century. Islands then began to form at the mouth of the Shatt-al-Arab as that stream began to enlarge its bed and to cut the great bend between Mohammerah and Abadan. Wilson suggests that the lacustrine region was formed by silt, sand and gravels brought down from the Arabian plateau during a period of high rainfall in the glacial age by the Batin, at a time when the mouths of the Euphrates and the Tigris were near Hit and Samarra respectively. This heavy material, together with lighter silt from the Karkhah and Karun have formed the barrier, and the intervening region has only succeeded in becoming more or less filled up in the last few generations.

Climate.—The climate of Mesopotamia is continental in type with great extremes, and Mesopotamia and the Persian gulf are among the hottest places on the face of the globe. The mean annual range is nearly 44° F in Baghdad, where the hottest month August has a mean temperature of 92·5°, a temperature as high as 123° having been recorded. The coldest month is January with a mean temperature of 48·8, the lowest recorded temperature being 19°. Except near the Persian gulf the humidity is low, making the extreme heat of summer less oppressive. The rainfall is usually under ten inches, falling mostly during the winter months, June to October inclusive being practically rainless, although on the hills there is a larger precipitation. On the plain irrigation is absolutely necessary for the crops, rain only falling on an average of 26 days in the year.



FROM MRS. S. ERSKINE, "THE VANISHED CITIES OF ARABIA"

A CARAVAN HALT IN THE DESERT ON THE PILGRIMS' ROUTE TO MECCA

In this hot dry land the winds are of importance, both for the relief they bring to the intense heat and for the dust storms they cause. The prevailing north-west wind, the *Shamal,* blows both summer and winter, sometimes blowing with great strength during the heat of the day.

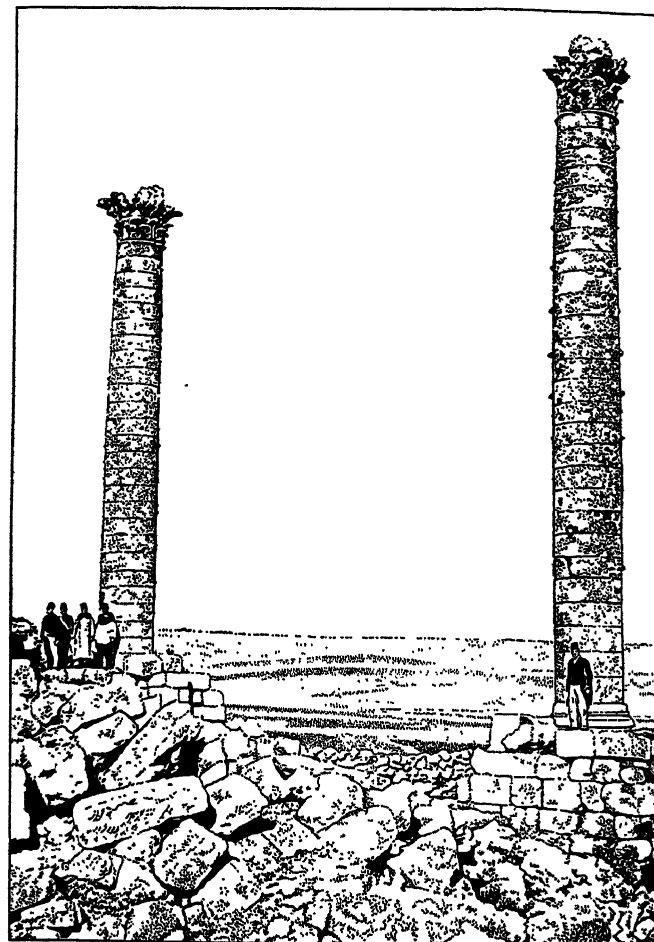
There is no exact information at present about the climate of Mesopotamia in ancient times. Such evidence as there is suggests that, within historic times at least, there has been no great change, such variations in the siting of cities and so on being rather due to an alteration in the direction of the rivers than to an actual change in climate. It is certain that in palaeolithic times the region was much wetter and no doubt at this time the dry wadis which lead down from the Arabian plateau carried water. The tributaries of the Tigris may have changed slightly (*see* TIGRIS) but insufficiently to warrant the suggestion that the desiccation is not of great antiquity, at least as far back as the Neolithic age.

Flora and Fauna.—While it may be said that Mesopotamia forms part of the region called by P. A. Buxton the "Palaearctic Desert" there are considerable differences in the flora and fauna

of the different parts. Northern Mesopotamia, the region through which the rivers flowed previous to the accumulation of the deltaic region, has a Mediterranean flora and fauna. It seems probable that wheat and barley are here close to their original wild home. On the whole the region is treeless, although there are trees on some of the hills. In southern Mesopotamia other conditions prevail. The rainfall is not really insufficient to support a considerable amount of vegetation but owing to the physical qualities of the soil, a very fine silt, combined with a high temperature and strong winds the evaporation is excessive. Under these circumstances the regions between the rivers often approach to more truly desert conditions than the north Syrian desert. As an example the unirrigated regions near Kish are in places absolutely devoid of vegetation and at one point in an area of about a square mile the only living plant found was a bush of Christ's thorn. Where however irrigation is practised and the water is allowed to drain off so that an excess of salts is not accumulated the soil produces good crops and after the crops abundant weeds of cultivation and a thorny flora of various species of a wide distribution in the palaearctic desert region. These weeds are extensively used for fire wood, a clear indication of the meagre floral resources of the country. The country is practically treeless, the only timber being supplied by the stems of the date palm, which grows along the rivers. There are also low beds of poplar. The vegetation along the rivers amounts to an extended oasis, although in places even the river banks are extraordinarily desolate. One of the characteristics of Mesopotamian vegetation as a whole is the comparatively few number of species which occur, a great contrast to the flora of the American desert. Secondly in common with all deserts the Mesopotamian vegetation shows a convergence of form between different species so that plants only distantly related are superficially similar. Thirdly, and this feature is also common to most deserts, the line which divides the green fertile land and the desert is very sharply marked, and the introduction of water by irrigation rapidly produces a marked change in the vegetation.

The fauna has as yet been imperfectly studied. Among large mammals the cheetah is not uncommon on the desert, the only other mammals of any size being various species of gazelles and antelopes. The lion so prominently figured on Assyrian bas-reliefs is said to exist, but recent records are uncertain. The wild ass is rare. Among the carnivora other than those mentioned the hyaena and species of wolves have been reported. The jackal is not uncommon and in certain regions wild pig abound. The desert hare is very common and where caves exist there are bats. Small mammals are extremely common, especially jerboas and their allies. Among the birds the ostrich reported as quite common by Xenophon is practically if not entirely extinct. The birds of prey are well represented, including the vulture, raven, owl and various species of hawks. In the steppe region the buzzard is very common, there are various species of sandgrouse and, where there is open water, ducks and geese; the black partridge is abundant near water. Among the reptiles one of the commonest and most interesting is the little lizard Agama. The details of the smaller animals are not yet worked out. P. A. Buxton has noted the fact that whereas in the stony desert the pebbles shelter a host of woodlice, millipedes, centipedes, spiders, scorpions, earwigs, cockroaches, crickets, beetles, bugs and ants and lice in southern Mesopotamia a similar fauna is found in the leaf-bases of the palm trees. Apart from technical lists the most interesting account of plant and animal life in Mesopotamia is found in P. A. Buxton, *Animal Life in Deserts*, London 1923.

Ancient Geography.—In most countries there is little change in the position of inhabited sites, which continue over long periods either on the same spot or on one nearby. In Mesopotamia on the other hand much of the desert is strewn with the ruins of ancient cities where now only an occasional shepherd is to be found. The reason for these changes is not always apparent but usually three causes appear to have operated. There may have been a change of climate, the rivers may have altered their position or their mouths, or in some cases political events may have triumphed over geographical situation. Whether there has been a change in climate or not in Mesopotamia since ancient times has been disputed. There is no doubt that in upper palaeolithic times the Syrian desert was sufficiently humid for permanent settlement, and Buxton found numerous traces of palaeolithic implements in districts now only inhabited by wandering Bedouins. There were even some traces of Neolithic peoples. In Mesopotamia itself we have no evidence before Sumerian times, since when most writers maintain that there is no evidence of any change of climate. Sir William Willcocks thinks the ancient canals were not in use at the same time and that the presence of all these waterways is not therefore evidence of a progressive desiccation. In the neighbourhood of Babylon and Kish where canals are particularly numerous a study of levels shows that there at least Willcocks' statement is abundantly justified. Thus the change in the siting of ancient cities was not due to a change in climate. Secondly there can be no reasonable doubt regarding the change in the position of the rivers, for both the Tigris and Euphrates have shifted their course since ancient times. All the cities of Sumer have therefore been left without water. Apart from Borsippa the only ancient city of Sumer on the river is Babylon, itself a relatively modern town which took the place of Kish, 15 miles away when a change in the river made that site no longer usable. It may seem difficult to understand how, if there has been no change in the climate, regions which are now desolate can once have been the site of prosperous cities. A study of the hydrography of ancient Mesopotamia will however explain this change. First the course of the old bed of the Euphrates, the river on which ancient Mesopotamia depended chiefly for its water supply, has changed its place very considerably. The modern stream runs ten and in places more miles east of its ancient course. Ancient Mesopotamia was therefore much smaller than modern 'Iraq. Apart from minor divergencies that have not yet been fully explored the Euphrates divided into two branches almost due west of where Baghdad now



FROM DR. S. GUYER, "MY JOURNEY DOWN THE TIGRIS" (MESSRS. E. BENN)
RUINS AT URFA. THE TWO ANCIENT COLUMNS BEAR SYRIAC INSCRIPTIONS CONTAINING THE NAMES OF THE PRINCES OF THE EDESSA DYNASTY

stands. One branch ran past Sippar and Cutha and the other followed the course of the present stream as far as Babylon, where it turned west and ran slightly north of but in the same general direction as the modern Shatt-al-Nil past Kish and Nippur. Lower it divided again, the western branch being in the general direction of the modern Shatt-al-Kar past the cities of Kisurra and Shuruppak and the more westerly branch running past the modern Bismya, the ancient Adab, in a south-easterly direction till it was joined by the Shatt-al-Hai, which communicates with the Tigris. From this point onwards its general direction was south, past the ancient city of Lagash. The true Mesopotamia therefore, the region between the rivers, as opposed to the lower marshes of both streams, was much narrower. Of all the ancient cities in Akkad—those in lower Sumer will be discussed later—only Borsippa lay away from this narrow strip and Borsippa was close at hand. In these circumstances it is clear that to a large extent the alteration in Mesopotamia has been the conversion of fertile land into desert and poor steppe in the central region, while on the western boundary the converse has taken place. But this movement of the rivers is not sufficient to explain the whole of the changes. In ancient times when the strip was narrower irrigation was comparatively easy. The normal method has always been to dig canals from one river to the other. When the Tigris was nearer at hand it was easier to ensure a more ready flow of water through the canals. It is also abundantly clear from an examination of the ancient canals that great difficulty was found in keeping them in proper condition. Further unless conditions are very favourable and the water used for irrigation is kept very dilute from certain salt solutions the irrigated land becomes very hard and impermeable. By itself the mere hardening of the land may not have been sufficient in ancient times to have converted cultivated land into desert, but it probably played its part. The increasing distance of the rivers and the consequent difficulty of irrigation has always been felt. Ancient Akkad consisted of a narrow strip of cultivated soil, bounded throughout much of its length by a river or canal on both sides, not as today a narrow strip along the Euphrates with desert to the west and a further strip of desert to the east, between the fertile lands and the Tigris.

In Sumer the changes have even been greater. Here also the country was much smaller. Pliny writing in the first century A.D. says that the Euphrates had in ancient times its own mouth, but that the men of Erech dammed it up, possibly as Sir A. T. Wilson suggests to irrigate the rich land near Suk-esh-Shuyukh. Before the time of Rim-sin the Euphrates ran west of Ur reaching open water near Eridu. This region is the only part of its course which in ancient times was more westerly than at present, but Ur is today only a little way from the stream. Rim-sin straightened out the course of the river so that it passed by Ur and left Eridu a waterless city. Here in ancient times Mesopotamia ended. It seems probable that both Eridu and Lagash were in ancient times on the edge of the sea and that they were closely connected owing to the ease of communications. The progressive silting up of this region and the action of Rim-sin and his successors have now left both cities in the desert and today the river runs east of Ur while Erech, which, in the opinion of ancient geographers was the cause of all the trouble, lies away in the waterless desert. South-east all the lands to Basra and the rich palm groves and marshes of modern Iraq were as yet to be. We do not know exactly where the true coast line was in ancient times but for all practical purposes Eridu marked the southernmost extension.

All these changes have been progressive, the Euphrates had ceased long before our era to flow past Cutha and Kish. Eridu was an inland city nearly four thousand years ago, and unless steps are taken the Euphrates threatens to run still farther to the west. The changing course of the rivers is partly due to natural causes and partly to methods of irrigation.

In spite however of these progressive changes most of the ancient sites do show evidence of continued occupation, at or near the spot where the ancient city stood. The Mongol invasion probably accomplished more in a few years than the hand of nature or the irrigation projects of ancient kings did in many centuries. In 1258 Hulagu Khan, a grandson of the great Genghiz sacked Baghdad and the invasion of the Mongols destroyed all the ancient irrigation systems and converted Mesopotamia into a desert. Many of the old towns had long ago ceased to exist but on many of the sites there are traces of continued occupation. The towns which grew up after the Mongol invasion have survived until today and mark the contrast between ancient and modern Mesopotamia.

The distribution of ancient cities in Mesopotamia is therefore extremely different from those in modern times. They fall into four groups, those of the northern foothills, the Assyrian group and the cities of Akkad and Sumer; all except the last two groups are widely separated from one another. In ancient times there were hardly any cities of importance on the middle Euphrates and as today few of any note on the lower Tigris. The foothill towns of the north including such cities as Samosata, Edessa and Nisibis were never of any great political importance except for their strategic value as border forts. Usually small in size they commanded various entrances between the plains and the mountains and passed from one hand to another, being used against the plain, or against the mountains according to the position of the dominant power. This line of towns was also of value as it still is owing to the fact that it commands the upper and easier route from east to west. Edessa and Nisibis therefore have played for a long time the dual rôle of forts in times of war and of *entrepôts* on a main caravan route in times of peace. The second group of cities lies within the fertile triangle of land which lies between the Tigris and the Greater Zab. It has always been a region of red earth and great fertility and is remarkable for the closeness of occupation in ancient times. To the north of the triangle, just below the mountains lay the city of Khorsabad, which has been generally accepted as being the site of Dur-Shurrukin, Sargon's city. Nineveh itself lay on the Tigris opposite the modern city of Mosul and about 40 miles above the confluence of the Greater Zab. Further south, but still in the triangle lay Kalakh, the modern Nimrud. The other cities of the group are more isolated. Ashur lies down the Tigris, about 60 miles from Nineveh, and separated from it by desert, an easy journey down stream, but more difficult up stream. The last city is Arbela, today Irbil. This is a foothill town of considerable importance lying almost due east of Kalakh and south of the river Zab. Of these cities it is interesting to note that three, Nineveh, Ashur and Arbela, are close to if not on the same site as a modern town. The foothill towns also have not moved. In lower Mesopotamia the towns are practically all on different sites.

Down the Tigris from Ashur there are no important ancient towns till the old glacial shore line is reached and the true alluvial valley begins. Here there are the first traces of ancient irrigation. The site of Opis, Upe, is probably on the Tigris close to its juncture with the Adhem. Apart from the site of Baghdad, which has always been an important centre and Ctesiphon, a little lower down the river the ancient cities from this point onwards lay on the old bed of the Euphrates. The most northerly of these cities is Sippar, probably on the actual edge of the glacial shore-line, and five miles from the present bed of the Euphrates. From this point onwards the traveller who abandons the modern river and passes along the old bed of the stream and the canals which have succeeded it will find a continuous string of imposing mounds in what is today a bare and monotonous plain, fringed along the western horizon by the palm trees which mark the course of the Euphrates. South of Sippar lay Agade, the city whose name is associated with that of Sargon. Cutha lay on the canal of Cutha, which may in ancient times have been one of the branches of the river. Below Cutha again, on what is today the Shatt-al-Nil, but which in ancient times was certainly the main stream, lay the great city of Kish. Fifteen miles westwards of Kish are the ruins of Babylon. These are today close to the Hilla branch of the Euphrates and since the foundation of the city it has always been on the river. It is from this point onwards that the main contrasts between ancient and modern Mesopotamia begin. When the river changed its course and flowed south past Babylon it deserted a whole line of ancient riparian cities and today there are only two ancient cities west of the modern course of the Euphrates, Borsippa, close to Babylon, and Ur far to the south. The

modern Shatt-al-Nil and the Shatt-al-Kar follow more or less the course of the ancient stream. Nippur lay south of Kish on the main river. Below Eridu there is only one ancient site, near Suk-esh-Shiyukh and all the modern marshland was non-existent. It is probable that southern Sumer consisted of a series of lakes and that much of what is now marshland was open water, although higher up the stream it is probable that marshes were still in existence. Otherwise the scenery of ancient Mesopotamia was probably not very different from what it is today, except for the alteration in position of the cities. Akkad, the northern alluvial plain, had the same steppe, the same fringing gallery of palms along the river, but this fringing gallery was at Kish and Nippur not at Hilla and Diwaniya. Where there are modern towns on the river there was desert or steppe, just as today the ancient cities are mere mounds waterless and bare. Southern Mesopotamia, Sumer, has altered considerably; most of the lakes have filled up, though they may recall their ancient form in flood time. The lakes have been succeeded by marshes and though some of these survive many have been transformed into steppe and desert. In each of the three areas there has always been a dominant town, shifting under the change of the rivers; in Assyria, Mosul is the direct descendant of ancient Nineveh and the site is almost the same. In Akkad the changes have been greater; the oldest paramount town is Kish. Agade was only temporarily important, and the hegemony shifted to Babylon and across the narrow neck of land to Seleucia and Ctesiphon on the Tigris, and later to Baghdad, itself on an ancient Sumerian site. In the south the changes have been greater. Larsa and Ur have ceased to hold a position of dominating geographical position, and the outlet of southern Mesopotamia passed under the Caliphs to Basra nearer to the Persian gulf. The true geographical history of Mesopotamia has a clear cut at the invasion of the Mongols and from this point begins the study of the modern cities.

Modern Geography.—Modern Mesopotamia, now the kingdom of Iraq, occupies most of the geographical region of Mesopotamia, although the eastern bank of the Shatt-al-Arab is under the Persian rule. It also extends westwards along a corridor into the Syrian desert. The delimitation of frontiers on the north and west has been a matter of considerable difficulty. It has been recognized that for pastoral nomads a sharply defined frontier, except where there are marked physical boundaries, is hardly possible. The nomads recognize definite frontiers, but these frontiers are rather to be expressed as grazing and water rights than as a definite line. These rights have been recognized and the frontiers allow the nomads to exercise their grazing rights irrespective of where the actual line has been drawn. Recent disturbances along the south-western border of Iraq have however shown that the existence of a paper frontier, even while it maintains traditional rights, will not always be a deterrent to raiding tribes. With these reservations however the frontiers of Iraq have now been delimited, and suitable allowance has been made for a zone in which grazing rights belong by ancient tradition to tribes on one side or other of the boundary. In the western corridor however the frontier is not at present clearly defined. It is extremely difficult to plot a frontier where the boundary is defined by natural features but where these features are not definitely located. Jebel Anaza is mentioned in the agreement and is stated to be 32° N. and 39° E., but Musil's map gives a location about two degrees south of this position. This western corridor is of considerable importance to modern Iraq. It is used at present as a motor route forming one of the readiest means of transporting passengers between Jerusalem and Baghdad. It is also used today by the Imperial airways who have a series of landing grounds plotted out between Amman and Rimadi.

Communications.—Apart from the airway and motor route Iraq possesses no direct communication by modern methods of transport except by sea to Basra. Internal communications are however better. During the World War a temporary line was laid along the lower Tigris. Since that time this line has been dismantled and a line from Baghdad to Basra along the Euphrates has been substituted, with a short branch to Kerbela. North of Baghdad there are two lines. One, standard gauge, runs to Kalat Shergat. This line is part of the proposed Baghdad railway. The original intentions of the builders were for this line to run northwards through Mosul and eventually by Nisibin and so connect with the Asia Minor and Syrian systems. The metre gauge runs along the Tigris to railhead at Kerkuk. It has recently been suggested that this line should be carried on to Mosul, as it travels through a comparatively highly populated area, whereas the old line would have to pass through practically uninhabited desert. As it is, the third most important town in Iraq is entirely without railway communications. Considering the size of Iraq it is at present extremely badly provided with railways, the most recent figures available being

Year	Route	Track	Sidings	Total
	Miles	Miles	Miles	Miles
1925 . .	757·30	757·30	243·86	1001·16
1926 . .	810·73	810·73	194·45	1005·18

About six hundred thousand passengers are carried a year.

In connection with the railways other communications have been developed. There is a weekly motor service connecting Baghdad and Syria, running across the desert to Damascus. From Kerkuk a new trade route has been developed to Tabriz via Ruwanduz, and Bulagh. The caravans go laden with teas and return with almonds and dried fruits which are sold in Baghdad. The second route via Khanakin does not seem at present to be very successful. There is a fairly regular service of cars to Teheran. In addition to the fortnightly air service with Cairo there are also air services between Baghdad and Mosul and Kerkuk and Sulaimaniya.

Apart from native boats the river services are practically limited to the Shatt-al-Arab and the Tigris. Sir William Willcocks was of opinion that the railways should be used for communications and the rivers for irrigation. Considerable divergence of opinion has existed on this point, but although developments seem quite possible (*see* TIGRIS; EUPHRATES) no great advances have been made at present. The most recent development of a river service has been between Basra and Siba, the Iraq frontier station opposite the Anglo-Persian refinery at Abadan.

Postal services have been considerably developed in Iraq since the war; in addition to the regular sea service by Basra the air routes take letters and parcels. Basra is an important wireless centre, in communication with Cairo, while the most recent development has been the establishment of a station at Rutba wells, in communication with Baghdad, Basra, Amman and Gaza. The telephone service has also been extended. With a touch of legitimate pride the post office reports the recent extension of the money order business to Esthonia.

Side by side with these developments the older routes and methods of travel exist and are used much as they have been for centuries. The two principal centres are Mosul, still without modern methods and Baghdad. Between these two cities are two roads, the shorter, the line taken by the railway follows the right bank of the Tigris via Samarra, Tekrit and Kalat Sherghat. The longer but better road follows the line of the Jebel Hamrin, and is considerably hampered by the necessity of crossing the tributaries of the Tigris which come down from the Persian highlands. It passes through Kirkuk and Erbil and then turns west to Mosul. This road avoids floods and passes through less desolate regions. It is nearer the centres of population and is usually preferred. From Mosul roads run west and east. The chief route to the Mediterranean goes to Nisibin and Mardin from which town there are roads to Erzerum and westwards to Alexandretta, and Aleppo, and from this point the railway can be reached. The eastern road to Persia from Mosul runs through Erbil. The Persian road from Baghdad runs along the same way to Khanaki which is now followed by the railway. This way is the regular route for the large number of pilgrims who visit the shrines of Mesopotamia. There are two main roads across the desert. Both cross the strip between the rivers and follow the right bank of the Euphrates as far as Deir and thence one goes south-west to Tadmor and Damascus or Homs, while the other follows the river to Meskineh whence it

crosses to Aleppo. It will be seen that apart from the western road where the prospect of a railway is still uncertain the railways closely follow the old roads with the exception of the Jebel Hamrin route which although it passes through centres of population presents considerable difficulties as rivers have to be crossed.

Distribution of the Population.—As in ancient times the population is distributed along the banks of the canals and rivers, only about 10% living elsewhere. Of the two rivers the Tigris is the least populated as was also the case in ancient times. On the Tigris the principal centres of population are round Amara, near the Shatt-al-Hai, to the north and north-west of Baghdad along the river and between the Tigris and the Diala, especially round Baquba. On the Euphrates there are three main centres of population, between Museyib and Diwaniya on the Hilla branch corresponding more or less to the ancient centre of population in Akkad near Kufa on the Hindieh branch and between Nasariye and Suk-esh-Shiyukh. By far the most densely populated part is however the Shatt-al-Arab.

In Upper Mesopotamia the population is sparse. The distribution is chiefly as follows. In the middle Euphrates valley, between the two rivers, especially on the northern and north-western side of the plain along the Jebel Sinjar and its foothills, east of the Tigris in the old land of Assur in the area north of the Lesser Zab as far as the line drawn from Erbil to Mosul, and in the Kurdish foothills. Elsewhere the population is limited chiefly to the nomads who wander from the plains to the mountains to find grazing for their cattle. The development of the system of irrigation is likely to extend the range of the population considerably.

The position of the towns corresponds closely to the possible lines of communication. Here as in ancient times there are three main centres. In the north Mosul, the centre of the wheat district and the starting point of the safest caravan route from east to west, corresponds to ancient Nineveh. While of lesser importance than formerly owing to the fact that the development of improved communications have helped its competitors, Baghdad is the capital city of Iraq not only for its mediaeval traditions and memories of the glories of the Caliphs but also because it commands the inner lines of communications. It takes the place of ancient Babylon, and still more ancient Kish because although in some ways less favourably situated than these it has in addition the command of the landroutes, for which in some ways the Euphrates valley is more favourable. It also forms a port on the navigable waterway of the Tigris, and forms a natural outlet for the trade route and the populous centres along the Diala. In event of the western railway or motor route developing Baghdad will naturally be the railhead of this route. Basra forms the gateway of the south, the only port of Iraq. Although owing to the rapid silting up of the river its position is threatened this may be mended by engineering projects to the Shatt-al-Arab. Not only is Basra the only port of Iraq and therefore the natural outlet of its produce but also it forms the capital city of the most populous region in the kingdom.

The other towns depend for the most part on their position on lines of communication between or from these three cities. But the exact siting has depended chiefly on three factors, first the possibility of markets, which has depended largely on positions along the rivers, and especially at the confluence of two rivers or canals, secondly a central position in a specially favourable district and thirdly, religious sanctity which has attached itself to a particular locality. Of these pilgrim centres the most important are Kerbela and Nejef, to which towns Shiah Muslims come from all over Mesopotamia and Persia and wherever else members of that faith are to be found. At Nejef there is the tomb of Ali, the finest of the Shiah monuments; it is also a starting point for one of the regular roads to Mecca, via the Wadi Jowf. Both these towns lie on the western boundary of Mesopotamia. Samarra on the Tigris, north of Baghdad, is a pilgrim centre of lesser importance.

The Euphrates towns group themselves first into those on the caravan route between Baghdad and Aleppo. This group which includes Birijik, Urfa, Diarbekr, Mardin, Nisibin and Jezireh-ibn-Omar have avoided the open plains and the southern end of the Karaja Dagh as being too insecure and waterless. Below Birijik on the middle Euphrates there are a series of towns of greatest importance. Rakka, the ancient Nicephorum, at the junction of the Belik and Euphrates lies somewhat off the road but Deir-ez-Zor near the junction of the Khabur and the main stream is of the greatest importance, because the regions both to the east and west are less arid than the corresponding regions lower down the river and are therefore more readily traversed by caravans. Further south along the river lie Werdi, Ana, Hit and Ramadi. All these towns, including Deir-ez-Zor lie on the western bank. At Ramadi there is a bridge of boats and the place is of some importance to-day as it forms the starting point of the overland motor route to Jerusalem. It is also an Air Force station, for apart from the Rutba wells out in the desert there is no other permanent water available till Amman is reached. A newer town is growing up on the other bank of the river. On the lower Euphrates apart from the pilgrim centres already mentioned there are a series of towns of growing importance owing to the presence of the railway. These are Hilla, close to the site of ancient Babylon, a great grain market, built on both sides of the river, the two parts of the town being connected with a bridge of boats. Hilla possesses large bazaars. It is of great interest as being a town which preserves, without any of the special prohibitions which attach to religious centres, the appearance of a truly oriental town little influenced by western culture. Lower on the river are Diwaniyeh, Nazariyeh and Suk-esh-Shiyukh, while Kurna lies at the junction of the twin rivers. There are few towns on the Tigris. Apart from Baghdad and Mosul the most important are Tekrit, with raft traffic downstream to Baghdad, an ancient industry in the time of Herodotus, and Kut-el-Amara and Kut. There are however a series of towns on the eastern frontier. Rowanduz in south Kurdistan is on the caravan route from Mosul to Tabriz, while Suleimaniye is the great market centre, being connected both with Mosul and Baghdad, and lies on the caravan route between this town and northern Persia. On the actual edge of the hills lie the towns of Erbil, Altun Kipri, Kirkuk, Tuz Khurmantli and Salahiye.

Economic Geography.—Mesopotamia is poor both in minerals and ores. There is little building stone and, with some exceptions the houses have from time immemorial been built either of mud, or in the marshy districts of reeds. There are deposits of iron ore in Upper Mesopotamia. In the Bohtan valley there are lodes of gold, lead and copper. From this point eastwards to the outlet of the Murad valley into the Euphrates these ores are found associated with platinum, silver and zinc. Of the earthy minerals both common salt and gypsum are abundant and are used locally. There are seams of brown coal in the Eocene beds north of Mardin at Harbol, near Jeziret-ibn-Omar and east of the Tigris. Brown coal is also worked at Nasaleh near Kufri. Poor as it is in ores, Mesopotamia has been famous from ancient times for its oil springs. The wells at Hit, Kirkuk and Jibbeh date from ancient times. The three localities which appear to be the most valuable are first in the Persian gulf; the wells here, however, though favourably situated geographically, are poor in quality. The second group on the Kuren, including the well at Qirab which is mentioned by Herodotus have been developed by the Anglo-Persian Oil Company. They lie outside the boundary of modern Iraq. The most promising field however lies within the boundaries of that state and extends in a southeasterly direction from Mosul to Kend-i-Shir and Mandala.

Apart then from oil Mesopotamia looks to agriculture chiefly to supply her economic needs. Such manufactures as she has, chiefly textiles, have given two words to most European languages, muslin from Mosul and tabby (watered silk) from a suburb of Baghdad, but these are to-day of little importance and Mesopotamia's development depends, as it has always depended, on irrigation to make the crops grow. Of these two are the most important, dates and cereals, although much is hoped from cotton in the future. V. H. Dowson has computed that out of the ninety million date palms in the world a third are grown in Iraq. Of these there are fifteen million on the Shatt-al-Arab, five million on the Hilla canal, one million round Baghdad, and the remainder on the Euphrates and in separate oases. Second in importance to the date is rice which is grown in the land bordering on the river

marshes over most of lower Mesopotamia, especially around Basra and to lesser extent in upper Mesopotamia. It is used both for home consumption and for export. Where the land is not suitable for rice, hard grain, especially barley and to a lesser extent wheat is grown. The Mosul district produces abundant cereals and with the development of railway communications will export a large amount. Fruit trees are cultivated throughout Mesopotamia varying from figs and pears to oranges, apricots and melons according to climate, while the apple is almost universal.

Live stock is a most important source of wealth, especially to the tribes who live on the borders of the desert. The camel belongs essentially to the nomad, but throughout the whole of Mesopotamia large numbers of sheep are kept, and the goats produce hair of high grade. In the south, water buffaloes are used but in the north the chief draught animal is the ox. Arab horses are bred, although the more or less settled tribes find great difficulty in finding fodder for their beasts in summer. The nomads solve this difficulty by migrating. Mules are seldom bred.

Although in an agricultural country the trade returns are not altogether a satisfactory estimate of the economic geography, an analysis of recent returns is very instructive. The figures are in lakhs of rupees (about £7,500, or $36,500).

Before the World War the Germans put very great faith in the cotton-growing possibilities of Iraq. The climatic advantages of the region lie in the fact that during the growing season there is a high and rising temperature, with none of the cold from which both Egyptian and American cotton suffer, there is no summer rain but from March to June when moisture is most needed it is available. There is no fall in temperature until after the period of growth at which time it helps to ripen the crop. The British Cotton Association is so hopeful of success in this direction that it has recently installed a modern ginnery which is capable of dealing with 10,000 bales a year.

BIBLIOGRAPHY.—Detailed bibliographies will be found at the end of each separate article on Mesopotamia, *e.g.*, BABYLON, EUPHRATES, etc. The following works all contain a fairly long bibliography. General: British Foreign Office Peace handbook, Mesopotamia, 1920; L. Delapotre, *Mesopotamia* (1925); L. H. D. Buxton and D. T. Rice, *Report on Excavations at Kish (Physical Anthropology)* (forthcoming). Geology, *British Admiralty Handbook*, 1918. Ancient Geography, *Cambridge Ancient History*, Vol. I. 1923; Sir A. T. Wilson, *Geographical Journal* 1925 LXV. Modern Geography; S. H. Longrigg, *Four Centuries of Modern Iraq* (1925). In addition to the above the annual colonial office reports are invaluable for modern statistics.

Racial History.—The basal type of the population of Mesopotamia belongs to a well marked type, extremely long-headed, slender boned and usually termed Eurafrican. This type is dominant in the earlier graves and has always formed the bulk of the population. In the earliest graves from Ur no brachycephals were found, but at the beginning of the third millennium this Armenoid type had already appeared at Kish, together with other skulls which closely resemble the ancient Egyptians and are of the type known as the "Mediterranean race." In spite of the invasions of many peoples, Semites, Sumerians, Kassites, Medes and Persians, the population of Mesopotamia to-day does not appear to differ essentially from that of the same region 5,000 years ago. The only intrusive racial type is the negro.

The grouping of the peoples of Mesopotamia depends largely on geographical surroundings, and in the towns also on religion. There is a marked distinction between the Arab of the desert, the true Bedouin, and the agricultural Arab of the irrigated land, though both belong to the same physical type. In the lower valley the so-called Marsh Arabs belong to a slightly different type. The urban communities contain a number of different trading peoples, though the Arab predominates.

Although the social organization of the desert intrudes to a certain extent on Mesopotamia this organization is most typical of Arabia. The agricultural communities however do not differ essentially. They form small groups under a patriarchal sheikh. Each family lives in a tent, or sometimes in a mud house. The typical form of marriage is that of first cousins, a man normally marrying his father's brother's daughter (*see* COUSIN MARRIAGE). Considerable attention is paid to keeping the blood pure and, apart from polygamy, the direct line is usually known for many generations. The village sheikh exercises a patriarchal rule, and claims certain dues from his subjects. Women are usually isolated, the women's part of the tent being separated from the men's part. The tribes in the settled area are better organized than most of the desert dwellers, and although the local sheikh has complete control within his own village, the district is governed more or less after the organization of the old Ottoman empire under a matasarrif.

Most of the inhabitants of Mesopotamia are Shia Moslems, whose sacred places (Kerbela being one of the most noted) are in the Baghdad region. They are mostly fanatical Muslims, but there is not that variety of religious sects so characteristic of the Mediterranean region of the Near East.

HISTORY

EARLIEST TIMES

Functionally, Mesopotamia is the domain that lies between Babylonia and the related trans-Tigris districts on the one hand and the west Asian districts of Maritime Syria and Asia Minor on the other. Its position has given it a long, complicated and exciting history. The great rivers, in later times theoretically regarded as its boundaries, have never really been barriers (cf. *e.g.* Winckler, *Altorient. Forschungen,* iii. 348), whence the vagueness of the geographical terminology in all times. Its position, along with its character, has prevented it often or long, if ever, playing a really independent part.

The earliest inhabitants of Mesopotamia in times approaching the historical period are known as the Sumerians. The earliest Sumerian monarch who exercised dominion as far as the Mediterranean is Lugalraggizi, king of Erech, 2775–2750 B.C. His empire was before long eclipsed by the rising power of the Semites. Sumerian traditions and dynastic lists give a complete reconstruction of early history, beginning with ten mythical kings who lived before the Flood, for nearly a half million years, and after the Flood the first capital was Kish, followed by the dynasties of Erech, Ur, Awan, Kish II., Hamasi, Erech II., Ur II., Adab, Maer, Kish III., Akshak and Kish IV., when we reach the kingdom of Lugalraggizi of Erech.[1] According to the actual figures of the records, the first capital was founded, at Kish, 3768 B.C., which is clearly a mythical date. Early inscriptions of the city Lagash in the extreme south, and from Ur, Nippur, Adab, Erech and Kish, and especially from the earliest known sites, Shunuar (ki) near Kish, and Shuruppak in the south, indicate an advanced Sumerian civilization, before 4000 B.C. With the founding of the empire of Agade by the Semites under Sargon of Kish, begins the definite consecutive history of Babylonia and Assyria. That Sargon was or became supreme in Mesopotamia cannot be doubted, since there is contemporary evidence that he conquered Amurru. The three versions of the proceedings of Sargon in Subartu leave us in doubt what really happened. As he must have asserted himself in Mesopotamia *before* he advanced into the maritime district (and perhaps beyond: *see* SARGON), what is

[1] S. Langdon, Oxford Editions of Cuneiform Texts, vol. II.

referred to in the Omens and the Chronicle 26,472 may be an immigration of new elements into Subartu—in that case perhaps one of the early representatives of the "Hittite" group. According to the Omens text Sargon seems to have settled colonies in Subartu, and suggestions of an anticipation of the later Assyrian policy of transportation have been found by L. W. King (*History of Sumer and Akkad*) under the rulers of this time, and there are evidences of lively intercommunication. Mesopotamia certainly felt the Sumero-Babylonian civilization early. It was from the special type of cuneiform developed there, apparently, that the later Assyrian forms were derived. Mesopotamia would naturally share in the wide trade relations of the time, probably reaching as far as Egypt. The importance of Harrān was doubtless due not only to its fame as a seat of the Moon-god Sin, honoured also west of the Euphrates, and to its political position, but also to its trade relations. Contemporary records of sales of slaves from Amurrū are known.

When the Semitic settlers living in the age of Sargon, *i.e.*, the Akkadians, had become thoroughly amalgamated with the population, there appeared a new immigrant element, the Amurrū, whose advance as far as Babylonia is to be traced in the troubled history of the post-Gudean period, out of the confusion of which there ultimately emerged the Khammurabi dynasty. That the Amurrū passed through Mesopotamia, and that some remained, seems most probable. Their god Dagan had a temple at Tirqa (near 'Ishāra, a little below Circesium), the capital of Khana (several kings of which we now know by name), probably taking the place of an earlier deity. At Tirqa they had month names of a peculiar type. It is not improbable that the incorporation of this Mesopotamian kingdom with Babylon was the work of Khammurabi himself.

Not quite so successful eventually was the similar enterprise farther north at Asshur (or Assur [*q.v.*]) on the east margin of Mesopotamia, although we do not know the immediate outcome of the struggle between Asshur and the first Babylonian king, Sumu-abi. Possibly the rulers of Babylon had a freer hand in a city that they apparently raised to a dominant position than the Semitic rulers of Asshur, who seem to have succeeded to men of the stock which we have hitherto called Mitanni, if we may judge from the names of Ushpia who, according to Shalmaneser I. and Esarhaddon, built the temple, and Kikia who, according to Ashur-rem-nisheshu, built the city wall[1]. The considerable number of such names already found in records of the Sumerian kingdom Ur III. (2709–2301) and of First Dynasty records seems to show that the people of this race were to be found at home as far south as Babylonia.

HITTITE TIMES

When Khammurabi's fifth successor witnessed the downfall of the Amorite dynasty in consequence of an inroad of "Hittites," these may have been Mesopotamian Shubaru-Mitanni; but they may, as Ungnad suggests, represent rather ancestors of the Hittites of later times. It is difficult in any case not to connect with this catastrophe the carrying away to Khana of the Marduk statue afterwards recovered by Agum, one of the earlier kings of the Kassite dynasty. Whether Hittites were still resident at Khana we do not know. The earlier Kassite kings of Babylon still maintained the Amorite claim to "the four quarters"; but it is improbable that there was much force behind the claim, although we have a document from Khana dated under Kashtiliash. It is just as uncertain how long Asshur remained under the Babylonian suzerainty of which there is evidence in the time of Khammurabi, and what the relation of Asshur to western Mesopotamia was under the early kings whose names have lately been recovered. All these matters will no doubt be cleared up when more of the many *tells* of Mesopotamia are excavated. Only two have been touched; 'Arbān on the Khābūr, where remains of a palace of uncertain date, among other things an XVIII. dynasty scarab, were found by Layard in 1851, and Tell Khalaf, where the confluents join, and remains of the palace of a certain Kapar, son of Hanpan of "Hittite" affinities but uncertain date, were found by

[1]Ungnad, *Beitr. z. Assyr.* VI. v. 13.

von Oppenheim in 1899. A long inscription of a Shamshi-Adad I., contemporary with the first Kassite kings, 17th century, exists in which his claims extend over the land between the Tigris and the Euphrates, and he says that he erected memorials of himself on the shore of the Great Sea.

The first mention of Mitanni, as we saw, is under Tethmosis III., who clearly crossed the Euphrates. It is at least possible that common enmity to Mitanni led to a treaty with Assyria (under Ashur-nadin-akhe)[1]. Victorious expeditions into Naharin are claimed for Amenophis II., Tethmosis IV. and Amenophis III. The Egyptian references are too contemptuous to name the rulers; but Shaushatar may have begun his reign during the lifetime of Tethmosis III., and from cuneiform sources we know the names of six other Mitanni rulers. As they all bear Aryan names, and in some of their treaties appear Aryan deities (Indra, Varuna, Mithra, etc.), it is clear that Mesopotamia had now a further new element in its population, bearing apparently the name Kharri[2]. Many of the dynasts in North Syria and Palestine in the time of Tushratta bear names of the same type. The most natural explanation is that Aryans had made their way into the highlands east of Assyria, and thence bands had penetrated into Mesopotamia, peacefully or otherwise, and then, like the Turks in the days of the Caliphate, founded dynasties. The language of the Mitanni state, however, was neither Aryan nor Semitic, and may very well be that of the mysterious "Hittite" hieroglyphic inscriptions (*see* HITTITES). Mitanni was one of the great Powers, alongside of Egypt and Babylonia, able to send to Egypt the Ninevite 'Ishtar.

Assyria was now free, and Ashur-uballit knew how to make use of his opportunities, and, in the words of his great grandson, "broke up the forces of the widespread Shubari" (*AKA*, p. 7, I. 32 *seq.*). Knowing what we know of the colonizing power of the Assyrians, we may assume that among the "Mitanni" and other elements in the Mesopotamian population there would now be an increase of people of "Assyrian" origin. On the tangled politics of this period, especially Mesopotamia's relations with the north-west, the Boghaz-Keui documents throw a great deal of light. We know already a little more of the chequered history of the Amorites in the Naharin district, beset by great Powers on three sides. When Mitanni fell, Babylon no doubt adhered to its older claims on Mesopotamia; but the Kassite kings could do little to contest the advance of Assyria, although several rectifications of the boundary between their spheres are reported.

Aramaeans.—Mitanni's fall, however, opened the way for others also. Hence when Ashur-uballit's grandson, Arik-den-ili (written PU.DI.ili), carried on the work of enforcing Assyria's claim to the heirship of Mitanni, he is described as conquering the warriors[3] (?) of the Akhlame and the Suti. The references to these people, who practically make their first appearance in the Amarna correspondence[4], show that they were unsettled bands who took advantage of the loosening of authority to introduce themselves into various parts of the country, in this case Mesopotamia. Gradually settlements were made, the names of many of which are given by the various Assyrian kings who had at one time or another to assert or reassert supremacy over them—such as Chindanu, Laqe, Suhi along the South Euphrates boundary of Mesopotamia, and various districts bearing names compounded with *Bit*=settlement (*see* above), such as Bit-Adini (nearly equal to the later Osroene; *see* EDESSA), or Bit-Zamani in the north near Diārbekr. The specific name Aramaean first appears in the annals of Tiglath-pileser I., unless we identify the Arimi of Shalmaneser I. in Tūr 'Abdin with the Aramu[5], but the name may probably with fitness be applied to a very large number of the communities mentioned from time to time. Their position in Mesopotamia must have been very like that of the Shammar at the present time (see *ad fin.*). As they gradually adopted settled life in various parts of the country the use of Aramaic spread

[1]See *e.g.* P. Schnabel, *Stud. z. bab.-ass. Chron.* p. 25 (1908).
[2]Winckler has identified the Kharri with the Aryans, to whom he assigns a state in Armenia (*Or. Lit.-Zeit.*, July 1910).

more and more (*see* below, "Persians").

ASSYRIAN INFLUENCE

Assyrian Empire.—Meanwhile Mesopotamia continued to be crossed and re-crossed by the endless marches of the Assyrian kings (such as Adad-nirari, Shalmaneser I. and his son), building and rebuilding the Assyrian empire (*see* BABYLONIA AND ASSYRIA), and eventually pushing their conquests towards Asia Minor at the expense of the Hittite domain. If, on the fall of the Kassites, Nebuchadrezzar I. established more direct relations between Mesopotamia and Babylon, his work was presently undone by the vigorous campaigns of Tiglath-pileser I., who seems even to have won Egypt's sanction of his succession to the Hittite claims. The tablet of Tukulti-Ninib, the grandfather of Shalmaneser II., is interesting from its account of an expedition down the course of the Tharthār to Hīt=Id (river and town now first mentioned in cuneiform sources) and up the Euphrates to the Khābūr district.

Now that Mesopotamia had passed out of the hands of Babylon, all that the later kings could do was to encourage local Mesopotamian rulers in their desire for independence (Nabuapluiddin). These were convinced that Assyria was master, but refused their tribute when they thought they dared. To overpower thoroughly the troublesome Bit-Adini (*see* above 3, viii.), which had naturally been aided by the states west of the Euphrates, Shalmaneser II. (860–825 B.C.) settled Assyrians in their midst. Harrān was one of the few places that remained on his side during the great insurrection that darkened his last days. Similarly the province of Guzanu (Heb. Gozan, Γαυζανῖτις) on the Kāhbūr, held with the capital Asshur in the insurrection that occurred in 763 (the year of the eclipse), when evidently some one (an Adad-nirari?) wore the crown, at least for a time. Harrān was clearly closely associated with Asshur in the rights and institutions that were the subject of so much party struggle in the new Assyrian empire that began with Tiglath-pileser IV. (*see* BABYLONIA AND ASSYRIA). When the policy of transporting people from one part of the empire to another was developed, new elements were introduced into Mesopotamia, amongst them Israelites, of whom perhaps traces have been found in the neighbourhood of Harrān at Kannu[1]. These new elements may have been more organically attached to the Assyrian state as such than the older inhabitants, to whom the affairs of state at Nineveh would be of little interest. On the conditions at Harrān some light is thrown by the census partly preserved in Ashurbanipal's library[2]. The governors of several Mesopotamian cities, such as Nasibin, Amid, took their turn as eponyms; but this would not have much significance for the people. Hence even the fall of Nineveh (612 B.C.) at the hands of Nabopolassar and the Medes would be a matter of comparative indifference; tribute paid to Babylon was just as hard to find as if it were going to Nineveh. Necho did not succeed, like his great XVIIIth dynasty predecessor, in crossing the Euphrates. He was defeated by Nebuchadrezzar at Carchemish (605 B.C.), and Mesopotamia was confirmed to Babylon. Its troubles began again shortly after Nebuchadrezzar's death; the Medes seized Mesopotamia and besieged Harrān. Before long, however, the overthrow of Astyages by Cyrus cleared Mesopotamia, and Nabonidus (Nabu-naid) was able, drawing on the resources of the whole of Syria for the purpose, to restore the famous temple of Sin at Harrān, where a few years later he erected in memory of his mother, who seems to have been a priestess there, the *stele* published in 1907 by Pognon.

Persians.—The fragmentary nature of the records does not enable us to follow the steps by which Cyrus became master of Mesopotamia, in which he probably met with little or no resistance. How much of Mesopotamia was involved in the revolt of what the Persian inscription calls Assyria (*Athur*) is not clear. Nor does it appear with certainty to which of the twenty satrapies into which, according to Herodotus, the Persian empire was divided, Mesopotamia belonged; probably it was included in *'Abar nahārā*. The fact is, we have no information from native sources[1]. The probability is that conditions remained very much what they had been; except, that the policy of transportation was not continued. The satraps and other high officials would naturally be of Persian extraction; but local affairs were probably managed in the old way, and there was no important shift of population. The large Aramaic infusion had by this time been merged in the general body of the people. These settlers doubtless influenced the "Assyrian" language[2]; but gradually, especially in the west, their own language more and more prevailed. Although Aramaic inscriptions of the Assyrian period, like those of Zanjīrli or that of King ZKR of Hamath, have not been found in Mesopotamia, already in the time of Shalmaneser II. mention is made of an Aramaean letter (Harper, *Ass. Bab. Letters*, No. 872, obv. l. 10.), and Aramaic notes on cuneiform documents begin to appear. Weights with Aramaic inscriptions (the oldest from the reign of Shalmaneser IV., 727–722) were found at Calah. By the Achaemenian period Aramaic had become the international language, and was adopted officially.

How Mesopotamia was affected by the passing of Persian armies on their way to suppress revolts in Syria or Egypt, or to conquer Greece, we do not know; on the whole it probably enjoyed unwonted peace. The expedition of Cyrus, the Younger, with which Xenophon has made us so familiar, only skirted the left bank of the Euphrates. The route followed by Alexander, though he also crossed at Thapsacus, took him unresisted across the northern parts; but the poor people of Mesopotamia suffered from the measures taken by their satrap Mazaeus to impede Alexander's progress. In spite of this, where Cyrus failed Alexander succeeded.

THE GRECIAN EMPIRE

Hellenism.—What would have happened had Alexander lived we can only guess. Under the Seleucids Babylon was moved across the plain to Seleucia; but before long the central authority was transferred to the other side of Mesopotamia, Antioch or elsewhere—a fateful move. It is improbable that cuneiform and the Babylonian language continued to be used in Mesopotamia during the Hellenistic period, as it did in Babylonia, where it was certainly written as late as the last century B.C.[3], and may have been a learned language till the second Christian century[4]. Unfortunately there are not native documents from the pre-Christian Hellenistic period. That the Hellenizing process went as far as it did in Syria is unlikely; and even there Aramaic remained the language of the people, even in the towns (*cf.* EDESSA). Still, Greek influence was considerable. This would be mainly in the towns, the growth of which was quite a feature of the Macedonian rule in Mesopotamia (Pliny, vi. 30, § 117)[5]. This is seen in the Greek names which now appear: such are Seleucia opposite Samosāta, Apameia (=Birejik) opposite Zeugma, Hierapolis (=Membij), Europus, Nicatoris, Amphipolis (=Thapsacus, or near it), Nicephorium (er-Rakka), Zenodotium (stormed by Crassus), all on or by the Euphrates; Edessa (*q.v.*) on the upper waters of the Belīkh, Ichnae (perhaps Khnēs, above the junction of the Qaramuch with the Belīkh). These are all in the Osroene district; but Nasībīn became an Antioch, and as its district was known as Mygdonia (from Macedon) there were doubtless many other Greek settlements. To a less extent the same influences would be at work in towns called even by Western writers by their real names, such as Batnae, Carrhae (Charran), Resaena.

Mesopotamia naturally had its share of suffering in the struggles that disturbed the time, when Eumenes or Seleucus traversed it or wintered there. It was invaded and temporarily annexed in

245 by Ptolemy III. Euergetes in his rapid expedition to beyond the Tigris. When Molon revolted on the accession of the youthful Antiochus III. (224 B.C.) he entered Mesopotamia from the south. Antiochus skirted the northern highlands by way of Nasībīn. In Mesopotamia a large part of the army of Antiochus VII. Sidetes was destroyed in 130 B.C., and the Syrian kings did not again seriously attempt to assert their rule beyond the Euphrates. When Phraates II. turned the Scythians against himself, however, even Mesopotamia suffered from the plunderers (*Joh. Antioch*, in Müller iv. 561). The immigration of Arabs must have been going on for long. About this time they even founded a dynasty in Aramaean Osroene (*see* EDESSA).

Parthian Period.—Under Mithridates II. Mesopotamia was a definite part of the Parthian empire, of which the Euphrates became the western boundary; but in 92 B.C. on that river his ambassador met Sulla, though the long duel did not begin immediately.

It was perhaps a Parthian governor of Mesopotamia who was called in to help Straton of Beroea against Demetrius III.; but before long Mesopotamia (especially the district of Nisībis) was attached to the growing dominions of Armenia under its ambitious king Tigranes, perhaps with the consent of Sinatruces (Sanatruces). The lost territory, however, was recovered by Phraates III., and Mesopotamia was guaranteed to Parthia by the treaties of Lucullus and Pompey (66 B.C.). It was traversed, however, several times by Roman troops crossing from Armenia to Syria, and Parthia's declaration of war against Armenia involved it with Rome. Gabinius crossed the Euphrates (54); but the command was assumed by Crassus, who, though he seized Ichnae, etc., and Raqqa (Rakka), fell near Carrhae (53), and the Parthian dominion was confirmed. The tragedy of the Ides of March saved Mesopotamia and the East from a great campaign by Julius Caesar, and it was at the hands of Ventidius Bassus, and west of the Euphrates, at Gindarus (north-east of Antioch), that the Parthians received the check that put an end to any real rivalry with Rome. Mesopotamia narrowly escaped being the scene of the struggle when Antonius in 36 finally decided to make his disastrous attempt against Phraates IV. by way of Armenia. In A.D. 36, Tiridates found support in his attempt to secure the throne of Artabanus III. in Mesopotamia, and it was there that he saw his army melt away. The expedition against Rome of Vologaeses I. (*q.v.*) of A.D. 62 reached no further westwards than Nisībis, and in 66 a peaceable arrangement was come to. Of the half-century that preceded Trajan's great oriental undertaking not much is known. When in 115 Trajan entered Mesopotamia from the north no serious resistance was offered, and it became a province as far as Singara. The woods at Nisībis, the headquarters, provided material for the boats with which in 116 he crossed the Tigris. Hatra, an interesting fortress which seems to have been Aramaean, fell, and the army advanced to Hīt, where it found the fleet that was subsequently transferred to the Tigris. For the revolt that occurred while Trajan was on the Persian Gulf, in which the Jews had an important hand, Nisībis and Edessa suffered capture and destruction. Hatra successfully withstood siege, however, and Hadrian abandoned Mesopotamia, setting the boundary at the Euphrates. Again for half a century there is not much to relate. Then, when Vologaeses, yielding to his growing discontent, took advantage of the death of Antoninus to invade Armenia the Romans were victorious (164), and after the storming of places such as Nicephorium, Edessa, Nisībis, western Mesopotamia was once more Roman as far as the Khābūr, Carrhae becoming a free city and Osroene a dependency.

By this time Christianity had secured a foothold, perhaps first among the Jews (*see* EDESSA), and we enter upon the earliest period from which documents in the Edessan dialect of Aramaic, known as Syriac, have been preserved. Unfortunately they contain practically nothing that is not of Christian origin[1]. On the death of Aurelius, Hatra aided Niger against Septimius Severus in 194; Osroene rose against Rome, and Nisībis was besieged and other Roman places taken; but Septimius Severus appeared in person (195), and from Nisībis as headquarters subdued the whole country, of which he made Nisībis metropolis, raising it to the rank of a colony, the Sinjār district, where Arabs from Yemen had settled, being incorporated. On his retiring everything was undone, only Nisībis holding out; but on his reappearance in 198 the Parthians withdrew. Again the Euphrates bore a Roman fleet. Hatra, however, was besieged twice in vain. Peace then prevailed till Caracalla's unprovoked attack on Parthia in 216, after he had reduced Osroene to a province. On his assassination near Carrhae (217), Macrinus was defeated at Nisībis and had to purchase peace, though he retained Roman Mesopotamia, reinstating the princely house in Osroene.

[1]The earliest inscription in Syriac yet known dates from A.D. 77, and was found at Serrīn (opposite Kal'at en-Najm) by von Oppenheim.

SASSANIAN PERIOD

Ardashir's power was rising when the Parthian Artabanus died in 224 (227); and Ardashir proposed to prove himself the successor of the Achaemenidae. Hatra resisted the first Persian attack as it had resisted Rome; but Mesopotamia was overrun, Nisībis and Carrhae being taken (233). It was immediately, indeed, recovered by Alexander Severus, and retained, whatever was the precise success of the war; but Nisībis and Carrhae were retaken by the Persians in the reign of Maximin. Under Gordian III. in 242 Mesopotamia was entered by a great Roman army which recovered Carrhae and Nisībis, and defeated the Persians at Resaena; but when Gordian after a difficult march down the Khābūr, was murdered at Zaitha below Circesium, Philip the Arabian (244) made the best terms he could with Shapur I. Whatever they were, the Roman garrisons seem not to have been really withdrawn. A rest for Mesopotamia seems to have followed; but in 258 Shapur, tempted by the troubles in the Roman empire, overran the country taking Nisībis and Carrhae, and investing Edessa, and when Valerian invaded Mesopotamia he was eventually made prisoner near Edessa (260). After Shapur's cruel victories in Syria, however, he was defeated by Odaenathus, who relieved Edessa, and Mesopotamia became for ten years practically part of an Arabian empire (*see* PALMYRA), as it was to be four centuries later. In consequence of the revolt of Zenobia Mesopotamia was lost to Rome, and the Euphrates became the frontier. Aurelian overthrew the Palmyran rule; but he was assassinated before he could carry out his intended expedition against Persia, Probus was assassinated before he was able to do anything (or much), and although Carus easily overran Mesopotamia, which became Roman again, and even took Ctesiphon, the Romans retreated on his death (283–284). The next incident is the defeat of Galerius, between Carrhae and Callinicus, where he had entered Mesopotamia (about 296), in the war provoked by Narses in consequence of his relations with Armenia. When it was retrieved by a signal victory, Diocletian advanced to Nisībis and thence dictated terms of peace by which Mesopotamia to the Tigris was definitely ceded to Rome (298).

After a forty years' peace the struggle was resumed by Shapur II. Nisībis thrice endured unsuccessful siege (338, 346, 350), although meanwhile Constantine had suffered defeat at Singara (348). Then Mesopotamia enjoyed two short rests (separated by a sharp struggle) while the rivals were engaged elsewhere, when in 363 Julian (*q.v.*) made his disastrous attempt, and Jovian bought peace at the price, among other things, of Singara and Nisībis, *i.e.*, practically all eastern Mesopotamia.

The surrender of Nisībis, which had been in the possession of Rome for so many generations, caused consternation among the Christians, and Ephraem (*q.v.*) moved to Edessa, where his "school of the Persians" soon became famous (*see* EDESSA). In the war of 421, in which the north-east of Mesopotamia was chiefly concerned, the Romans failed to take Nisībis, and it became a natural rallying point for the Nestorians after the decision of Ephesus (431). Matters were still more complicated when the Western Christians of Edessa found themselves unable to accept the ruling of Chalcedon against Monophysitism in 451 (*see* MONOPHYSITES), and there came to be three parties: Nestorians (*q.v.*), Jacobites (*see* JACOBITE CHURCH) and Melchites (*q.v.*).

In the beginning of the 6th century there was another severe struggle in Mesopotamia, which found an anonymous Syriac historian (*see* EDESSA), and in infringement of agreement the Ro-

mans strongly fortified Dārā against Nisībis. The Persian invasion of Syria under Kavadh I. (*q.v.*) was driven back by Belisarius; but the latter was defeated in his pursuit at Rakka (531). The peace begun by Chosroes I. (532) was not long kept, and Roman Mesopotamia, except the pagan Ḥarrān, suffered severely (540), Edessa undergoing a trying siege (544). The fifty years' peace also (562) was short lived; the Romans again failed in an attempt to recover Nisībis (573), whilst Chosroes' siege of Dārā was successful. Mesopotamia naturally suffered during the time of confusion that preceded and followed the accession of Chosroes II., and the Romans recovered their old frontier (591).

With the accession of Phocas (602) began the great war which shook the two kingdoms. The loss of Edessa, where Narses revolted, was temporary; but the Roman fortress of Dārā fell after nine months' siege (*c.* 605); Ḥarrān, Rās al-'Ain and Edessa followed in 607, many of the Christian inhabitants being transported to the Far East, and Chosroes carried the victorious arms of Persia far into the Roman empire. Finally Heraclius turned the tide, and Kavadh II. restored the conquests of his predecessor. The Syrian Christians, however, found that they had only exchanged the domination of a Zoroastrian monarch for an unsympathetic ecclesiastical despotism. In the confusion that followed, when men of letters had to live and work in exile, Nisībis set up for a time (631–632) a grandson of Chosroes II. Finally all agreed on Yazdegerd III.; but, while Chosroes II. and Heraclius had been at death grips with each other a great invasion had been preparing in Arabia. (S. L.; H. W. H.)

MEDIAEVAL AND MODERN TIMES

The Arab Conquest.—The Muslim Arab conquest both of 'Iraq (southern Mesopotamia) and of Jazirah (northern Mesopotamia to Urfa) was rapid and complete. By 640 Heraclius had lost the northern cities. Conversion to Islam became general. The invaders were tolerant by comparison with the Byzantines and the rapid spread of Islam among the conquered was due as much to its simplicity and fashionableness as to the disabilities which it imposed on non-Muslims. An effect of the Arab conquest was the gradual ousting of Syriac by the kindred Arab speech, the language of religion and of government, already well-established in parts of Mesopotamia by the Christian Arab tribes.

The Caliphate.—The religious and political history of Mesopotamia during the next six centuries is given elsewhere. (*See* CALIPHATE, ISLAM, PERSIA.) Here it need only be said that the people of Mesopotamia could not escape the consequences of their geographical position and of the wealth of their country and were involved in the sectarian and political disputes of their Arab lords. The Omayyad Caliph Merwan abandoned Damascus for a Mesopotamian capital at Harran and the Abbassids, whose power was based as much on Persian as on Arab support, ruled Islam from 'Iraq.

Qarbala (Kerbela) in 'Iraq was the scene of the tragedy (680) which made the great schism in Islam permanent. Qarbala and Nejef are still the great Shiah holy cities and Southern 'Iraq is predominantly Shiah to this day, while the north and the Jazirah are Sunni. Aramaean Christian influences, emanating from Harran, are thought to have contributed to the development of the Mu'tazilite heresy, and the revolutionary Kharijite sect found militant supporters in the Jazirah. But there is no evidence that these occasional civil and religious wars of the first two Muslim centuries seriously damaged the prosperity of the region. The irrigation system of 'Iraq was preserved by the Arabs; the centre of Islam attracted wealth from the outlying provinces and at the beginning of the 9th century no region in the world was wealthier.

Decay set in rapidly. The introduction of black slaves from East Africa for the cultivation of the marshlands of 'Iraq resulted in the long servile "War of the Zanj" (869–883). More fatal was the introduction of the Turkish soldiery, as hardy as Arabs and more amenable to discipline, first as slaves who received a veneer of Mohammedanism in barracks, and later, when Islam had established itself in southern Turan as professional soldiers coming singly or in war-bands to play the part which the Teutonic *foederati* had played during the Roman decline. Mutasim (833–847) son of Harun Al-Rashid first formed a Turkish bodyguard and, when his people murmured, transferred his capital to Samarra.

Ambitious or rebellious governors could hire Turks as well as the Caliphs and political disintegration had begun before the 9th century ended. The Saffarids revolted in Persia; Ahmad-ibn-Tulun of Egypt seized part of the Jazirah and Arab Hamdanids and Oqailids followed him. A Byzantine revival under the Macedonian dynasty threatened the northern borders in the last half of the 10th century and the Caliphs, terrorized by their Buwaihid Amirs (practically "Mayors of the Palace"), their sovereignty restricted to little more than the Euphrates valley, were reduced to the defensive. The Seljuk invasion of Western Asia in the middle of the 11th century rallied Islam but the Seljuk power waned quickly. Their Anatolian Satrapy separated itself from Persia, and the intervening Jazirah became a hunting ground for Turkish princelets (Atabegs) and Crusaders till Zangi expelled the latter from Edessa (1144). But for a generation after him the north remained a mosaic of warring Turkish states. The great Kurd Saladin, having checkmated the Franks in Syria, established Egyptian supremacy in northern Mesopotamia, but with his death polyarchy revived. In spite of earlier Karmathian devastations the south was fairly prosperous while the Caliph Nasir (1180–1242) intrigued against the decaying Seljuks with the more vigorous and barbarous rulers of Khwarezm and, when these rude warriors threatened him, called in the Mongols of Jenghiz Khan to destroy the Muslim buffer between him and the disciplined heathen of the north.

The Kingdom of Khwarezm went down in 1219. In 1258 Mesopotamia paid for the policy of Nasir. Hulagu Khan, grandson of Jenghiz and ruler of Persia, inspired by his queen and by his general Kitbugha (both Nestorian Christians), picked a quarrel with the last Caliph Mutasim, killed him, sacked Baghdad, and made 'Iraq into a wilderness. Next year it was the turn of the north. Two murderous campaigns wiped out the principalities and most of their populations and the Mongol flood rolled on into Syria.

The Decadence (1258–1534).—The conquest was unprecedentedly ruinous. By ordering the destruction of the embankments and headworks of the rivers and canals Hulagu converted vast areas of 'Iraq into steppe or swamp. The cultivators, thinned first by massacre and then by malaria and famine, were too weak to rebuild the canal system and prevent the nomads of Arabia terrorizing the countryside and encroaching on the remnants of cultivation. Henceforth the internal history of 'Iraq is that of an unending struggle between a few towns and the pastoral tribes—Arabs in most of the region, Kurds and Turkomans in the north—who regarded farmer and townsman as inferiors to be blackmailed and robbed.

For 80 years after the conquest 'Iraq was a poor province of the empire of the Ilkhans, the house of Hulagu. When their empire broke up Hasan Jalair, a Muslim Mongol noble, seized its western provinces and made Baghdad his winter capital. His successors ruled the Eastern Jazirah. The Ortoqids, the only Atabeg dynasty to survive the Mongols, were more or less independent on its western flank. In 1393 Timur the Tatar took Baghdad, but the Jalair expelled his governor. He returned in 1401 and sacked the city only less barbarously than Hulagu. On his death the Jalair returned but were soon overthrown by their rivals, the Turkomans of the Black Sheep (Qara-Qoyunly), whose capital was at Van. But their unstable power was challenged by the Turkomans of the White Sheep (Aq-Qoyunly), whose power was based on Diyarbekir. Their chief, Uzun Hasan, conquered 'Iraq and the Jazirah, but the new empire was distracted by rebellion and threatened by the growing ambition of the Osmanli Turks and of the new Persian dynasty of the Safawids. In 1508 Shah Ismail's general, Lala Hussein, took Baghdad and soon added Mosul, the capital of the Jazirah, to his master's empire.

Turco-Persian Rivalry (1512–1638).—In 1512 Selim the Grim girt on the sword of Osman and promptly made war on the Safawis. Shah Ismail's defeat at Chaldiran gave the Turk Ardalan, Mosul, Amadia and Raqqa, but Kirkuk and Baghdad remained Persian until 1534, when Suleiman the Magnificent took Baghdad

Basra was taken 12 years later by the Turks.

Unfortunately frequent wars with Persia and the turbulence of the tribes prevented the Turks organizing an anarchical country as they had organized their more central conquests. Their hold on Basra was precarious and the province was practically independent during most of the 17th century under a local dynasty. Shahrizor (the Kirkuk region) was constantly disputed by the Persians, sometimes aided, sometimes opposed, by local Kurdish chiefs. Local treachery brought the Persians into Baghdad in 1623. After 15 years Murad IV. retook the city and massacred many Persian prisoners. For three generations there was peace between Persian and Turk. From 1724, when war broke out again, to 1747 fighting was almost continuous and the exploits of Nadir Quli, who became Nadir Shah, and of his opponent Topal Osman Pasha gave an epic grandeur to an indecisive struggle. The wars of 1774–79 and of 1820–23 were less destructive and equally indecisive.

The Tribal Problem.—Wars with the Arab tribes were constant from 1638 to the middle of the 19th century. The names of the tribes or confederacies changed but there was no change in their politics. The close proximity of Arabia and of the vast Syrian steppe gave rebels a sure refuge. In 1641 the Shammar from Nejd reached the Euphrates and long controlled the towns of Anah and Zor.

The central government was at its weakest between 1760 and 1820 owing to foreign war and the ambitions of provincial pashas. In Mesopotamia it tolerated a succession of "Slave Pashas," mostly Georgian freedmen, who ruled as independent satraps of 'Iraq, though they never renounced their allegiance to the sultan.

The Last Phase.—The period of direct Ottoman rule began in 1831 when Ali Riza Pasha deposed Daud, the last slave pasha of 'Iraq. The Jalili were followed into exile or retirement by the ruling families of the Kurdish hill states. Mohammed "the Blind" of Ruwanduz had a brief period of rebellious success but was captured and made away with, and the last and best of the Kurdish princes disappeared when the Babans of Suleimaniyah ceased to rule (1850). In the south Qarbala was sternly disciplined (1842 and 1852). But until Midhat Pasha no Mesopotamian governor made any attempt to solve the tribal problem by other means than striking, often feebly, at the elusive nomads in the hope that they would be compelled to obedience. Midhat (*see* Midhat Pasha) won his reputation as a reformer in Baghdad (1869–72) by imposing conscription and founding municipalities and administrative councils and by inaugurating a policy of land settlement. His aim was to wean the tribes from nomadism by selling state lands to their sheikhs upon easy terms giving security of tenure; where the sheikhs became landlords, as among the Muntafiq, their power over their followers waned and by the beginning of the 20th century the nomad Arabs, though by no means tamed, were less powerful and dangerous.

Meanwhile the development of international communications had brought Mesopotamia and especially 'Iraq into the sphere of European politics. Great Britain sought a rapid route to India through a country where her Indian traders prospered and her consuls at Baghdad had been almost ambassadors since 1807. Captain Chesney brought the first steamer down the Euphrates from Birijik in 1836. A Turkish steamship company for river navigation was formed in 1855 and in 1861 the Lynch Company obtained a concession for the maintenance of two steamships on the Tigris, though the idea of the Euphrates line as a mail-route to India had been abandoned. The telegraph was introduced between 1861 and 1864; railway schemes, first mooted in 1842 and temporarily abandoned owing to the opening of the Suez canal were revived by the Germans, who in 1899 obtained the original concession for a railway to the Persian gulf. The subsequent effect of this great scheme upon international politics and particularly upon the relations of Great Britain, Germany and Turkey is described elsewhere (*see* Baghdad Railway; Turkey). The section from Baghdad to Samarra was completed on the eve of the World War. Schemes for the revival of prosperity by the repair of the old irrigation works began to interest the Turks, and the Hindiyah Barrage was completed by Sir W. Willcocks in 1913.

But though the latest Turkish rulers were more efficient in some respects than those of the 19th century they were equally unpopular. Their ideas on education went no further than the conversion of Arabs and Kurds into indifferent copies of the Turkish *effendi;* their justice was still venal; their customs officials were still corrupt and the accessible taxpayer still paid for those whom the tax-collector dared not assess or was bribed not to see. Hopes disappointed by the Turkish revolutionaries of 1908 began to turn to Arab nationalism and the outbreak of the World War found the Arabs of Mesopotamia with few exceptions either hostile to the Turk or, more often, indifferent to what might befall him. (For subsequent history *see* 'Iraq.) (P. Gr.)

Bibliography.—For the conditions since the Arab conquest, Guy le Strange, *Lands of the Eastern Caliphate* (1905), is especially useful. For the Mongol invasions, Leon Cahun, *Turcs et Mongols* (1907), is good. Of recent works the following are valuable: M. v. Oppenheim, *Vom Mittelmeer zum Persischen Golf* (vol. ii. 1889); D. G. Hogarth, *The Nearer East* (1902) *passim;* Sir M. Sykes, *Dar ul Islam* (1904) and *The Caliphs' Last Heritage* (1915) and, above all, S. W. Longrigg, *Four Centuries of Modern Iraq* (1925). The annual consular reports most nearly bearing on Mesopotamia were those for Aleppo, Mosul, Baghdad and Basra.

Maps.—The following deserve special mention: v. Oppenheim *op. cit.,* a most valuable large scale map in pockets of volumes; Sir M. Sykes, *Geog. Journal* xxx. op. p. 356 and xxxiv. op. p. 120; Hogarth, *op. cit.,* Longrigg, *op. cit.,* tribal map.

MESOPOTAMIA, OPERATIONS IN. The Anglo-Indian operations of 1914–18 in Mesopotamia were in their initial stages conceived on, comparatively speaking, modest lines. The object at the outset was merely (1) to protect the Anglo-Persian oil installations, (2) to occupy the greater part of the Basra vilayet so as to secure possession of the Shatt al 'Arab and the districts immediately round the head of the Persian gulf, and (3) to impress the Arabs and others in this region and in the territories intervening between the Ottoman empire and India. Steps had already been taken before relations between the Entente Powers and the Porte were actually broken off, and a brigade of the 6th Indian Div. had been despatched to an island near the head of the Persian gulf. Then, on Nov. 7, two days after the British declaration of war on Turkey, these advanced troops appeared in their transports at the mouth of the Shatt al 'Arab.

The fort guarding the entrance was taken, and the brigade encamped some miles up the stream on the right bank. On learning this, the Turks hurried all available forces down from Basra; but, the rest of the 6th Div. having arrived under Sir A. Barrett, they were on the 17th attacked and overthrown. Basra fell on the 21st, and Barrett then promptly pushed troops up to Al Qurna, which was taken on Dec. 9. As considerable Turkish reinforcements were arriving from Baghdad, he was not altogether comfortably situated; but the Osmanlis were not in aggressive mood, and the invaders were little interfered with during the first three months of 1915. The Indian Government in March decided to raise the expeditionary force to the strength of an army corps by adding the 12th Indian Div., and early in April Sir J. Nixon took over command from Sir A. Barrett, General Townshend at the same time taking over the 6th Division.

I. THE BRITISH ADVANCE UP THE TIGRIS

During the latter part of April the Turks showed a marked increase of activity; but all their offensive efforts were frustrated, and Nixon, encouraged by these successes, decided to occupy Imara, 60m. north of Al Qurna on the Tigris. The task was entrusted to Townshend, who carried it out by making free use of water transport for moving his troops, and who made himself master of the place on June 3, capturing 17 guns and 1,800 prisoners. Nixon now resolved on a blow against An Nasiriya, on the Euphrates, and the 12th Div. took possession of that town on July 25, capturing another 17 guns and 1,000 prisoners. The expeditionary force could then claim that it had effectually achieved the original object of the campaign.

Occupation of Kut.—The authorities at Simla accepted Nixon's proposal to advance up the Tigris to Kut al 'Amara—180m. into the heart of the enemy's country—and early in August Townshend, with the 6th Div., began pushing forward from

'Amara. On Sept. 15 he drove an advanced Turkish force out of a position on the right bank of the Tigris about 15m. from Kut, and on the 28th completely defeated the enemy a little farther on at Es Sinn, taking 1,650 prisoners, 13 guns, and much war material Kut was occupied, and the cavalry pursued the fleeing Osmanlis as far as Al 'Aziziya, half way to Baghdad.

Kut was a place of strategical importance, because at this point the Shatt al Hai, issuing from the Tigris, created a link with the Euphrates near An Nasiriya and provided the line of communications which would naturally connect Turkish forces on the lower Euphrates with Baghdad. It was furthermore the most populous spot between 'Amara and An Nasiriya on the one hand and Baghdad on the other.

The idea of pushing on as far as Baghdad had already taken shape even before the occupation of Kut. The August discomfiture in the Gallipoli Peninsula (*see* DARDANELLES CAMPAIGN), coupled with a belated realization that the Dardanelles venture would not succeed, had rendered the British Government eager for some dramatic achievement in Mesopotamia. The Indian Viceroy had advocated an advance on Baghdad when the start up the Tigris from 'Amara was materialising, and Townshend's triumph acted as a powerful stimulus to such aspirations. Nixon intimated early in October that he could open a road to Baghdad, under the circumstances then existing, but could not hold the city if it were taken. The military authorities at home, while admitting the possibility of capture, regarded permanent retention as out of the question with the limited numbers available, and they declared that if the place was to be held Nixon must be reinforced by two divisions. But, influenced by political considerations, the Government became insistent. Nixon was told on Oct. 31 that he might advance on the city.

First Baghdad Offensive Fails.—Townshend was unable to begin his advance for a fortnight, even after receiving the order to advance, owing to shortness of supplies and the need of organization for the hazardous effort. He advanced from Al 'Aziziya on Nov. 11, and on approaching Ctesiphon some days later he found the Turks to be assembled there in strong force and expecting reinforcements. He attacked them on the 21st and was at first successful; but additional Ottoman troops arrived during the fight and recovered much of the lost ground, Townshend's losses in the action proved very heavy and on the night of the 25th he moved off. He halted on the 29th. Next day the pursuing Turks came up and delivered a resolute attack, which was, however, beaten off, and after that the sorely tried little Anglo-Indian army was not seriously interfered with on its way to Kut, which was reached on Dec. 3. So, for the moment, ended the ill-advised Baghdad adventure.

II. THE SIEGE OF KUT

With the approval of the Home and Indian Governments, Nixon decided that Townshend was to remain where he was, although if he did so he was bound to be invested. They assumed, too readily, that he would be relieved before his supplies ran out. By Dec. 8 Kut was hemmed in on all sides. Its situation, in a deep loop on the left bank of the Tigris, rendered the place readily defensible against assault or siege approach, and the German Field-Marshal von der Goltz, who had just taken supreme command of the Ottoman forces in Mesopotamia, realized that unless it fell to an early assault the main Turkish task in this region would be to guard against a relief. Nur-ed-Din, the Turkish commander on the spot, had four divisions at his disposal, and on Dec. 10, 11, and 12 he delivered unavailing onsets upon the narrow front that was not covered by the river. After that the siege became a blockade, part of Nur-ed-Din's troops moved down the river some distance so as to confront any relieving force that might try to approach, and fortifications were erected.

Attempts at Relief.—Meanwhile the 7th and 3rd Indian Divisions had been detached from the Western Front in Europe, and began arriving in the middle of December in the Shatt al 'Arab. Gen. Aylmer took charge of the troops who were to undertake the relief of Kut, and units as they disembarked were pushed on to 'Amara with all speed and proceeded thence up the Tigris. In spite of a lack of artillery the Turks were driven out of their advanced position at 'Ali Gharbi, were again defeated at Shaikh Sa'ad and, after a further defeat, fell back to the lines of Umm al Hanna, 20m. from Kut on the left bank of the Tigris. When on Jan. 21 the relieving force essayed the storming of the Umm al Hanna position the effort failed and so numerous were the casualties that Aylmer felt compelled to pause in his offensive and to await reinforcements. About the same date Sir P. Lake succeeded Sir J. Nixon in the chief command.

Improvement of Organization.—Lake set himself to place Aylmer's line of communication on a better footing, to improve the medical arrangements, and to develop the wharves at Al Qurna and Basra. Material of all kinds was, however, deficient, and the Turks were in the meantime developing their lines of defence on both banks of the Tigris below Kut, rendering the task of a relieving force more and more difficult. The British Government had, on receipt of the bad news about Umm al Hanna, ordered the 13th Div. to proceed from Egypt to Mesopotamia; but to move these troops from Suez to the front of the Tigris necessarily took some weeks. Aylmer attempted no forward movement during February, but on the night of March 7–8, without waiting for the 13th Div., he advanced from near Shaikh Sa'ad against the Es Sinn position, intending a surprise.

This was on the right bank of the Tigris, less than 10m. from Kut, considerably higher up than Umm al Hanna and the defile caused by the Suwaiqiya marshes on the farther bank; but owing to the Turks holding that defile Aylmer's flotilla was prevented advancing above Umm al Hanna. When the assailants advanced against the reinforced Turks, they were beaten back and had to retire to Shaikh Sa'ad.

Surrender of Kut.—The garrison of Kut was already on much reduced rations; but Gen. Gorringe, who had succeeded Aylmer, could make no fresh attempt for nearly a month owing to transport and supply problems. On April 5, however, the 13th Div., under Gen. Maude stormed the Hanna lines and penetrated well into the defile on the left bank of the Tigris; but, when first the 7th Div. and then the 13th Div. attacked the Sanniyat lines at its farther end, they were in each case repulsed. A final effort was made by the 7th Div. on the 22nd against Sanniyat, which nearly succeeded. Finally, on the night of the 24th, a steamer loaded with provisions tried to run the blockade but failed, and on the 29th Kut, with its garrison of 9,000 British and Indian troops, surrendered. The efforts to save it had cost 24,000 casualties.

British Opinions.—A Royal Commission was set up a few months later to enquire into the operations that had taken place in Mesopotamia, and its conclusions were to the effect that the undertaking of a campaign on so ambitious a scale without adequate forethought and efficient preparations was worthy of blame; it also animadverted in strong terms on the very unsatisfactory character of the medical arrangements during the early stages of the venture.

III. THE BAGHDAD OFFENSIVE

Great developments took place on the Anglo-Indian line of communications, and at the base, during the summer. A reasonable amount of heavy artillery was gradually accumulated. An additional division arrived from India. Landing facilities at the ports were vastly improved. A change, moreover, took place in the chief command, for, after replacing Gorringe in charge of the forces at the front in July, Gen. Maude a few weeks later became commander-in-chief—*vice* Sir P. Lake, whose health had broken down. By the beginning of December Maude had been furnished with enough river craft, his supply system was sufficiently advanced and he had the necessary war material at his command to justify his embarking on offensive operations of a far-reaching kind, and on Dec. 13 he struck.

Disposition of the Forces.—Von der Goltz had left Mesopotamia and Khalil Pasha was now in command. It must be pointed out that Maude started his offensive with a force four times the strength of that which, under Townshend, had advanced to Ctesiphon a year earlier. His army astride of the Tigris was of necessity disposed in échelon, with its left (the II. Army Corps under

Gen. Marshall) about Es Sinn, and its right (the I. Army Corps under Gen. Cobbe) facing Sanniyat. Maude's plan was to push his left yet farther forward, to clear the right bank of the Tigris to well above Kut, and, when these dispositions should have taken effect, to force the lines of Sanniyat with his right.

Marshall opened the offensive by forcing the Shatt al Hai after a night march, and by capturing some of the Turkish defences which formed a bridgehead south of Kut. During the struggles that ensued, which lasted some weeks, Khalil's troops offered a stout resistance, so that although Maude's operations on the right bank of the Tigris were almost uniformly successful, they proceeded slowly and by successive stages. By the middle of February the whole of the Turkish entrenched camp on that bank was in Anglo-Indian hands, and the Ottoman troops had all withdrawn to the farther side of the great river. No sooner had this part of the programme been accomplished than Cobbe on the 17th attacked Sanniyat. The effort failed for the moment; but when the assault was repeated five days later it proved successful, and after a stern contest the formidable lines were at last carried. On the same day Marshall by a brilliant feat of arms forced a passage across the Tigris at Shumran, and no course was then left open to the Ottoman commander but to abandon Kut and retire in haste up the left bank of the river.[1] Maude's flotilla, hitherto blocked by Sanniyat, pushed up at once past Kut, and the Anglo-Indian army won a victory that went far towards wiping out the discomfitures of the previous year.

Turkish Retreat from Kut.—With his supplies guaranteed by the arrival of the water transport, Maude pressed on along the left bank of the Tigris on the heels of the fugitive Osmanlis. The river channel between Kut and Al 'Aziziya has many loops and bends, making it difficult for a naval force and a military force to act in concert; but on Feb. 26 the British gunboats after a smart action destroyed or captured practically the entire Turkish flotilla. The question of proceeding to Baghdad now arose. The army commander had from the outset contemplated the capture of that city after he should have expelled the enemy from Kut, and now received permission to carry out his plan. He found himself obliged to halt for some days at Al 'Aziziya, however, for fear of outrunning his supplies. On March 4 the Anglo-Indian army resumed its advance, and it was found that the Turks had fallen back behind the Diyala. Maude threw a bridge across the Tigris, and by March 11 Baghdad was in British hands.

The Turks had withdrawn northwards, but Maude allowed no pause in the offensive to take place. Cobbe pushed up the right bank of the Tigris, along which a stretch of railway ran from Baghdad as far as Samarra, heavily defeated an opposing force at Mushahida, while Marshall conducted a most successful campaign on the Shatt al 'Adhaim. Cobbe, moreover, completed the operations on the right bank of the Tigris by the capture of Samarra.

Further Progress Northwards.—The virtual conquest of Mesopotamia in a four and a half months' campaign had been brought about by the resolute execution of a plan of operations that was based on correct calculation of requirements—by a triumph of forethought on the part of a chief who always relentlessly followed up his successes in the field. Neither the stout resistance offered by the Ottoman troops nor the formidable defence works which they had elaborated around Kut had in reality proved the greatest stumbling block in Maude's path.

A railway was constructed from Kut to Baghdad, sanitation and policing were established in the capital, comforts and recreation were provided for the troops, and effective steps were taken to tap the supply resources of the fertile tracts that were in occupation of the army. In the late summer it appeared that the Turks under German instigation were contemplating an effort to recover Baghdad. This made Maude the keener to resume the offensive, and on Sept. 28 he struck his first blow by the capture of Ramadi on the Euphrates. This victory was followed up by successful operations in clearing the Jabal Hamrin, and by the occupation of Tikrit on the Tigris at the beginning of November. A few days later, however, the army commander was struck down by cholera, and he died on the 10th. He was succeeded by Sir W. Marshall.

IV. OPERATIONS IN 1918

The country traversed by the Tigris above Tikrit and extending north for a long distance is a sterile tract, hilly and broken at some points; the ordinary route from Baghdad to Mosul does not therefore follow the river but takes a direction to the east through Kifri and Kirkuk.

Maude's Plan.—Maude had intended to conduct his main advance by this line, but his death just at the moment when the project was to be put in execution created some delay; his successor, however, set troops in motion through the Jabal Hamrin in December, and by these Kifri was occupied in Jan. 1918. Having secured that point, Marshall suddenly set his extreme left wing on the Euphrates in motion in the middle of February, with the result that Hit was captured and the Turkish division which had retired up the river was surrounded, 5,000 prisoners and all its guns being taken. Transport difficulties were hampering the advance beyond Kifri on the other flank, but on April 29 the Ottoman forces were heavily defeated on the road to Kirkuk, losing 3,000 prisoners, and a week later Kirkuk was taken. Marshall, however, decided to withdraw his advanced troops in this quarter to Kifri, and active operations then practically ceased for five months.

An endeavour to preserve Baku from the Turks failed; but it at least prevented the despatch of some of the Ottoman troops in Transcaucasia to confront the Anglo-Indian army in northern Mesopotamia.

Closing Stages of the Campaign.—The fall of Baku occurred just when the season had again become suitable for active operations on and about the Tigris, and Marshall was now directed to occupy Mosul, an undertaking for which he had been preparing all the summer. The best of the Turkish divisions were at this time assembled astride of the Tigris at Al Fatha, the point where the river breaks through the Jabal Hamrin range of hills. Here a naturally formidable position had been strongly fortified, and another position a few miles higher up the river had also been prepared for defence. Marshall decided to throw an adequate force across the Ottoman communications between Al Fatha and Mosul. He entrusted the conduct of the operations as a whole to Gen. Cobbe, and arranged for a column to advance simultaneously from Kifri by Kirkuk towards Mosul.

Surrender of Ismail Hakki.—The final campaign in Mesopotamia began on Oct. 23 and it lasted only one week. Two cavalry columns, that with the shorter distance to cover being accompanied by some infantry, crossed the Jabal Hamrin many miles to the east of Al Fatha, passed the Little Zab a long way above its junction with the Tigris, and hit off that river several miles to the rear of the Turkish positions at and above Al Fatha. In the meantime the 17th Div. operating on the right bank and the 18th Div. operating on the left bank of the Tigris moved forward from above Tikrit. Finding himself threatened by the cavalry forces which were approaching the river between him and Mosul, Ismail Hakki Pasha, who commanded the Turks, now withdrew from the Al Fatha position to the one higher up at the confluence of the Little Zab, followed up by the two Anglo-Indian divisions. But the 18th Div., advancing on the left bank of the Tigris, forced a passage across the Little Zab on the 25th, thus turning Ismail Hakki's left flank, and the Pasha thereupon transferred his troops across the river and broke up his bridge.

On the 27th the 17th Div. was pressing the Turks, who were now all collected on the left bank of the river, and on the same day one of the cavalry columns forded the stream and began moving down that side of the channel against the enemy's rear. The 17th Div. was heavily engaged on the 28th before it finally made itself master of Ismail Hakki's position at the confluence of the Little Zab. That commander thereupon retreated to Sharqat, but on the morrow the last hope of the trapped Turkish

[1]In justice to earlier efforts and to the Turkish resistance, it should perhaps be pointed out that the British had now a four to one superiority of force over the enemy; further, that owing to the failure of the cavalry pursuit the Turkish forces escaped disaster and retreated in relatively good order.

force was destroyed when a relieving column that was approaching from Mosul was defeated by Cobbe's cavalry. All that day Ismail Hakki resisted the advance of the Anglo-Indian forces on Sharqat. On the morning of Oct. 30, however, just as the 17th Div. was about to launch a final attack, the white flag was displayed within the Turkish lines, and the whole of one Ottoman division, together with the bulk of another one, surrendered, 11,000 prisoners, 51 guns, and imposing stores of war material falling into the victor's hands.

The Kirkuk column had in the meantime been steadily working its way forward towards Mosul, almost unopposed, and Cobbe's forces were about to advance on the city from about Sharqat, when tidings came to hand of the signing of the Armistice. Mosul was occupied a week later, but the Ottoman power of resistance in this theatre of war was in any case shattered as a result of Marshall's final blow. Thus the long drawn-out struggle in Mesopotamia, which had proved so consistently favourable to the Anglo-Indian arms since Maude had launched his offensive at the close of 1916, ended in a blaze of triumph two years later, concurrently with what constituted the most sweeping tactical success that had been gained by either side during the course of the campaign.

(C. E. C.)

MESOXALIC ACID crystallises from water in deliquescent prisms and melts with partial decomposition at 119–120° C. Mesoxalic acid (Dihydroxymalonic acid), $(HO)_2C(CO_2H)_2$, was obtained originally by J. v. Liebig (1838) by alkaline hydrolysis of alloxan (*q.v.*) but the most convenient preparation is from sucrose, dextrose, laevulose, lactose, maltose or starch by oxidation with strong nitric acid. Although this oxidation has attracted attention for 150 years, only recently has it been shown that by this process 100 grams of sucrose yield 11 grams of sodium mesoxalate together with 40 grams of oxalic acid (F. D. Chattaway and H. J. Harris, 1922). Both anhydrous and hydrated esters are known. *Ethyl oxomalonate*, $O:C(CO_2 \cdot C_2H_5)_2$, a golden yellow liquid, boils at 103–108°/13 mm. and is obtained by the action of dry nitrous anhydride, N_2O_3, on ethyl malonate at 0° C. It changes into its colourless hydrate, ethyl dihydroxymalonate, which crystallises from benzene, chloroform and other organic solvents in plates or prisms melting at 57° C (O. Kamm and others, *Organic Syntheses*, New York, 1925). Mesoxaldialdehyde, CHO·CO·CHO, when anhydrous is a pale yellow brittle hygroscopic mass obtained in hydrated form by decomposing phorone diozonide with iced water. (*See* OZONIDES.)

MESOZOA, a small group of minute parasitic animals, comprising two classes: (1) the *Rhombozoa,* which are found only in the kidneys of Cephalopods, and (2) the *Orthonectida,* which infest Ophiurids, Polychaets, Nemertines, Turbellaria and possibly other groups.

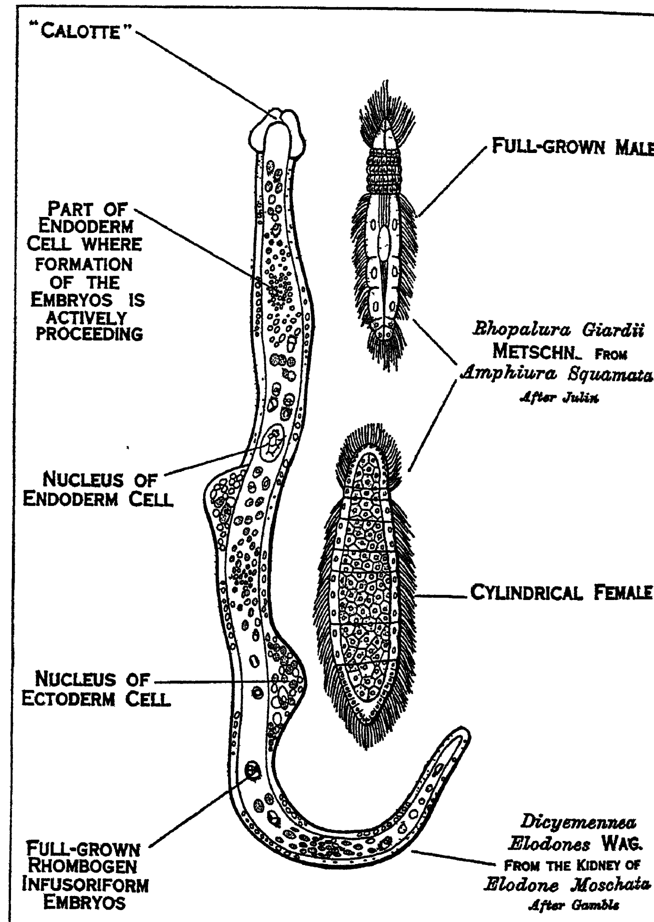
Class I. RHOMBOZOA.—These animals consist of a central cell from which certain reproductive cells arise, enclosed in a single layer of flattened and for the most part ciliated cells; some of them are modified at the anterior end and form the polar cap. There are two orders, the *Dicyemida,* with a polar cap, by which they are fixed in the renal cells of their host; and the *Heterocyemida,* with no polar cap and hence free. There are two phases. The "Nematogen" gives rise to vermiform larvae like itself which never leave their host. The "Rhombogen" gives origin to infusoriform larvae, which escape from their original host and probably infect new ones. A Rhombogen may secondarily develop into a Nematogen.

Class II. ORTHONECTIDA.—The Orthonectida contain animals with a central mass destined to form male and female reproductive cells surrounded by a single layer of ciliated ectoderm cells arranged in regular rings. Muscular fibrils occur between the outer and inner cells. The sexes are separate and unlike, and there are two kinds of females, cylindrical and flat, the latter from parthogenetic eggs. There are two genera, *Rhopalura* and *Staecharthrum*, the latter found in a Polychaet.

See Parker and Haswell, *Text-book of Zoology,* Vol. I. (1928).

MESOZOIC ERA, in geology, the name given to the period of time between the Palaeozoic and Kainozoic eras; it is synonymous with the older and less satisfactory term "Secondary" as applied to the major divisions of geological time. *See* GEOLOGY

MESQUITE or **HONEY LOCUST,** in botany, a tree, native of arid regions in the south-western United States and extending southwards to Chile and the Argentine Republic. It is known botanically as *Prosopis juliflora,* and belongs to the family Leguminosae (suborder Mimoseae). It reaches 40 or 50 ft. in height with a trunk usually not more than 6 to 12 in. in diameter, and divided a short distance above the ground into numerous irregular crooked branches. The remarkable development of its main root in relation to water-supply renders it most valuable as a dry-country plant; the root descends to a great depth in search of water, and does not branch or decrease much in diameter till this is reached. It can thus flourish where no other woody plant can exist, and its presence and condition afford indications of the depth of the water-level. When the plant attains the size of a tree, water will be found within 40 or 50 ft. of the surface;



FROM "THE CAMBRIDGE NATURAL HISTORY" (MACMILLAN)

THE TWO CLASSES OF MESOZOA, AS ILLUSTRATED BY DICYEMENNEA ELODONES, ON LEFT, AND RHOPALURA GIARDII, ON RIGHT. THESE PARASITES INHABIT, RESPECTIVELY, THE KIDNEY OF CEPHALOPODS AND BODY CAVITIES OF AMPHIURA

when it grows as a bush, between 50 or 60 ft.; when the roots have to descend below 60 ft., the stems are only 2 or 3 ft. high. These woody roots supply valuable fuel in regions where no wood of fuel value is produced above ground. The wood is almost indestructible in contact with soil, and is largely used for fence-posts and railway ties. The ripe pods supply a nutritious food; and a gum resembling gum arabic exudes from the stem.

An allied species *Prosopis pubescens,* a small tree or tall shrub, native of the arid regions of the south-western United States, from western Texas to southern Utah, Nevada and California

and south to Mexico, is known as the screw-bean or screw-pod mesquite from the fact that the pods are twisted into a dense screw-like spiral; they are used for fodder and are sweet and nutritious, but smaller and less valuable than those of the mesquite. The valuable fodder grasses of the prairies of the United States known as mesquite grasses, belong to the genus *Boutelona*.

See C. S. Sargent, *Silva of North America* (1892); G. B. Sudworth, *Forest Trees of the Pacific Coast* (1908); and W. L. Jepson, *Trees of California* (1909) and *Manual of the Flowering Plants of California* (1925).

MESS, a dish sent to table (late Lat. *missum*, past participle of *mittere*, to send or place in position). The term is also used of persons who are in the habit of eating their meals together, and thus of the parties into which a ship's company or a regiment is divided. Originally, a mess in this sense was a group of four persons sitting at one table and helped from the same dishes. In the Inns of Court, London, the original number is preserved, four benchers or four students dining together.

MESSAGE. A communication either verbal, written or printed, sent from one person to another. Message is the term generally applied to the official communications addressed by the heads of states to their legislatures at the opening of the session or at other times. These, though written, have the force of a face-to-face speech. The sessional and other messages to Congress of the president of the United States of America are printed State documents. Washington and John Adams delivered them in person, but this was discontinued by Jefferson.

In Scottish law a messenger-at-arms is an official appointed by Lyon-King-at-Arms to execute summonses and letters of diligence connected with the Court of Sessions and Court of Justiciary (*see* WRIT: *Scotland*). Technically the term "messenger" is given to an endless rope or chain, passing from the capstan to the cable so that the latter may be hauled in when the messenger is wound round the capstan; also to a similar contrivance for hauling in a dredge.

MESSAGER, ANDRÉ CHARLES PROSPER (1853–1929), French musician, was born at Montluçon on Dec. 30, 1853; he studied at Paris and in 1874 became organist at St. Sulpice. The production of his comic opera *La Basoche* in 1890 at the Opéra Comique (English version in London the following year) established his reputation, which was increased by the light operas as *Madame Chrysanthème* (1893), *Mirette* (1894), *Les Petites Michus* (1897), and *Véronique* (1898), the latter of which had a great success in London. He was conductor and director at the Opera Comique and was made a Commander of the Legion of Honour in 1927. He died Feb. 24, 1929.

MESSAGERIES MARITIMES, COMPAGNIE DES. This steamship company, the oldest French navigation enterprise, arose first from a Convention passed on Feb. 28, 1851 with the Minister of Finance, "for the establishment and exploitation of a maritime postal service in the Mediterranean." The first sailing under the Messageries flag was the departure of the "Hellespont" for Civita Vecchia on Sept. 9, 1851. On Jan. 19, 1852 the Compagnie des Services Maritimes des Messageries Nationales was constituted and was authorised as an active company by a decree of the President of the Republic, dated Jan. 22, 1852. Its present name was adopted on Aug. 1, 1871.

The first regular lines of the company were from Marseilles by Malta and Italy to Constantinople and Alexandria and in 1853 the company extended its services to different parts of Greece. In the following year the services to Algeria and Tunis were instituted and in 1855, the 16 original ships had grown to 58. In 1860 on the authority of the State, an Atlantic Mail line was inaugurated from Bordeaux to Senegal, Brazil and La Plata. In 1862 services to the chief ports of India, Indo-China, Dutch East Indies and China proper were instituted and two years later Reunion and Mauritius Islands were included. In 1866 the lines were extended to take in Japan. In 1872 the fleet owned by the company numbered 64 ships, in 1912, 62, representing a gross tonnage of 285,161. The earlier ships were not suited to the long voyages undertaken and their replacement was a long and tedious affair. In 1914 there were 60 steamers in the company's service (tonnage 284,000); a little over 10 years later the company had lost 22 ships (117,000 tons) in war and 31 ships from other causes, a total of 258,000 tons. In the same period 55 ships were added to the company (representing 469,000 tons gross).

In 1921 the entire organization of the company was altered. The whole fleet of passenger liners was transferred, by law of July 28, 1921, to a new company, called the Société des Services Contractuels des Messageries Maritimes. This new company runs regular passenger services from Marseilles to all parts of Asia and Africa, to Australia, to the islands of the Pacific via the Panama Canal, to all the important ports of Asia Minor and the Mediterranean, as well as circular tours, and is responsible for the fulfilment of the postal services.

The Compagnie des Messageries Maritimes however still exists, but is now mostly concerned with cargo-boats. These sail regularly from Marseilles or the north of the Continent, to the principal ports in the world, with the exception of those in America. It also possesses several coastal services in Australia, Indo-China and Madagascar. (J. D. DU S.)

MESSAGE-STICKS. Amongst the natives of Australia, a branch of a tree is taken and notches made upon it in the presence of the messenger, who receives his instructions while they are being made. The messenger carries the message-stick in a net bag, and on arriving at the camp to which he has been sent he hands it to the headman at some place apart from the others, saying to him, "So-and-so sent you this," and he then gives his message, referring as he does so to the notches on the stick.

The American Indians used a notched stick to record various incidents, such as the number of days spent on an expedition, the number of enemies slain, and the like.

See B. Spencer and Gillen, *Native Tribes of Northern Australia* (1914).

MESSALLA CORVINUS, MARCUS VALERIUS (64 B.C.–A.D. 8), Roman general, author and patron of literature and art. He was educated partly at Athens, together with Horace and the younger Cicero. In 43 B.C. he was proscribed, but escaped to the camp of Brutus and Cassius. After the battle of Philippi (42) he went over to Antony, and later supported Octavian. In 31 Messalla was appointed consul in place of Antony, and took part in the battle of Actium. He subsequently held commands in the East, and suppressed the revolted Aquitanians; for this he celebrated a triumph in 27.

Messalla restored the road between Tusculum and Alba, and many handsome buildings were due to his initiative. He was a patron of letters after the model of Maecenas, and his immediate circle included Tibullus and the poetess Sulpicia. He was a friend of Tibullus and a patron of Ovid. There are two panegyrics on him by unknown authors, one printed in the poems of Tibullus as iv. 1, the other included in the *Catalepton*, the collection of small poems attributed to Virgil.

As an orator, he followed Cicero instead of the Atticizing school, but his style was affected and artificial. Later critics considered him superior to Cicero, and Tiberius adopted him as a model.

Monographs by L. Wiese (Berlin, 1829), J. M. Valeton (Gröningen, 1874), L. Fontaine (Versailles, 1878); H. Schulz, *De M. V. aetate* (1886); "Messalla in Aquitania" by J. P. Postgate in *Classical Review*, March 1903; W. Y. Sellar, *Roman Poets of the Augustan Age. Horace and the Elegiac Poets* (Oxford, 1892), pp. 213 and 221 to 258; the spurious poem ed. by R. Mecenate (1820).

MESSALLINA, VALERIA, the third wife of the Roman emperor Claudius (*q.v.*). She was notorious for her profligacy, avarice and ambition, and exercised a complete ascendancy over her weak-minded husband, with the help of his all-powerful freedmen. During the absence of Claudius from the city, Messallina forced a handsome youth named Gaius Silius to divorce his wife and go through a regular form of marriage with her. The freedman Narcissus, warned by the fate of another freedman Polybius, who had been put to death by Messallina, informed Claudius of what had taken place, and persuaded him to consent to the removal of his wife. She was executed in the gardens of Lucullus, which she had obtained on the death of Valerius Asiati-

cus, who through her machinations had been condemned on a charge of treason. She was only 26 years of age. By Claudius she was the mother of the unfortunate Britannicus, and of Octavia, wife of Nero.

See Tacitus, *Annals*, xi. 1–38; Dio. Cassius lx. 14–31; Juvenal vi. 115–135, x. 333, xiv. 331; Suetonius, *Claudius*; Merivale, *Hist. of the Romans under the Empire* (1850, etc.) ch. 50; A. Stahr, "Agrippina" in *Bilder aus dem Alterthume*, iv. (1865).

MESSAPII, the name of an ancient tribe which inhabited, in historical times, the south-eastern peninsula or "heel" of Italy, known variously in ancient times as Calabria, Messapia, and Iapygia. Their chief towns were Uzentum, Rudiae, Brundisium, and Uria. They are mentioned (Herod. vii. 170) as having inflicted a serious defeat on the Greeks of Tarentum in 473 B.C. Herodotus adds a tradition which links them to the Cretan subjects of "King Minos." Their language is preserved for us in a scanty group of perhaps 50 inscriptions, of which only a few contain more than proper names, and in a few glosses in ancient writers. Very few originals of the inscriptions are still in existence, though some few remain in the museum at Taranto.

The inscriptions, so far as it is safe to judge from the copies of the older finds and from facsimiles of the newer, are all in the Tarentine-Ionic alphabet. For limits of date, 400–150 B.C. may be regarded as probable. The genitival character of the endings *aihi* and *ihi* and the conjunctional value of *inthi* have been ascertained. Even now, hardly more than a few words can be said to have been separated and translated with certainty—*kalatoras* (masc. gen. sing.), "of a herald" (written upon a herald's staff which was once in the Naples Museum); *aran* (acc. sing. fem.), "arable land"; *mazzes*, "greater" (neut. acc. sing.), the first two syllables of the Latin *maiestas;* while *tepise* (3rd sing. aorist indic.), "placed" or "offered"; and forms corresponding to the article (*ta*-=Greek τὸ) seem also reasonably probable.

Some phonetic characteristics of the dialect may be regarded as quite certain: (1) the change of the original short *ŏ* to *ă*; (2) of final *-m* to *-n;* (3) of *-ni- -ti- -si-* respectively to *-nn- -tθ* and *-ss-;* (4) the loss of final *d*, and probably of final *t;* (5) the change of original *dh* to *d* (*anda*=Gr. 'έθα) and *bh* to *b;* (6) *-au-* before (at least some) consonants becomes *-ā-*. (7) The form *penkaheh* is probably identical with the Oscan stem *pompaio*, which is a derivative of the Indo-European numeral **penque* "5."

The proper names in the inscriptions show the regular Italic system of gentile nomen preceded by a personal praenomen; and some inscriptions show the interesting feature which appears in the Tables of Heracleia of a crest or coat of arms, such as a triangle or an anchor, peculiar to particular families. The same reappears in the Iovilae (*q.v.*) of Capua and Cumae.

MESSEL, RUDOLPH (1848–1920), Anglo-German chemist, was born at Darmstadt on Jan. 14, 1848, and educated at the universities of Zürich, Heidelberg and Tübingen. He came to England in 1870, and took up industrial chemistry, making notable discoveries, especially in connection with the "contact" process for obtaining sulphuric acid (*q.v.*) for use in dye manufacture. He was elected a fellow of the Royal Society in 1912; and died in London on April 18, 1920.

MESSENE, an ancient Greek city, capital of Messenia, founded in 369 B.C., after the battle of Leuctra and the first Theban invasion of the Peloponnese, by the combined Theban and Argive armies and exiled Messenians, invited to found a state independent of Sparta. The site, chosen by Epameinondas, lay on the western slope of the mountain which dominates the Messenian plain. The peak Ithome (2,630 ft.) served as acropolis. Messene remained important under the Romans, but we hear nothing of it in mediaeval times. The hamlet of Mavromati occupies a small part of the site.

Pausanias describes the city, its temples and statues, its springs, its market-place and gymnasium, its place of sacrifice, the tomb of Aristomenes (*q.v.*) and the temple of Zeus Ithomatas on the summit of the acropolis. What chiefly excited wonder were the fortifications of Messene, which excelled all others of the Greek world. Of the wall, some 5½ m. in extent, considerable portions remain. Almost the entire circuit can still be traced. The wall is flanked by towers about 31 ft. high: these have two storeys and are entered by doors on a level with the top of the wall reached by flights of steps. Of the gates only two can be located, the eastern or Laconian, and the northern or Arcadian gate. The theatre, the stadium, the council chamber or bouleuterion, and the propylaeum of the market also remain, while on the shoulder of the mountain are the foundations of a small temple, probably that of Artemis Laphria.

Bursian, *Geographie von Griechenland*, ii. 165 *sqq.*

MESSENIA (Gr. Μεσσήνη or Μεσσηνία), the S.W. district of the Peloponnese, bounded on the E. by Mt. Taÿgetus, on the N. by the river Neda and the Arcadian Mountains, on the S. and W. by the sea. Its area is some 825,000 acres. Historically and economically important is the great plain, watered by the river Pamisus (mod. Pirnatza), the most fertile tract in Greece, producing oranges, citrons, almonds, figs, grapes and olives. The plain is bounded N. by the Nomian Mountains (mod. Tetrási, 5,210 ft.); W. by the mountains of Cyparissia (4,000 ft.), which attains 3,160 ft. in Mt. Mathía (mod. Lykódimo). Off the south coast of the S.W. peninsula lie the three Oenussae islands and the islet of Theganussa (Venetikó).

At the present day Messenia forms a department with its capital at Kalamata, and a population numbering (according to the census of 1907), 127,991.

HISTORY

The earliest inhabitants of Messenia are said to have been Pelasgians and Leleges (*qq.v.*). Then came an Aeolo-Minyan immigration. In the Homeric poems eastern Messenia is represented as under the rule of Menelaus of Sparta, while the western coast is under the Neleids of Pylos. Dorians under Cresphontes invaded the country from Arcadia and extended their rule over the whole district. The Dorians blending with the previous inhabitants produced a single Messenian race with a strong national feeling. But the fertility of the soil, the warm and genial climate, the mingling of races and the absence of opposition, combined to render the Messenians no match for their hardy and warlike neighbours of Sparta. War broke out which ended in the subjection of Messenia to Sparta (*c.* 720 B.C.). Two generations later the Messenians revolted, and under the leadership of Aristomenes (*q.v.*) kept the Spartans at bay for some 17 years; those Messenians who did not leave the country were reduced to the condition of helots.

Revolt broke out again in 464 B.C.; the insurgents defended themselves for some years on the rock-citadel of Ithome, but eventually they had to leave the Peloponnese and were settled by the Athenians at Naupactus. After the battle of Leuctra (371 B.C.) Epameinondas invited the exiled Messenians to return to their country. The city of Messene (*q.v.*) was founded in 369 B.C. to be the capital of the country and, like Megalopolis in Arcadia, a check on Sparta. A great part of the land remained very sparsely peopled, and Messenia never again became really powerful. After the fall of the Theban power it became an ally of Philip II. of Macedon. Subsequently it joined the Achaean

League, and we find Messenian troops fighting at Sellasia. The Spartan tyrant, Nabis, succeeded in taking the city but was forced to retire by Philopoemen and the Megalopolitans. It again joined the Achaean league, though much weakened by the loss of Abia, Thuria and Pherae, which entered the league as independent members. In 146 B.C. the Messenians were brought under Roman sway by L. Mummius.

In the Middle Ages Messenia shared the fortunes of the rest of the Peloponnese. It was overrun by Slavic hordes, and was one of the battlefields of Byzantines, Franks, Venetians and Turks, who struggled for the possession of the Morea, as recalled by the ruins of the mediaeval strongholds of Kalamata, Coron (anc. *Asine*, mod. Korone), Modon (*Methone*) and Pylos.

MESSIAH (Dan. x. 25, 26) and **MESSIAS** (John i. 41; iv. 25). The word answers to the Hebrew *ha-māshīah*, "the anointed." There can be no doubt that magical power was ascribed to the anointing oil; the king was thereby rendered sacrosanct (1 Sam. xxiv. 6 *sqq.*; 2 Sam. i. 14 *sqq.*; iv. 9 *sqq.*), and was considered to be endowed with a special virtue. Thus, whoever cursed the king is stoned as though God Himself had been cursed (2 Sam. xix. 22). In ancient Egyptian cultus the priest, after he had solemnly saluted the gods, began the daily toilet of the god, which consists in sprinkling his image, clothing it with coloured cloths, and anointing it with oil (Erman, *Die aegyptische Religion*). In the magical texts of Babylonia a similar virtue was attached to oil: "bright oil, pure oil, resplendent oil that bestows magnificence on the gods . . . the oil for the conjuration (*siptu*) of Marduk" (Tallquist, *Maklu series*, tablet vii. col. 1, 31, *sqq.*; *cf.* Gressmann, *Der Ursprung der israelitisch-judischen Eschatologie*). We have evidence from the Tell el-Amarna tablets that the anointing of kings was known in Egypt and Syria *c.* 1400 B.C.

On the intimate relation which in primitive times subsisted between the sorcerer and the king, *see* Priest. "Classical evidence points to the conclusion that in prehistoric ages . . . the various tribes or cities were ruled by kings who discharged priestly duties" (Frazer, *Early History of Kingship*). Thus the early kings of Assyria were priests of Assur (Asur), the tutelary deity of Assyria. Tiglath-Pileser I. (*c.* 1100 B.C.) calls his predecessors Samsi-Adad and Ismi-Dagan, *issakku* (pa-te-si) of God Assur. Later kings, *e.g.*, Shalmaneser II. and Assur-bani-pal call themselves by the more definite title of *sangu* of Assur. The Hebrew word with the article prefixed occurs in the Old Testament only in the phrase "the anointed priest" (Lev. iv. 3, 5, 16, vi. 22). But "Yahweh's anointed" is a common title of the king of Israel, applied in the Historical books to Saul and David, in Lam. iv. 20 to Zedekiah, and in Isa. xlv. i. extended to Cyrus.

The definite emergence of the Messianic hope in the strict sense can hardly be traced in the Old Testament with absolute certitude. Perhaps the clearest expression of such an idea is to be found in Isaiah ix. 1–6 and xl. 1–9. Here it is to be noted that the former of these passages apparently gives up the connection of the Messiah with the Davidic dynasty, though the latter reaffirms this.

It is important to notice that what may be called the Messianic age is often represented in the prophets without any personal Messiah. So the great Judaean prophets of the eighth century connect the salvation of Israel with the rise of a Davidic King, full of Yahweh's spirit, in whom all the energies of Yahweh's transcendental kingship are as it were incarnate (Isa. x. 6 *seq.*; xi. 1 *seq.*; Micah v.). This conception, however, is not one of the constant elements of prophecy; other prophecies of Isaiah's look for the decisive interposition of Yahweh in the crisis of history, without a kingly deliverance. Jeremiah again speaks of the future David or righteous sprout of David's stem (xxiii. 5 *seq.*; xxx. 9) and Ezekiel uses similar language (xxxiv., xxxvii.); but that such passages do not necessarily mean more than that the Davidic dynasty shall be continued in the time of restoration under worthy princes seems clear from the way in which Ezekiel speaks of the prince in xli., xlvi. The beginning of the process can probably be traced within the canon itself, in the book of Joel and the last chapters of Zechariah; and if this be so, we see from Zech. ix. that the picture of the ideal king claimed a place in such constructions. In popular expectation the national Messiah was to be a scion of the house of David. Born at Bethlehem (Mich. v. 2) and destined to redeem Israel from the power of its foreign oppressors.

Carefully to be distinguished from the above is the idea of the heavenly Messiah which meets us in certain Apocalyptic books. Though the "Son of Man" of Daniel vii. 14 does not appear to be a strictly Messianic figure, nevertheless it has exercised an important influence on Messianic doctrine. This is a very remarkable development, and one that is of great importance for the proper understanding of New Testament doctrine.

The idea of a heavenly being who thus comes to view as a feature in old apocalyptic tradition is the source of the conception of the heavenly Messiah—the Son of Man—of the Similitudes of the Book of Enoch (1 Enoch xxxvii.–lxx.). The heavenly being "like unto a Son of Man" of Dan. vii. was in all probability identified by the author of Daniel with Israel's angel-prince Michael; this angelic being was later, it would seem, invested with Messianic attributes, and so became the pre-existent heavenly Messiah of the Book of Enoch, who is to judge both men and angels. His standing designation in the Similitudes is "this (or that) Son of Man" seldom "the Son of Man." In other passages he is called "the Righteous One" (xxxviii. 2, liii. 6, etc.), "the Elect One (xxxix. 6, xl. 5, etc.); "the Elect One of righteousness and of faith" (xxxix. 6), and "God's 'Anointed' " (*i.e.*, Christ) (xlviii. 10, lii. 4).

Unlike the earthly Messiah of the national hope, who is born on earth of the seed of David, the angelic Son of Man of the Similitudes has his home in heaven "under the wings of the Lord of the Spirits" (xxxix. 7). He is pre-existent in heaven (xlv. 1, *seq.*); his name was named "before the sun and the signs were created, and before the stars of the heaven were made" (xlvii. 3); he was "chosen and hidden" before the Lord of the Spirits, "before the creation of the world" (xlviii. 6). A real pre-existence of the Heavenly Messiah is here taught. It is noteworthy that emphasis is laid on the pre-existence of his name. The wonderful Name of the Messiah is already dwelt upon in Isaiah ix. 6, and in the LXX. of Psalm lxxi. (=Heb. lxxii.) 17 the same doctrine is unmistakably affirmed: His (Messiah's) Name endures before the sun.

The wonderful and mysterious character of the Name is sometimes dwelt upon (*cf.* Ascension of Isaiah viii. 7, ix. 5), a feature which re-appears in the Johannine Apocalypse, where the Messiah bears a "name written which no man knoweth but he himself" (Rev. xix. 12).

It would seem that in this idea Jesus found the most adequate expression of his own Messianic consciousness but he profoundly modified the conception by combining it with the idea of the "suffering servant" of Isaiah liii. All the evidence suggests that the idea of the heavenly Son of Man was not commonly known or understood in a Messianic sense; *cf.* John xii. 34, where the multitude in Judea are represented as asking in surprise "Who is this Son of Man?" Possibly it originated in Galilee where Jesus and his disciples became acquainted with it.

MESSINA, city, Sicily, 7 m. south-south-west of the promontory of Faro (anc. *Promontorium Pelorum*) which forms the north-east angle of the island, capital of the province of Messina and seat of an archbishop. Pop. (1921) 114,051 (town); 176,485 (commune). The site curves round the harbour, between it and the strongly fortified hills of Antennamare (highest point 3,707 ft.). The straits, which take their name from the town, are here about 3½ m. wide (over 2 m. at Faro). The passage through them is extraordinarily beautiful. It was a flourishing and beautiful city

when in 1908 early in the morning of December 28 one of the most disastrous earthquakes ever recorded destroyed it totally. At Messina about 84,000 lives were lost: the damage was done chiefly by the shock and by the fires which broke out afterwards. The seismic wave which followed did vast damage elsewhere along the strait, notably at Reggio, Calabria, which was also totally destroyed. (*See* also EARTHQUAKE.)

The façades of buildings at Messina in great part withstood the earthquake, but the remainder of the buildings was destroyed. The cathedral, begun in 1098, had a fine Gothic façade: the interior had mosaics in the apses dating from 1330, and the nave contained 26 granite columns, and a fine wooden roof of 1260. The rest was in the baroque style; the high altar (containing the supposed letter of the Virgin Mary to the people of Messina), richly decorated with marbles, lapis lazuli, etc., was begun in 1628 and completed in 1726. The building is now being carefully restored. The new residential quarters, occupying a far larger space to the south of the old town, have very wide streets and low buildings: while the public buildings are being re-erected rapidly on the old site. A museum has also been formed containing the works of art that were saved. The importance of Messina is due to its harbour, a circular basin open on the north only, formed by a strip of land curving round like a sickle, from which it took its original name, Zancle (*ζάγκλον*, or rather *δάγκλον*, the Sicilian equivalent of the Greek *δρέπανον*, from which Trapani is derived).

Zancle was first founded by pirates from Cumae, and resettled from Cumae under Perieres, and from Chalcis under Crataemenes, in the first quarter of the 8th century B.C. Mylae was occupied very soon afterwards, but the first regular colony of Zancle was Himera (648 B.C.). After the capture of Miletus by the Persians in 494 B.C. Milesians and Samians joined Anaxilas of Regium in occupying Zancle in the absence of its king Skythes, and the name was changed to Messene, which is found on coins of the Samian type. About 480 Anaxilas established his authority at Messene. In 426 the Athenians gained the alliance of Zancle, but failed to obtain it in 415.

Messina fell into the hands of the Carthaginians (397 B.C.). They destroyed the city, but Dionysius recaptured and rebuilt it. Timoleon finally expelled the Carthaginians in 343 B.C. In the wars between Agathocles of Syracuse and Carthage, Messina supported the latter. After Agathocles' death, his mercenaries, the Mamertines, treacherously seized the town about 282 B.C. They came to war with Hiero II. of Syracuse and obtained help from Rome. This led to the first Punic War. At its close (241 B.C.), Messina became a free and allied city. During the civil wars Messina held with Sextus Pompeius; and in 35 B.C. it was sacked by Octavian's troops, but it continued to flourish as a trading port, as the discovery of a large Roman necropolis (1st–3rd cent. A.D.) shows. In the division of the Roman empire it belonged to the East; and in A.D. 547 Belisarius collected his fleet here before crossing into Calabria. The Saracens took it (831), and it was the first permanent conquest of the Normans (1061).

In 1190 Richard I. of England, with his crusaders, passed six months in Messina. He quarrelled with Tancred, the last of the Hauteville dynasty, and sacked it. In 1194, with Sicily it passed to the Hohenstaufen under Henry VI., who died there in 1197; and after their fall was contended for by Peter I., of Aragon, and Charles I., of Anjou. At the time of the Sicilian Vespers (1282), Messina defended itself against Charles; Ruggiero di Loria defeated the French off the Faro; and from 1282 to 1713 Messina remained a possession of the Spanish royal house. In 1571 the fleet fitted out by the Holy League against the Turk assembled at Messina, and in the same year its commander, Don John of Austria, celebrated a triumph in the city for his victory at Lepanto (statue in the Piazza dell' Annunziata). Internal quarrels between the Merli, or aristocratic faction, and the Malvezzi, or democratic faction, fomented by the Spaniards, helped to ruin the city (1671–1678). The French at first came to its aid, but then abandoned it. In 1743 the plague carried off 40,000 inhabitants. The city was partially destroyed by earthquake in 1783. During the revolution of 1848 against the Bourbons of Naples, Messina was bombarded for three consecutive days. In 1854 the deaths from cholera numbered about 15,000. Garibaldi landed in Sicily in 1860, and Messina was the last city in the island taken from the Bourbons and made a part of united Italy under Victor Emmanuel.

Messina was the birthplace of Dicaearchus, the historian (*c.* 322 B.C.); Aristocles, the Peripatetic; Euhemerus, the rationalist (*c.* 316 B.C.); Stefano Protonotario, Mazzeo di Ricco and Tommaso di Sasso, poets of the court of Frederick II. (A.D. 1250); and Antonello da Messina, the painter (1447–1499). During the 15th century the grammarian, Constantine Lascaris, taught in Messina; and Bessarion was for a time archimandrite there. (T. A.)

MESSINA, STRAITS OF. The straits between Sicily and Italy, about 2 m. wide at the north extremity and 8 m. at the south, while the line taken by the trainferry between Reggio di Calabria Villa S. Giovanni and Messina is 5 m. long. At the north end a lowering of the water level of about 300 ft. would produce a small isthmus; and the origin of the separation of Sicily and Italy may be post-palaeolithic. (*See* MALTA.) The straits were much feared by sailors in antiquity, especially owing to the rocks and whirlpools known as Scylla and Charybdis (*q.v.*); and the currents do, as a fact, present considerable difficulties, especially in a strong wind. The main current runs from south to north, and the subsidiary current in the reverse direction. They generally alternate every six hours, and are affected by the sun, the moon, and the winds. When the current runs from south to north, the level of the water in the straits falls from 6 to 8 in. and rises as much with the other current: when they are specially strong, they tear seaward from the bottom, and sometimes throw up fish with atrophied or abnormal eyes, and with organs for the production of phosphorescence. Some 140 kinds of fish are caught in the straits, and they are especially rich in *plankton*. There is an Institute of Marine Biology at Messina, the straits being naturally a very favourable spot for such studies, as so many fish must pass through when migrating. Much damage was done on both sides of the straits by the sea movement produced by the earthquake of Dec. 28, 1908.

MESSINES, BATTLE OF, 1917. This British victory in the World War (*q.v.*), one of the rare examples of an attack conceived and mounted on a true siege-warfare basis, is described under YPRES, BATTLES OF, 1917.

MESSIRIA: *see* BAKKARA.

MESSUAGE, in law, a term equivalent to a dwelling-house, and including outbuildings, orchard, court-yard and garden.

MESTIZO, a term originally meaning a half-breed, one of whose parents was Spanish, and now used occasionally of any half-breed, but especially to denote persons of mixed Spanish (or Portuguese) and American Indian blood (Span. from Port. *Mestiço*, Lat. *miscere*, to mix).

MEŠTROVIĆ, IVAN (1883–), Yugoslav sculptor, was born at Vrpolje in Slavonia, the son of Croatian peasants. The rudiments of his art were taught him by his father and at the age of 13 he was apprenticed to a marble cutter at Split (Spalato), and three years later entered the Vienna Academy where he studied under Hellmer until 1904. He exhibited at the Vienna Secession, at the Austrian exhibition at Earl's Court, London (1906), at Munich, Venice and Paris—where he attracted the notice of Rodin. He was largely responsible for a nationalist artistic movement which included the sculptors Rosandić and Dujan Penić, the painter Rački and the architect Plečnik, and which culminated in the exhibition at Zagreb in 1910 and the Rome international exhibition of 1911.

Meštrović also made a large number of religious reliefs and figures in walnut, of which two Pietà reliefs, one in the National Gallery of British Art and one in private possession, are typical of his bold cutting and great powers of design. His portraits include those of his mother (1908), Madame Banac (1913 and 1915), his wife (1915), Sir Thomas Beecham (1915, in the National Gallery of British Art), Lady Cunard (1915) and Miss St. George (1915). Among his later works the most important are the richly decorated Račić memorial chapel at Cavtat, near Dubrovnik (Ragusa), Dalmatia (1920–22), the designs for the projected mausoleum of Bishop Petar Petrović Njegoš, the Montenegrin poet, to be erected on the summit of Mount Lovćen

(1924), and figures of St. Francis of Assisi and "The Artist's Mother in Prayer" (1925). In 1924 exhibitions of his work were held at the Fine Art Society in London and the Brooklyn Museum.

See M. Curčin, *Ivan Meštrović, a Monograph*, with bibliography and list of works (1919). For details of the Račić Chapel, see *Deutsche Kunst und Dekoration*, LII. (1923).

META, the Latin word for the goal which formed the turning-point for the chariot races in the Roman circus. The metae consisted of three conical pillars resting on a single podium.

METABOLIC DISEASES. All disease is primarily due to alterations, quantitative or qualitative, in the chemical changes in the protoplasm of some or all of the tissues of the body.

Obesity (*see* also CORPULENCE).—It is as fat that the surplus food absorbed is stored in the body; but the power of storing fat varies enormously in different individuals, and in some is pathological. The reasons of this are probably manifold. One undoubted cause is taking a supply of food in excess of the energy requirements of the individual. The amount of food may be *absolutely* large, or large *relatively* to the muscular energy evolved in mechanical work or in heat-production; but in either case, when fat begins to be deposited, the muscular activity of the body tends to diminish and the loss of heat from the surface is reduced; and thus the energy requirements become less, and a smaller diet is sufficient to yield the surplus for further storage of fat. Fat is formed from carbo-hydrates, and possibly indirectly from proteids (*see* NUTRITION). Individuals probably vary in their mode of dealing with these substances, some having the tendency to convert them to fat, some to burn them off at once. Probably the difference is to be sought in endocrine action. In all cases the fat stored is available as a source of energy, and numerous fat "cures" consisted in giving enough proteids to cover the requirements of the body, with fats and carbohydrates insufficient to meet the energy requirements of the individual. This is illustrated by the dietaries of some of the best known of these "cures":—

	In grams per diem			
	Proteid	Fat	Carbo-hydrates	Calories
Banting's cure	172	8	81	1112
Oertel's „	156–170	25–45	75–120	1180–1608
Ebstein's „	102	85	47	1401

In a normal individual in moderate muscular activity about 3,000 calories per diem are required (*see* DIETETICS), and therefore under the diets of these "cures," especially when accompanied by a proper amount of muscular exercise, the fats stored in the body are rapidly used up. At the present time such diets are combined with administration of thyroid extract (*see* MYXOEDEMA, below).

Diabetes (*see* also DIABETES MELLITUS; INSULIN), as distinguished from transitory glycosuria, is produced by an inability of the tissues to use the sugar presented, which thus accumulates in the blood and escapes in the urine. One great source of energy being unavailable, the tissues have to use more fats and more proteids to procure the necessary energy, and hence, unless these are supplied in very large quantities, there is a tendency to emaciation.

The power of storing and using sugar in the tissues is strictly limited, and varies considerably in healthy individuals. Normally, when about 200g. of glucose are taken at one time, some appears in the urine within one hour. In some individuals the taking of even 100g. leads to a transient glycosuria, while others can take 250g. or more and use it all. But even in the same healthy individual the power of using sugar varies at different times and in different conditions, muscular exercise markedly increasing the combustion. Again, some sugars are more readily used than others, and therefore have a less tendency to appear in the urine when taken in the food. Milk-sugar and laevulose appear in the urine more readily than glucose. This power of using sugar possessed by an individual is now known to depend upon a due provision of insulin in ordinary cases, but glycosuria after poisoning by carbon monoxide or phloridzin or after puncture of the fourth ventricle of the brain is susceptible of other explanations.

The disease may be divided into two forms:—

1. *Slight Cases.* The individual can use small quantities of sugar, but the taking of larger amounts causes glycosuria. Supposing that the energy requirements of an individual are met by a diet of—

Proteid	100 g.	410 Calories
Fat	100 "	930 "
Carbohydrate	400 "	1,640 "
		2,980

then if only 100g. of glucose can be used, the energy value of 300g., *i.e.*, 1,230 calories, must be supplied from proteids and fats. To yield this, 300g. of proteids or 132g. of fats would be required. If these are not forthcoming in the diet, they must be supplied from the tissues, and the individual will become emaciated; hence a diabetic on an ordinary diet is badly nourished, and hence the huge appetite characteristic of the disease.

2. *Grave Cases.* From the products of the splitting of proteids sugar can be formed, probably in the liver, and in the more serious form of the disease, even when carbohydrates are excluded from the food, some of the sugar thus formed escapes consumption and may be excreted. Theoretically, 1grm. of nitrogen will be set free for each 7·5g. of glucose formed. In the urine of grave cases of diabetes on a proteid diet, the proportion of nitrogen to sugar is about 1 to 2. This may mean that the theoretically possible amount of sugar is not yielded, or that some of the sugar formed is used in the economy. Both hypotheses may be correct, but the latter is supported by the fact that even in grave cases the decomposition of proteid may be diminished by giving sugar, and that in muscular exercise the proportion of sugar may fall.

In the course of the disease the amount of sugar which the tissues can use varies from day to day. It is in the utilization of glucose—the normal sugar of the body—that the tissues chiefly fail. Many diabetics are able to use laevulose, or the inulin from which it is derived, and lactose (milk-sugar) to a certain extent. Under the administration of these sugars, however, the excretion of glucose may be increased, the tissues, apparently by using the foreign sugar, allowing part of the glucose which they would have consumed to escape.

The increased decomposition of proteid leads to the appearance of a large quantity of nitrogen in the urine—*azoturia*—and to the formation of various acids. Sulphuric acid and phosphoric acid are formed by oxidation of the sulphur and phosphorus in the proteid molecule. Organic acids of the lower fatty acid series β oxybutyric and aceto-acetic acid with their derivative acetone also appear. They are in part formed from proteids and in part from fats. To neutralize them ammonia is developed and hence the proportion of ammonia in the urine is increased. By the development of these various acids the alkalinity of the blood is diminished (acidosis). The development of these acids in large quantities precedes the onset of diabetic coma.

Disease of the Thyroid.—1. *Myxoedema.* The thyroid gland forms a material which has the power of increasing the metabolism of proteids and of fats; and when the thyroid is removed, a condition of sluggish metabolism, with low temperature and a return of the connective tissues to an embryonic condition, supervenes, accompanied by the appearance of depression of the mental functions and by other nervous symptoms. The disease myxoedema, which was first described by Sir William Gull in 1873, was shown by Ord in 1878 to be due to degenerative changes in the thyroid gland. It affects both sexes, but chiefly females, and is characterized by a peculiar puffy appearance of the face and hands, shedding of the hair, a low temperature and mental hebetude. The symptoms are similar to those produced by removal of the thyroid. The nervous symptoms may be in part due to some alteration in the metabolism, leading to the formation of toxic substances. The administration of thyroid gland extract causes the symptoms to disappear. (*See* GOITRE.)

2. *Cretinism* (*q.v.*) may be defined as myxoedema in the infant, and is associated with non-development or degeneration of the thyroid gland. The characters of the disease are due to diminished metabolism, leading to retarded development, and the treatment which has proved of service, at least in some cases, is the administration of various thyroid preparations.

3. *Exophthalmic Goitre* (Graves's Disease or Basedow's Disease) chiefly affects young women, and is characterized by three main symptoms: increased rate and force of the heart's action, protrusion of the eyeballs, and enlargement of the thyroid gland. The patient is nervous, often sleepless, and generally becomes emaciated and suffers from slight febrile attacks. The increased action of the heart is the most constant symptom, and the enlargement of the thyroid gland may not be manifest. The condition is caused by increased functional activity of that gland or by changes in the parthyroids.

Gout (*q.v.*).—The accumulation of urate of soda in the tissues in gout formerly led physicians to believe in a causal relationship between an increased formation of that substance and the onset of the disease. That uric acid is increased in the blood is undoubted, but recent work points to the accumulation being, like the other symptoms of the condition, a result of some unknown modification in the metabolism and a purely secondary phenomenon. The important fact that in leucaemia (von Jaksch), in lead-poisoning (Garrod) and in other pathological conditions, uric acid may be increased in the blood and in the urine without gouty symptoms supervening, is one of the strongest arguments against the older views. The source of the uric acid so widely deposited in the gouty is largely the phosphorus-containing nucleins of the food and tissues. These in their decomposition yield a series of di-ureides, the purin bodies, of which uric acid is one. Their excretion is increased when substances rich in nuclein, *e.g.*, sweetbreads, etc., are administered. While uric acid itself has no injurious action, the closely allied adenin produces toxic symptoms. After the discovery of this source of uric acid, physiologists for a time inclined to regard it as the only mode of production. But it must be remembered that in birds uric acid is formed from the ammonia compounds coming from the intestine and muscles, just as urea is formed from the same substance in mammals. Uric acid is a di-ureide—a body composed of two urea molecules linked by acrylic acid—an unsaturated propionic acid. It is therefore probable that in many conditions the conversion of ammonia compounds to urea is not complete, and that a certain amount of uric acid is formed apart from the decomposition of nucleins.

Rheumatism.—Rheumatic fever was at one time regarded as due to some disturbance in the metabolism, but it is now believed to be of streptococcal origin. Excluding peculiar changes in the joints which occur in rheumatoid arthritis and in Charcot's disease and are almost certainly dependent on affections of the nervous system, a large number of individuals suffer from pain in the joints, in the muscles and in the fibrous tissues, chiefly on exposure to cold and damp or after indiscretions of diet. This so-called chronic rheumatism appears to be a totally distinct condition from rheumatic fever; and although its pathology is not determined, it may be due either to a diminished elimination or an increased production of some toxic substance or substances, but so far we have no evidence as to their nature.

Rickets (*see* Rickets; Medical Research) is undoubtedly a manifestation of a profound alteration of the metabolism in childhood and is now regarded as being in large measure a food deficiency disease (avitaminosis).

See Carl von Noorden, *Metabolism and Practical Medicine* (1907).

METABOLISM, the biological term for the process of chemical change in a living cell (*see* Nutrition; Diet and Dietetics).

METALLGESELLSCHAFT A.G., a German company, was founded in 1881, by Mr. William Merton, as a limited company, taking over the metal business of the private firm Philipp Abraham Cohen established in the beginning of the 19th century. Because of its dealings in metals, ores, pyrites, etc., the Company took interests in mining enterprises as well as in smelting works and metal manufactories. During several years a special company, the Metallbank and Metallurgische Gesellschaft A.G. conducted the technical and financial part of the business, but in 1928 the two companies were amalgamated under the name of Metallgesellschaft A.G.

The Metallgesellschaft with its branch offices and its foreign connections is one of the most important metal concerns in the world. The war caused considerable changes in its foreign relations, and untiring efforts had to be made to regain for the Company its former strength. New connections had to be built up, new fields of business had to be looked for; the industrial activity of the Company is much greater now than before the World War.

Metallgesellschaft A.G. is carrying on wholesale trade in non-ferrous metals, in ores, and in certain chemicals connected with the metal industry. A great deal of the copper, tin, spelter, lead, and aluminium dealt with are produced either in its own smelters or smelters under its control, such as Norddeutsche Affinerie in Hamburg, Berzelius on the Rhine, Hans-Heinrich-Hütte in the Harz, etc. In its own works at Heddernheim, Mannheim, Cologne, Nuremberg, etc., copper, brass, aluminium, and lead are being manufactured. Particular attention is concentrated on the production and propagation of light metals (aluminium alloys). Large research laboratories are keeping up to date the technical processes concerning the concentration and smelting of ores and the refining and manufacturing of metals. Branch ("Lurgi") companies are used for the exploitation of technical processes concerning chemistry and metallurgy.

The present capital of the Company is 76,000,000 Reichsmark. Its headquarters are in Frankfurt-on-Main, and it is represented in all big commercial centres of the world. (S. Au.)

METALLOGRAPHY. A polished piece of metal presents an appearance of complete homogeneity which does not suggest the existence of a complex internal structure. When the metal is broken, however, the fracture indicates a structure or texture capable of microscopic examination. This fruitful method, which forms the foundation of the science of Metallography, was first applied to metals by H. C. Sorby of Sheffield in 1861. It was subsequently developed in Germany by Martens, in France by Osmond and in England by Roberts-Austen and many others.

The microscopic examination of metals cannot well be made by the use of sections thin enough to be transparent. It is therefore made by looking *at* a prepared surface of the specimen, and not through it. Careful preparation of the surface eliminates all accidental markings and scratches. An ordinary "polished" metal surface is much too rough for the purpose. Metallographic surfaces are prepared by rubbing a flat specimen on successively finer grades of special emery papers, the scratches made by one grade being replaced by finer ones made by the next grade. The finest scratches are removed by a revolving disk covered with soft cloth or leather and fed with water and extremely fine polishing material, such as specially washed alumina or magnesia powder.

The featureless mirror, so produced, is covered with a very thin surface layer of "flowed" metal which has been smeared or dragged over the surface during the polishing process. This surface is lightly attacked by an "etching reagent." For many metals a weak solution of nitric acid in alcohol, or of picric acid in alcohol, serves as a useful etching reagent, but a great variety of solutions has been developed. Lists of these are to be found in the textbooks, etc.

Structures of Metals.—The etching reagent, after removing the surface film, differentiates the various constituents which are present in the section so as to make them visible under the microscope by the production of differences in the light-reflecting power of the metal surface. Such differences may result either from the actual "colouring" of the surface by the formation of a coloured film or from a roughening of the surface by partial solution—*i.e.*, the partial "unbuilding" of the structure at certain points.

First we have the simple aggregate of crystals which we find in pure metals and in those alloys which consist of a single solid solution. A typical example is shown in fig. 1, Plate I. The structure, seen under "normal" lighting, presents the appearance of an irregular tesselated pavement; each of the roughly polygonal

Surface of pure metal showing "slip bands" or cross hatching due to plastic deformation or strain

fields into which the surface is divided is the section of a crystal of metal, the mutual boundaries of these crystals being determined, however, not by their geometrical shapes or properties but by the manner in which adjacent crystals have met. Within their boundaries, however, these crystals possess the typical geometrical regularity of true crystals. Another structure often found in alloys is the finely laminated duplex structure, illustrated in fig. 2, Plate I., which is typical of what are known as "eutectic" alloys. These are the alloys of lowest melting point which occur in certain series of the alloys of two metals. Many alloys consist of simple crystals of the type illustrated in fig. 1, Plate I, embedded in a matrix of the laminated type. An example is shown in fig. 3, Plate I. There are many other types of structure, such as those which occur when a well-defined chemical compound of two metals occurs in the alloy. An example is given in fig. 4, Plate I. Further types of micro-structure are found in alloys which undergo changes—as many alloys do—after they have become completely solid. An example of the complex structures which are sometimes produced in this way is shown in fig. 5, Plate I. Other examples will be found in reference to ALLOYS and in connection with the articles dealing with particular metals and alloys, such as STEEL, COPPER, BRASS, BRONZE, ALUMINIUM and others.

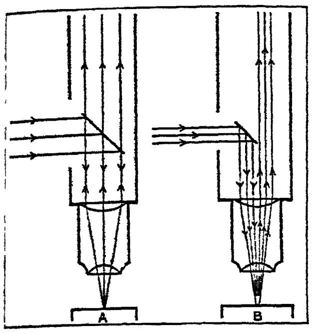

FIG. 1.—DIAGRAM OF VERTICAL ILLUMINATION. A. TRANSPARENT REFLECTOR: B. OPAQUE REFLECTOR

Metallurgical Microscope.—The metallurgical microscope differs from other microscopes mainly in being specially designed for the observation of opaque objects requiring, in some cases, the highest available resolving and magnifying powers. The two typical methods of illumination employed in the examination of metals are indicated in the diagrams in fig. 1. Light from the source or lamp falls upon a reflector placed within the microscope tube, close above the objective. This reflector is, in fig. 1 (a) a small totally reflecting prism or mirror so placed as to cover one-half of the objective; in fig. 1 (b), the reflector is a thin slip of flat glass placed at an angle of approximately 45 degrees above the objective. Either type of reflector sends a portion of the incident light down through the objective on to the surface of the specimen, which reflects some of this light back into the objective. A part is inevitably returned to the lamp, but a part passes upwards through the transparent reflector or through the uncovered half of the objective to form the image at the upper end of the microscope tube. It will be seen that where the surface of the specimen is truly horizontal the incident light is fully reflected back into the microscope, and that portion of the surface will appear bright in the resulting image. Where the surface is roughened, however—for instance by the formation on it of numerous minute facets inclined to the horizontal—the light will be reflected to some extent away from the object lens of the microscope and such roughened areas will appear more or less dark in the resulting image. Where the distance between objective lens and specimen is sufficiently great—as it is with the lenses used for more moderate magnifications—it is possible to vary the mode of illumination by throwing a strong beam of light obliquely upon the surface from one or more sides. This completely alters the character of the image observed, parts previously dark now appearing light and vice versa. When a suitably etched specimen of a pure metal is thus obliquely illuminated and is then slowly rotated, a remarkable effect, known as that of the "oriented lustre" of the crystals, is observed. The same effect can be seen with the unaided eye where specimens of metal having a very coarse crystalline structure are available. An example of this kind, showing the radiating crystals of a piece of cast lead, is illustrated in fig. 6, Plate I.

A typical example of a metallurgical microscope designed for prolonged visual work as well as for photography, is illustrated in fig. 2, which shows the Rosenhain metallurgical microscope. The main feature of an instrument of this kind is that the tube carrying the optical system is fixed and that all focussing, both coarse and fine, is done by movements of the stage. In recent years, however, the inverted or Le Chatelier type of microscope, in which the specimen is placed face downwards on the stage, has become popular owing to its convenience for photomicrographic work. A disadvantage is that while it facilitates photography it renders visual observation difficult and tiring and workers take photographs rather than study their specimens in detail.

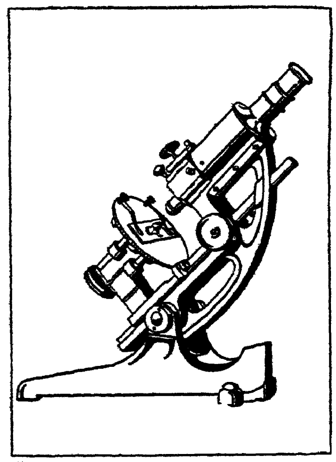

FIG. 2.—METALLURGICAL MICROSCOPE (ROSENHAIN TYPE), WITH FIXED BODY TUBE, HAVING THE ILLUMINATOR INSERTED IN IT, AND MOVABLE STAGE

The magnifications are limited only by the resolving power of the microscope. Classical optical theory places this limit at not much more than 1,000 diameters, but recent American workers have employed much higher magnifications with some measure of success. The attempt is also being made to utilise ultra-violet light of very short wave-length and therefore of correspondingly higher resolving power.

Much depends on the specimen to be examined. It is only in materials of great uniformity that any section cut at random will give a structure typical of the whole. In the early days of metallography doubt was widely felt whether the examination of so small an area as that which can be seen under the microscope could furnish reliable information regarding masses of metal weighing perhaps many tons. It is now, however, recognised that sections cut from properly chosen parts of a mass of metal furnish most valuable information. It is advisable to cut and examine sections taken in at least two directions in each place and often taken from a number of places in the same piece of metal before a true picture can be formed.

"Macroscopic" Examination and Sulphur Printing.—Considerable guidance can be obtained by what is known as "macroscopic" examination. For this purpose a relatively large area of the metal—usually a complete cross-section—is roughly polished, leaving the surface covered with fairly fine emery scratches. This surface is then exposed to the action of a fairly vigorous solvent. In the case of iron and steel, a solution containing slightly acid copper chloride is often used, but there are a number of special reagents for this purpose. These are allowed to act for a much longer time than is required for microscopic etching, and they produce a deep attack on the surface, generally roughening and darkening it. None the less the surface thus attacked shows a pattern which is known as the "macro-structure" which indicates the general arrangement of the crystals. Where the process is applied to a casting, or to an ingot which has not undergone much deformation, the arrangement of the original crystals formed during solidification can generally be clearly seen. In a forging it is possible, as a rule, to trace the lines of flow of the metal. This is particularly the case in regard to iron and steel, where the presence of non-metallic impurities and the persistent segregation of phosphorus make the outlines particularly distinct.

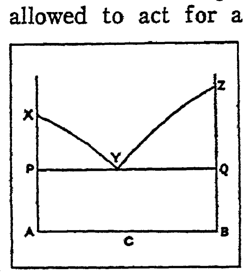

FIG. 3.—EQUILIBRIUM DIAGRAM OF ALLOY SYSTEM OF TWO METALS, A AND B, FORMING A EUTECTIC ALLOY

A method applicable mainly to iron and steel is known as "sulphur printing." It was originated by Baumann in Germany. A roughly polished surface is again prepared but instead of etching it, a piece of photographic silver bromide paper soaked in a 10 per cent solution of sulphuric acid is brought into contact

with the surface. Wherever sulphide enclosures are present they are attacked by the acid and sulphuretted hydrogen is evolved. This immediately forms a spot of silver sulphide on the paper and a print, showing traces representative of all the sulphide enclosures present, is obtained. This is an excellent means of showing the presence of segregation in steel. An example taken from a segregated steel rail, is shown in fig. 7, Plate I.

Equilibrium Diagram.—The micro-structures can only be understood if the formation during the solidification and subsequent cooling of the alloy is studied. The close analogy between alloys and salt solutions was realised and the theory of "heterogeneous equilibria" was applied to alloy systems by Bakhuis, Roozeboom and others. Progress was then made by the determination of the equilibrium diagrams of alloys, at first in rough and very inaccurate ways, but more recently with great accuracy and in much detail.

The equilibrium diagram is a chart, plotted upon the composition of the alloys in percentages as base line and with temperature as ordinate. A series of lines indicate the temperatures at which the alloys undergo changes, which are generally accompanied by evolutions of heat on cooling and absorptions of heat on heating. Starting with a molten alloy, the first change which occurs on cooling is the commencement of solidification or freezing. This is readily determined by means of cooling curves which show thermal irregularities as the alloy cools. The freezing points or, rather, the points where freezing begins, are connected by a curve in the equilibrium diagram which is known as the "liquidus." Similarly, the temperatures at which the alloys become completely solid on cooling are connected by a line or lines known as the "solidus." Beyond these two curves or groups of curves, the diagram is divided into areas or "fields" which delimit the conditions of composition or temperature under which the various possible constituents of the alloys can exist in equilibrium. This state of complete equilibrium, however, is not always, or indeed, often, reached by alloys, although with very slow cooling or after prolonged heating at suitable temperatures, the constitution of the alloys tends to approach closely to the equilibrium condition. Alloys as ordinarily cooled, however, are usually in an intermediate or meta-stable state, the exact condition depending on the rate of cooling. The diagrams as determined for the various alloy systems follow certain well-defined types; only two examples of these types can be given here. Fig. 3 is the diagram of the alloys of a pair of metals which, while completely soluble in one another in the liquid state, separate into distinct crystals on cooling. Alloys of this type are known as "eutectiferous" since a low-melting "eutectic" is formed along the horizontal line PQ of the figure. The structure typical of such an alloy, corresponding to the point *C* of the diagram, is illustrated in fig. 2, Plate I. Fig. 4 represents an alloy system of the extreme opposite type, in which the two metals retain in the solid state the mutual miscibility which exists when they are molten, the alloys forming a continuous series of what are known as "solid solutions." These alloys, when very slowly cooled, exhibit the same structure throughout as a pure metal, although the alloys may differ widely from one another in physical properties, colour, etc. There are intermediate types, and others in which the formation of definite intermetallic compounds is indicated by a break or by a maximum in the liquidus curves.

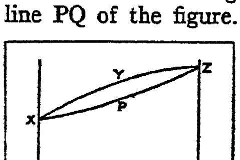

FIG. 4.—EQUILIBRIUM DIAGRAM OF ALLOY SYSTEM OF TWO METALS, A AND B, FORMING A SERIES OF SOLID SOLUTIONS

The equilibrium diagram gives a clue not only to the microstructure and thermal behaviour of the alloys, but also to their physical properties. Conversely, all these properties have been used for the determination of the equilibrium diagram. Reference has already been made to thermal methods whereby the temperatures at which a specimen crosses certain lines of the equilibrium diagram can be determined by irregularities—halts or retardations—in the heating and cooling process. The microstructure, both of slowly cooled specimens and of specimens rapidly quenched from a definite temperature, also affords an insight into the location of the lines of the diagram. Thus, if a specimen of an alloy is quenched from a temperature above the "solidus," *i.e.*, in a condition where traces of liquid are present, these can be recognized as so-called "fusion spots" in the structure. Such spots are illustrated in fig. 8, Plate I.

Dilatometry consists in the measurement of the changes in length of small rods of an alloy when it is slowly heated or cooled. Apart from the normal thermal expansion or contraction, it is found that alloys exhibit comparatively abrupt changes of length when they undergo internal changes such as allotropic transformations or the appearance of a new constituent or the disappearance of one previously present. The points at which such changes begin or end are fairly clearly marked on the dilatometer curves, usually recorded photographically by means of dilatometers of the Chevenard type. This method of studying alloys has the advantage that very slow rates of heating and cooling can be employed so that some approach to equilibrium conditions is obtained. This advantage also applies to the study of alloys by measurement of the changes of electrical conductivity with temperature. If this method is carefully used, with adequate precautions against accidental disturbing factors, it is capable of giving valuable results. It is not, however, certain that changes of electrical conductivity always occur at the precise points which are sought for the purpose of determining equilibrium diagrams.

X-ray Crystal Analysis.—By X-ray spectrometry we can not only determine the exact manner in which the atoms of a given type of crystal are arranged in space, but also identify the presence of a particular type of crystal in an alloy or mixture. For the latter purpose, however, the method is much less sensitive than microscopy or the other methods already mentioned, but has, on the other hand, the great advantage of affording a means of definitely identifying crystals of a particular type. Much more important, however, than its use in connection with equilibrium diagrams, is the application of X-ray crystal analysis to the study of the inner structure of metallic crystals. Not only has this method of examination confirmed the earlier conclusions derived from microscopic evidence, that metals are essentially crystalline aggregates, but it has also shown that they remain crystalline even after the most severe plastic deformation. The proof, however, only shows that a good deal of crystalline metal is present even in severely deformed material, but does not show that the metal is entirely or even mainly crystalline in that condition. (Consult articles on "Strength of Materials" and "Fatigue.") When a previously polished and etched specimen of a pure or nearly pure metal is plastically deformed, the surfaces of the crystals seen in the section become cross-hatched with fine black lines. These lines, known as "slip bands," are illustrated in fig. 9, Plate I. It has been shown that these fine lines are in reality little steps in the surface which have been produced by minute slips occurring on some of the crystal planes. It is by successive slips of this kind, occurring within each of the crystals of a piece of metal, that the material takes up the new shape imposed upon it when it undergoes plastic deformation, as—for instance—when it is stretched when drawn out into wire or flattened during rolling. As a result of the slipping process, the individual crystals become elongated in the direction in which the metal has been extended. On subsequent heating to a sufficiently high temperature (without melting, however) the metal "recrystallises" and the crystals resume their normal shape of approximately equal length in all directions. In some of the softer metals, such as lead and cadmium, the recrystallisation process occurs gradually at ordinary temperatures but in iron and steel there is neither "crystallisation" nor "recrystallisation" at room temperatures, whether the metal be at rest or exposed to violent vibration. (W. Rn.)

METALLURGY, a term formerly defined as "the art of extracting metals from their ores" has now a wider meaning. It is applied by modern metallurgists to the structure of metals and of alloys, to their constitution and its relation to their physical properties and to the thermal and mechanical treatment of metals.

The immense increase in the scale of metallurgical work and the increased scientific knowledge of metals and alloys constitute the most striking features of modern metallurgical development.

Both are accompanied by a great increase in economy in the extraction of metals and in their more efficient use and preservation. Indeed, there are signs that in the case of some metals the increasing rate of consumption may lead to gradual exhaustion if not of the entire world's supply, at least of the best ores. Even in regard to iron there is food for thought in the immense increase of annual production and consumption, coupled with the losses due to corrosion alone. These losses have been estimated at 30 million tons of iron and steel per annum.

The production of metals and alloys in the form in which they are used in the industries and the arts involves a series of processes, beginning at the mine or quarry and ending in the workshop of the engineer or of the manufacturer. These operations differ widely in character according to the nature of the metal, and to some extent—especially in the later stages—to the use to which the metal is to be put.

ORE TREATMENT

Where Metallurgy Begins.—Beginning with the quarry or mine, it is difficult to determine precisely where the province of mining ends and that of metallurgy begins. Metals occur in nature only rarely in the free state, but usually in the form of "ores"—*i.e.,* of minerals in which the metal exists in chemical combination with other elements, chiefly oxygen, sulphur, arsenic and silicon. A great many important ores are sulphides. When a metalliferous deposit is first discovered, the ore—for example in many of the American copper deposits—is of the nature of a carbonate, having been altered by the chemical action of the atmosphere from the original sulphide condition. These "oxidised" surface ores are easily worked and afford an initial advantage in opening up a new mineral region. As the ore is pursued to greater depths, however, its character usually changes and the carbonates and oxides are replaced by sulphides which are much more difficult to work. There are, of course, exceptions to this rule, as in the case of aluminium and of gold. The latter usually occurs in the free metallic state and at an early stage in the working of an auriferous region is generally obtained by the simple process of washing or "panning" the alluvial mud of the rivers. Platinum and osmiridium are obtained in similar ways. Such alluvial deposits, however, indicate the existence of gold-bearing rock at higher levels. In the rock the gold is usually associated with quartz and may occur either in a comparatively massive form as fine veins or streaks, or in a very finely almost colloidal form, as in the quartz lodes of the Witwatersrand.

The extraction of alluvial gold is an example of a very simple type of ore treatment which is, however, typical of the methods adopted. The metal-bearing mineral, whether it be oxide, carbonate, sulphide or free metal, always occurs intimately associated or mixed with non-metalliferous material, often constituting the country rock in which the mineral "lode" or "vein" is embedded. In mining operations efforts are made to separate the mineral as much as possible from the adjacent valueless rock or "gangue," but usually the separation is very incomplete until special processes are applied to the product. These separating or "ore dressing" processes depend on differences of properties between the mineral and the gangue. In the case of gold "washing" the property utilised is the higher density of the gold as compared with the mineral matter of the surrounding mud. Similar gravity separation in flowing water is frequently used, but can as a rule be applied only after the product of the mine has been ground to a fine powder. After grinding, the ore is frequently "graded" by various methods, such as screening or sieving, in order that the product subjected to the next operation may be of a standard degree of fineness.

Apart from the separation of the heavier mineral from the lighter gangue particles by means of water, other methods are also employed. In some cases magnetic separation is possible, when the mineral is either markedly attracted by powerful electro-magnets or—less strongly—repelled by them. Such methods can, however, be used only for minerals, like iron, nickel or cobalt, which possess well-marked magnetic properties.

Flotation Process.—The most important modern development in regard to mineral separation is the "flotation" process, which has rendered possible the profitable treatment of ore bodies, and even of residues from older and less efficient methods of treatment. The flotation process consists in stirring up the finely divided ore in water to which certain additions have been made in order to produce froth when the water is violently agitated or air is blown through it. This froth carries with it to the surface of the water the fine particles of mineral, leaving the particles of gangue at the bottom. In this way it is possible to remove and to concentrate the mineral values out of a very poor ore, the operation being both rapid and cheap.

There is still some divergence of opinion whether flotation phenomena are the result of purely "surface tension" forces or whether electrical effects play the most important part. The operations consist of three steps which may, however, overlap and merge into one another. The first is the "oiling" process and consists in adding to the wet pulp or mixture of water and finely-ground ore some substance of a more or less oily nature. This may be either an essential oil—oil of eucalyptus is largely used—or one of a great range of organic substances The choice of the most suitable "oiling" reagent for a given kind of ore is a matter of great importance and often requires extensive preliminary investigation. Only a very small amount of the "oiling" reagent is used. Its effect is to produce some change in the surfaces of those minerals having a metallic or semi-metallic character. Zinc-blende is a typical example of such a mineral. The surface of the mineral thus "oiled" becomes less easily "wetted" by the water of the pulp. The gangue of the ore, on the other hand, is either not affected at all or affected to a much smaller extent than the mineral, and this brings about the different behaviour of the two kinds of material towards the froth bubbles. In some cases, however, it is necessary artificially to increase the difference in this respect between ore and gangue by the introduction into the pulp of some reagent which renders the gangue particles more readily wetted by the liquor. These "gangue modifiers" are usually either mineral acids or alkalies.

The next step consists in adding to the pulp some substance which assists in the formation of a stiff and lasting froth when the liquid is aerated. The introduction of air may be brought about either by simply agitating the liquid or by blowing air through it. Frequently the "oiling reagent" serves also as froth producer. When the pulp thus prepared is treated so as to produce a froth, the oiled mineral particles adhere very strongly to the froth bubbles. The combined buoyancy of the air-bubble with its mineral burden is sufficient to cause it to float to the surface, where the bubbles accumulate to form a very stiff mineralised froth which can be separated in various ways. There is also flocculation of the mineral particles by the oil emulsion in contact with the air-bubbles. The finest mineral particles thus become attached to the air-bubbles in large and heavy agglomerations—a circumstance which contributes to efficiency.

The flotation process is applied to sulphide ores, such as those of copper, lead and zinc, and in this connection alone it has attained great industrial importance. Its application to other types of minerals is not quite so easy but considerable success has been attained. Minerals having a more or less metallic surface are particularly well adapted to flotation, so that the process is readily applicable to the treatment of ores containing finely divided metallic gold. None the less, for the treatment of ores of this nature at the Rand in South Africa, the older cyaniding processes hold their own, although flotation is used in some cases in combination with cyaniding.

Oxidation.—The methods of ore treatment which have been mentioned above relate to processes of concentration which are "mechanical" in the sense that the chemical composition of the metalliferous minerals is not changed by the treatment. Following on such mechanical treatment, and in many cases preceding it, are a whole series of operations which act upon the chemical composition of the mineral. Some of these are, like the mechanical processes, of an essentially preliminary nature, but they include the processes by which the metal is finally reduced and refined. Among the preliminary treatments, those which exert

an oxidising influence on the mineral may be first considered. The action of atmospheric agencies on sulphide minerals near the surface produces enrichment by converting them into carbonates and oxides. Artificial methods for producing similar effects are widely used. One of the simplest consists in "bedding" the ore, after crushing to a suitable size, in such a way as to expose it to air and water—a process practised among others at the copper mines of Rio Tinto. The sulphide ore thus becomes gradually oxidised but the process occupies many months.

More frequently, oxidation is brought about by the application of heat in the "roasting" process. This constitutes an important part of the treatment of many sulphide and arsenical ores. Appliances for this purpose vary from simple "heap-roasting" to the elaborate sintering and roasting machine of the Dwight-Lloyd type in which the ore is fed on to a long continuous chain, each link of which is in reality a furnace grate. The link or plate only comes into action as a furnace, however, after passing first through an igniting chamber in which a flame plays upon the ore and heats it sufficiently to ignite, when it passes into the next chamber where air is drawn through the mass. Here the greater proportion of the sulphur in the ore is burnt, sulphur dioxide and trioxide being formed. The ore itself, thus purified, is sintered into a porous mass and, as the chain passes on, is tipped out while still hot. The porous mass thus produced is particularly suited for further reduction and purification in the blast-furnace (*see* below).

In other roasting processes, such as that of Huntington and Heberlein, the ore is roasted in a large pot where air is blown through it. In other processes, again, the ore is roasted in furnaces provided with a series of shelves which are heated by a flame passing under them while a separate stream of air is drawn over the layers of ore. The ore is raked down successively from one shelf to the next lower one and the roasting process is complete when the ore reaches the lowest shelf and is raked out of the furnace. In many of these roasting processes the sulphurous gases are utilised for the production of sulphuric acid. This utilisation of one of the waste products of a process is typical of modern economic metallurgical operation. The use of blast-furnace gases for the production of heat and power is another example of the same kind. In many processes the value of such "by-products" is an important factor in determining whether the process can be profitably worked.

Concentration.—In ore treatment the primary object is concentration. The metal occurs in the product of the mine frequently in a widely dispersed or "diluted" form and it is essential to reduce the weight and bulk of the material to the lowest possible amount. This necessity arises first from the need of keeping down the quantity of material which is to be treated in the later stages of metal production, whether in furnaces or in the wet way. There is, however, a further consideration. Mines are often placed in distant parts of the world, far away from the centres of industry where the finished metal is required and this involves relatively costly transport. It is therefore necessary to reduce the weight and bulk of the material to be transported and, in the last resort, this is achieved by carrying the treatment of the ore at or near the mine to the point of the final production of the metal. In a few cases this is done, but in others, where the refining processes are elaborate, the reduction operations are not carried to the final stages but only to a certain degree of concentration. There are, for instance, cases in which it would not be profitable to export, say from the Congo or even from Arizona, the crude sulphide ores. On the other hand it might not be worth while to instal electrolytic copper refineries in those places, partly on account of difficulties of power supply, lack of skilled labour, etc. The intermediate course is frequently adopted and a crude variety of copper, or even the sulphur-bearing intermediate product known as a "matte" is produced at the mine and sent forward to refineries situated near the centres of industry or near the sea. It is obvious that an intermediate product containing, for example, two or three per cent of impurities, will cost very little more for transport than the fully refined metal. On the other hand, it is always the removal of the last traces of undesirable impurities which is most difficult and demands the greatest skill and care. Purely economic factors, such as cost of labour and commercial organisation also play an important part in such matters.

The refining operations which can be applied to ores after they have undergone preliminary concentration processes, depend entirely upon the nature of the concentrate, and upon the facilities available in the locality where the work is to be done. Although the changes to be brought about are essentially of a chemical nature, the methods which can be applied depend to some extent on the physical characteristics of the substance in question. Thus a finely-divided material cannot be treated in blast furnaces, while a strongly sintered product is not so well suited as a finely divided material to treatment with aqueous solvents or "leaching."

Reduction Methods.—Broadly the reduction methods applicable to ores may be divided into two groups involving respectively furnace treatment and wet processes. Processes involving the use of mercury for "amalgamation" are allied to the true "wet" methods. The furnace methods depend upon chemical changes which occur at high temperatures; these may involve the oxidation of impurities which it is desired to eliminate and the oxygen for this purpose may be derived from the air or from oxidised compounds which may be added to the ore or slag during or prior to the treatment. There are also reduction processes, in which oxygen is removed from the ore either partially or completely. Here the oxygen is removed, *i.e.*, the oxides in the ore are "reduced," by the action of such agents as carbon, hydrogen, hydrocarbons or even other metals. It is a frequent sequence to find that at an early stage of a process the actions which take place involve oxidation and that reducing actions, which finally result in the production of the metal itself, are subsequently applied. The heat required for these operations may either be supplied by the combustion of fuel which may be mixed with the ore or burnt separately, or the heat may be generated by the combustion of such substances as sulphur or carbon already present in the ore or intermediate product.

Another method of metal production which is intermediate between the typical furnace processes and the wet-way electrolytic methods is that of "fusion electrolysis." Here the purified metalliferous substance is brought into a state of fusion, usually by admixture with some other substance which serves as flux—*i.e.*, has the function of rendering the mixture much more fusible—while itself remaining as nearly as possible neutral. The "solution" of oxide of aluminium in molten cryolite is perhaps the most important example of this kind. The fused mixture then serves as electrolyte and the pure metal is separated at the cathode exactly as in wet-way electrolysis, except that the reduced metal is frequently formed in the liquid state and is run off periodically into suitable moulds. In other cases—as in the production of magnesium, calcium and other light metals the deposited metal is solid and is formed as a stick on a cathode rod which is steadily withdrawn from the bath. These processes find their application to metals which it is difficult or impossible to reduce satisfactorily by ordinary furnace methods and which cannot be produced by wet-way electrolysis because they react vigorously with water.

The wet methods of ore reduction afford a similarly large variety. In some few cases it is possible to extract the desired mineral direct from the mine by a leaching process. In the majority of cases, however, the solvent solution is applied to the ore after it has been removed from the mine and subjected to preliminary concentration, as, for example, by flotation. In other cases preliminary roasting, either purely oxidising or "chloridising"—in which chlorides are added to the ore with a view to converting the mineral into an easily-attacked chloride—is employed before leaching is applied. In some cases, in fact, the ore is reduced to a crude form of the metal before it is subjected to wet-way (electrolytic) refining.

Gold.—The metallurgy of gold owes its characteristic features to two principal factors:—the chemical inactivity of gold and the high value of the product. It is probable that the most com-

plete recovery of gold could be obtained by smelting methods, *i.e.*, by subjecting the ore to furnace treatment in which, however, the relatively great mass of siliceous and other matter accompanying the gold would have to be fluxed or molten. Less costly methods, although they do not yield so full a recovery, are preferred. This is an interesting example of the factors which determine the choice of metallurgical methods. At every stage of extraction it becomes a matter for careful calculation whether the cost of more complete extraction will be compensated by the value of the metal recovered. The conclusion in each particular case will depend upon the methods of treatment and recovery available. Improvement not only in the nature of the methods available, such as the introduction of flotation, cyaniding, etc., but also improved methods of mechanical handling, design of machines, etc., all of which tend to cheapen the cost of recovery, affect the result so that, as methods are improved, it not only becomes profitable to carry extraction further but to treat poorer ores or even to re-treat the "tailings"—*i.e.*, the rejected matter—from earlier reduction processes. In the case of gold, the amalgamation and cyaniding processes are the most important, although chlorination is also applied.

Amalgamation is the older process but is still widely used for the extraction of the gold from certain types of "free milling" ores in which it occurs in a form readily absorbed by mercury. In other cases amalgamation is used as a preliminary to cyaniding for the purpose of extracting in a cheap manner those portions of the gold which are most readily accessible, at the same time leaving the ore, after this treatment in a more uniform condition so far as gold content is concerned, and thus better adapted to cyaniding. Amalgamation itself is carried out either during actual grinding (pan amalgamation) or during the passage of the pulp produced by grinding over amalgamated copper plates. The amalgam thus formed is heated in retorts, when the mercury is driven off and spongy gold is left behind.

Mercury has the power of forming amalgams with silver, lead and other base metals and if these are present in a gold ore they rapidly contaminate the mercury which is said to "sicken" and becomes incapable of taking up gold from the ore pulp. Mercury is also lost by becoming so finely divided that it is carried off with the ore pulp.

Cyaniding is a wet-way process of the "leaching" type. It depends upon the fact that a well-aerated dilute solution of potassium or sodium cyanide will dissolve gold and, by sufficiently prolonged exposure can be made to extract a very large percentage of the gold present from a finely-divided pulp which is agitated with it. From this solution the gold is afterwards precipitated by means of finely-divided zinc.

Silver.—Both amalgamation and cyaniding are applicable to silver, so far as chemical principles are concerned. Their practical application, however, offers serious difficulties. Silver is much more slowly amalgamated by mercury than is gold, while the presence with it of lead and zinc tends to foul the mercury too rapidly. Further, silver frequently occurs in the form of minerals which do not directly lend themselves to amalgamation. As regards cyaniding, on the other hand, silver requires much stronger solutions of the cyanide and even in these dissolves far more slowly. As a result, the extraction of silver is more frequently carried out by entirely different methods which depend upon the solubility of certain silver salts. The chloride, for instance, is soluble under certain conditions in strong brine, while a solution of sodium thio-sulphate (commonly called "hyposulphite") is capable of extracting certain forms of silver from the ore pulps. From these solutions the silver can be readily precipitated —for example, as the chloride—which is then readily reduced to the metallic state by the action of zinc.

Copper.—While the treatment of copper ores by wet-way extraction processes occupies an important part in the metallurgy of that metal, the most typical processes applied to it come under the heading of "smelting"—*i.e.*, treatment in furnaces. Apart from the roasting processes to which reference has already been made, three types of furnace treatment are applied to copper ores. These are the blast-furnace, the reverberatory smelting and refining furnace and the "converter." In this respect, the metallurgy of copper resembles that of steel but in principle rather than detail. Ferrous metallurgy is on by far the larger scale.

The blast-furnace (*q.v.*) as used for the treatment of copper ores is a much smaller thing than the huge furnaces used for iron. It has also to carry out somewhat different functions. These differ according to the nature of the ore or concentrate to be treated. If this is of the oxidised type then it is fed into the blast furnace together with fuel (coke) and a suitable flux, with the object of bringing about the reduction of the oxides to the metallic state. The carbon of the fuel combines with the oxygen of the ore, while the other constituents of the ore combine with the flux to form a slag. The resulting products are an impure form of metallic copper and a slag containing very little copper. If, on the other hand, the ore contains much sulphur, together with—as a rule—sulphide of iron or iron pyrites, the function of the blast furnace is to burn away the sulphur and to produce a copper "matte" containing only a small proportion of sulphur. This matte is afterwards treated in the "converter" to form crude copper. In the copper blast furnace as used for "pyritic smelting" the minimum amount of fuel is employed to generate the necessary heat, while a large excess of air is blown through in order to oxidise the sulphur. The fluxing materials are designed to combine with the oxides or iron formed by the oxidation of the iron pyrites, so that the iron passes into the slag. This treatment, however, is only practicable when the sulphur content of the material is not too high.

While the copper blast furnace is essentially a vertical shaft into which air is blown by nozzles or "tuyeres" at a suitable point near the bottom, the "converter" is a vessel, either cylindrical or pear-shaped, capable of rotation on trunnions. This is provided with air-nozzles so arranged that the molten charge can—by rotating the vessel—be brought to cover the air-nozzles. When this is done the air is forced through the molten charge and rapid oxidation takes place. The heat of combustion of the sulphur serves to maintain and to raise the temperature of the charge, so that no supply of fuel is required.

At one time it appeared probable that smelting by the blast-furnace and the converter would become the means of production of the great bulk of the world's copper supply; practice tended towards an ever-increasing size of unit. But flotation methods of concentrating copper ores have created a difficulty in the use of the blast furnace. The great rush of air in this type of furnace tends to blow finely-divided ore into the flues, necessitating expensive after-treatment and recovery of the flue dust. This difficulty has to some extent been overcome by the development of the roasting and sintering machines such as those of Dwight-Lloyd which convert the finely-divided product of flotation into a fairly hard and porous sintered product at the same time as roasting it. None the less, there has been a great development in the use of the reverberatory furnace for copper smelting. These furnaces consist essentially of shallow basins which hold the charge and the layer of covering slag while the heating flame plays over the charge and against the furnace crown. In principle, these reverberatory furnaces are similar to the refining furnaces and to the open-hearth steel furnaces used in ferrous metallurgy, although the temperatures to be attained and, therefore, the methods of firing, are different. Another important factor in the development of the reverberatory furnace for copper smelting has been the introduction of pulverised coal firing. For the blast furnace it is necessary to employ coke, since the fuel must be sufficiently hard and strong to bear the superimposed weight of the charge without crushing unduly. Only in this way can the charge be kept sufficiently "open" to allow of the free passage of the gases. The production of coke involves expensive plant, even if the recovery of by-products more or less covers the cost of the coking operation itself. Only certain types of coal, moreover, lend themselves to the production of metallurgical coke. For pulverised coal firing, on the other hand, finely divided coal of very moderate quality, much of which had formerly to be regarded as practically waste, can be used. For furnaces where very high temperatures are required and pre-heating of the air

is essential, the use of coal-dust firing offers some serious difficulties. The ash, which represents anything from about eight to twenty per cent of the powdered coal, is necessarily blown into the furnace with the coal and most of it passes into the flues. In the high-temperature regenerative furnaces the hot products of combustion pass through regenerator chambers which serve the purpose of heating the incoming air, and the ash from the coal-dust tends to clog and destroy the brick-work of these chambers. This difficulty applies with great force to steel melting, but does not arise in the metallurgy of copper, since the temperatures are not high enough to require regenerative furnaces.

The further refining of copper may be carried out either by furnace methods or electrolytically. In the former process—which is much the older—the crude "blister" copper is melted in reverberatory furnaces and subjected first to strongly oxidising influences—as by blowing air through the molten metal. When the impurities have been oxidised as completely as possible and have been removed by scraping away the resulting surface slag, the metal is subjected to a reducing action by the process of "poling." "Poles" of wood—sometimes the trunks of trees of moderate size—are pushed down into the molten mass, while charcoal is sprinkled on the surface. As the wood burns, the products of combustion reduce the cuprous oxide in the molten metal to copper. The process is stopped when the metal has reached a condition known as "tough pitch" which is usually judged by the appearance of a small quantity which is ladled out and allowed to solidify. The examination of the fracture of a small bar is also a good guide. The "tough pitch" condition cannot, in the case of refinery copper, be defined by any specific oxygen content, since the proportion of oxygen required depends upon the amount of other impurities present, notably arsenic. Furnace refined copper is rarely if ever free from the latter impurity.

Electrolytic refining has increased greatly. The process consists in using the crude copper as anode or positive plate in an electrolytic cell. The copper of the anode is dissolved, under the action of an electric current, in the copper sulphate solution which constitutes the electrolyte of the cell, pure copper being deposited on the negative plate or cathode. The impurities present in the crude copper accumulate as a slime at the bottom of the electrolytic cell and this slime is collected and treated for the recovery of other metals, particularly platinum, gold and silver. The recovery of these by-products plays an important part in the economy of the electrolytic refining process.

The product of electrolytic refining, known as "cathode copper" is a metal substantially free from all impurities except a little sulphur, the latter due to the mechanical enclosure of particles of the sulphate solution used in the electrolysis. For some purposes the cathode copper is used in that condition—as, for example, in the preparation of alloys. As produced in the refining cell, however, it is not suitable for mechanical treatment, such as rolling or drawing and where it is to be used as raw material for such purposes, remelting is required. This is done in large reverberatory or open-hearth furnaces, conditions during melting being kept oxidising in order to eliminate any traces of sulphur. This oxidising melting is followed by "poling" in order to lower the oxide content and bring the metal to the "tough pitch" condition.

The relative merits of electrolytic and furnace-refined copper were, for a long time, the subject of acute discussion and there are still a few metallurgists who prefer the "best selected" copper—*i.e.,* the refinery product—to the high-purity material. The choice between electrolytic and refinery copper is now, however, almost solely a question of price.

Much attention has been given in recent years to an accurate study of the effects of impurities in copper, some very thorough work on the subject having been carried on for a number of years for the British Non-Ferrous Metals Research Association at the National Physical Laboratory, England, although much important work on the subject had been done earlier, as for example by Hampe in Germany and by Skowronski in America. All impurities are found to render copper harder and less ductile and to lower the electrical conductivity. Bismuth is particularly potent, while arsenic, on the other hand, appears to make the metal tougher rather than more brittle unless the proportion is very high. In considering these effects of impurities, however, it must be borne in mind that a certain small amount of oxygen in the form of cuprous oxide is always present in copper that has been melted. While the effects of small proportions of oxide both upon the physical and electrical properties of copper are small compared with those of phosphorus or bismuth, these effects must be taken into account when the simultaneous presence of another impurity is considered. Thus it has been shown that arsenic tends to counteract the effects of oxygen and it would not be surprising to find that arsenic has a similar action in regard to the deleterious effects of antimony and even of bismuth. If this is the case it may be found possible to admit proportions of antimony and bismuth which, in the absence of a suitable amount of arsenic, are known to be prejudicial.

The metallurgical processes which have been considered in outline above, serve as illustrations of the processes and methods used in the reduction of non-ferrous metals. Every individual metal, of course, requires the use of special processes and methods, but it will not be possible here to deal with further examples of such processes, except in regard to two metals typical of entirely different conditions. One of these, zinc, owes its interest to the fact that it is volatile at the temperatures required to bring about its reduction by carbon, while the other—aluminium, is a metal whose chemical activity especially with regard to oxygen, is so high that reduction by carbon and heat alone is not possible.

Until a comparatively recent time the whole of the world's zinc supply was produced by distillation in the retort. In this process, oxide of zinc is mixed with finely divided carbon, generally in the form of coal, and heated in long fire-clay tubes or "retorts." The product of the reaction in these retorts is a vapour consisting of metallic zinc and oxygen—probably volatilised zinc oxide. This is caught in receivers, placed at the mouths of the retorts outside the furnace, where metallic zinc is condensed. A certain proportion of the product, however, condenses as a fine bluish-white powder, known as "blue powder" which is a mixture of metallic zinc and zinc oxide. It is not commercially feasible to recover the zinc from this powder and its production constitutes a loss in the process, although for chemical purposes a reasonably satisfactory market for a certain amount of this powder has, in recent years, been found.

The product of the zinc-distillation furnace suffers from a serious disadvantage. The ores of zinc and the concentrates which are treated in the furnace always contain considerable proportions of lead. This lead is rather less volatile than zinc, but sufficiently so to bring about a contamination of the zinc produced which may amount to one or two percent. Formerly no great importance was attached to this impurity, but the effects of impurities in metals and alloys have come to be more fully recognised and there is now an increasing demand for metals of the highest possible purity.

Special interest attaches to the rapid development, during recent years, of electrolytic zinc production both in America and Australia—at Port Risdon in Tasmania. The zinc produced is of very high purity as compared with the product of the distillation furnace. Although the cost is still somewhat higher than that of furnace-produced zinc, the pure electrolytic metal is rapidly winning wide markets, thanks to the absence of lead and the complete regularity of composition. Cadmium is a by-product of Australian zinc production and this metal is now becoming industrially important. It is finding uses in electro-plating, for solders of higher melting point than the ordinary lead-tin solders (alloys of zinc and cadmium) and as an alloying element which, in small quantities, serves to harden and strengthen copper conducting wires without decreasing the electrical conductivity so much as other additions. Electrolytic zinc production is also making rapid advances in America and has attained an output which is about one fifth of the world's total zinc production.

Aluminium.—Brief reference has been made above to the production of aluminium by fusion electrolysis. (*See* also ELECTROMETALLURGY.) It is, in this respect, typical of a group of metals whose oxides cannot be reduced by heating them with

carbon or by the action of ordinary reducing gases. Among these magnesium, calcium, sodium and potassium, and latterly, beryllium may be mentioned. The processes differ widely in detail, but are all based on similar principles. The essential features are the use of a sufficiently fusible electrolyte in which an oxide or a salt of the metal can be dissolved and from which the pure metal is separated by electrolysis. The whole technique of fusion electrolysis differs widely from the aqueous process as practised in the refining of copper. The necessity of keeping the electrolyte in the molten condition requires the application of heat which may be furnished separately or by the electrolysing current itself. Heavy currents and relatively high current densities are consequently required. Usually, these electrolytic processes are only feasible where very cheap power is available, usually from water power. Alternatively, very cheap fuel may serve the same purpose, as at the great works at Bitterfeld, Germany, where cheap brown coal fuel is now employed mainly for the production of magnesium. This is produced by the electrolysis of a chloride electrolyte from which chlorine gas is also evolved, and this gas is itself an important product.

The production of aluminium is carried out on a much larger scale than any of the other fusion-electrolysis processes and has been brought to a high degree of efficiency. The electrolyte, like most of those used in processes of this type, is of a halide character. It consists of double fluorides of aluminium and sodium (cryolite) which have the power to dissolve aluminium oxide. This oxide is decomposed during electrolysis and is replaced by fresh oxide fed to the furnaces. In the fusion electrolysis of other metals it is usually necessary to convert the metal from the ore into a chloride or fluoride before it can be incorporated in the electrolyte, which is usually also a double fluoride.

Another important feature which applies to most of the metals produced by fusion electrolysis is that they are of low density—so-called "light metals." This has an important effect on the methods which have to be employed in their production, since there is a strong tendency—unless the relative densities are carefully regulated—for the metal to rise to the surface of any molten bath and there to become rapidly oxidised or burnt away. Even in the case of aluminium, great care has to be taken to maintain the electrolyte at a density sufficiently low to allow the fluid metal to accumulate at the bottom of the bath. In the case of the very light metals such as magnesium and beryllium this would be almost impossible and instead of carrying out the electrolysis at such a temperature that the resulting metal is fluid—as is done in the case of aluminium—the temperature employed leaves the deposited metal just solid. Deposition occurs at the end of a rod cathode which, as it is built up by deposited metal, is gradually raised out of the bath. The result is the production of a solid stick or rod of the metal attached to each of these rising cathodes. Even with such readily oxidisable metals as calcium and beryllium this method has proved successful. It entails, however, the task of finding an electrolyte sufficiently fusible to be liquid at a temperature at which the metal itself is solid. In the case of beryllium, with a melting point above 1,250° C this is not difficult, but the problem is more serious with metals of relatively low melting points like magnesium or calcium.

Two other methods of reducing metals from their oxides to the metallic state deserve mention. The first is applicable to metals which, while themselves reasonably fusible, are difficult to reduce and have a strong tendency to form carbides. Chromium and manganese are examples of this type. In some cases the method of "alumino-thermic" reduction invented by Goldschmidt is applicable. This depends upon the powerful reducing action of metallic aluminium. The process consists in mixing the pure oxide of the metal with finely divided aluminium metal and igniting the mixture by the local application of intense heat. The reaction once started, sufficient heat is as a rule generated not only to melt the resulting metal but even to bring the aluminium oxide which is produced into fusion. The process, when iron oxide is used with aluminium, is in fact employed as a means of generating molten iron at a temperature high enough to serve for welding purposes. With chromium and manganese, also, the heat generated is sufficient to melt the resulting metal. On cooling after the reaction, a solid mass of the desired metal is found in the bottom of the crucible in which the operation has been carried out—or alternatively, the molten metal can be poured out into moulds. The resulting metals are free from carbon or carbides, but they contain an appreciable quantity of aluminium and the impurities derived from that metal, viz.: iron and silicon, while impurities derived from the containing vessel may also be present. For many purposes, however, these aluminium-reduced metals are sufficiently pure and their use makes it possible to prepare alloys free from carbon.

In the case of a few very refractory metals—notably tungsten and molybdenum, another method of reduction has to be employed. Here the oxide is first reduced to the metallic state, generally by the action of hydrogen gas at a high temperature. The metal is thus obtained in the form of a finely-divided powder which is useless except for the preparation of alloys. To bring the metal into the massive form sintering and swaging processes are employed. The metal powder is strongly compressed mechanically and the rather fragile rods thus produced are raised to a very high temperature in an atmosphere of hydrogen and are then submitted to prolonged and vigorous hammering in a swaging machine, the metal being kept surrounded by hydrogen throughout. Finally, the swaged rods are strongly heated by the passage of an electric current, when the particles of the original powder coalesce to such an extent that the rod presents the external appearance and the internal micro-structure of a solid piece of metal. The large quantities of tungsten used in the manufacture of electric lamp filaments are produced by this method. The process, it may be remarked, as a resemblance, in principle, to that by which wrought iron is produced without the fusion of the purified iron, while certain modern processes of reducing iron from the ore by a "direct" process of gas reduction without fusion come into the same category.

Iron and Steel.—Our survey of metallurgical processes has been illustrated so far with references exclusively to the non-ferrous metals. The same principles apply to the metallurgy of iron and steel but their application differs in important respects. These differences arise mainly from the fact that the value per ton of iron and steel is much lower than that of the non-ferrous metals and very low cost of production is therefore essential. This factor, together with the immense quantities and large sizes in which ferrous products are required have led to the development of processes on a scale much larger than that generally employed in connection with non-ferrous metals.

In the preliminary treatment of iron ores considerations of cost do not allow of elaborate concentration methods, while the relatively widespread and plentiful occurrence of suitable ores tends rather to the selection of those best fitted for a particular purpose than to special pre-treatment. The raw material of ferrous metallurgy may therefore be regarded as some form of iron oxide, contaminated in varying degrees by silicates and compounds of sulphur and phosphorus. The beginnings of modern ferrous metallurgy were located at points where coal and iron ore were both available. The relation to coal-fields has been maintained, but modern facilities of transport now make it possible to use ores derived from distant sources—such as the Spanish and Swedish ores which are largely used in England. Further, while in the earlier days of steel production ores containing more than a small amount of phosphorus could not be used, the development of the "basic" processes, following the discoveries of Thomas and Gilchrist, has rendered available great deposits of phosphoric iron ore, such as the "minette" ores of Lorraine.

In modern practice the oxide of the iron ore is reduced to the metallic state by the action of carbon; the crude and impure product is known as "pig iron." This corresponds to some extent with the matte or at most to "blister copper" in copper smelting and is also carried out in blast furnaces, but the iron blast furnaces are of very great size. The blast furnace is a vertical shaft or tower which is fed from the top with alternate layers of ore (iron oxide), coke (carbon) and limestone. A blast of pre-heated air is driven into the tower at the sides near the bottom by means

of water-cooled nozzles or "tuyeres" and the coke in the charge is burnt, with the formation of a large amount of carbon monoxide. At a higher level in the furnace, part of this gas, and also to some extent the solid carbon of the charge, react with the iron oxide, metallic iron being liberated. This gradually falls to the bottom of the furnace and accumulates as liquid iron at the bottom. Meanwhile, most of the silica present in the ore combines with the lime of the limestone and with other oxides, to form a fairly fusible slag which also runs down to the bottom of the furnace and forms a layer above the molten iron. From time to time the furnace is "tapped"—*i.e.*, molten iron is allowed to run from an opening made at the base of the furnace tower. The molten iron flows into a sand-bed.

Efforts have been made to improve the efficiency of the blast-furnace by treating the air which is blown into it. The first step, which has long since passed into universal practice, is the pre-heating of the blast. More recently it has been suggested to remove the moisture from the air of the blast. Extensive trials, especially in America, have shown that the furnace works better with dry air, but the methods of drying available some years ago—mainly by refrigeration—were too expensive. More recently the remarkable drying powers of "silica gel" which is obtained by drying gelatinous precipitated silica, have been utilised and it seems probable that the application of this drying process to blast furnaces may find large-scale application. Another improvement can be effected by enriching the air of the blast with oxygen. Undoubted advantages can be obtained by this means, but its economy depends upon the cost of oxygen.

Since large volumes of air are blown into the blast furnace, corresponding volumes of gas must pass through the top. Formerly these were allowed to burn at the top of the furnace. This waste of valuable fuel is now avoided by closing the top of the furnace. The gas is collected and used in a variety of ways. It supplies the heat required for pre-heating the blast for the furnace and it may be burnt under steam boilers to generate the power required for the blowing engines that produce the blast while the surplus may produce electric power for other purposes.

Certain difficulties arise in the utilisation of blast-furnace gas from the fact that the gas carries with it a large volume of dust. Even if the gas is to be burnt almost immediately under a steam boiler, the bulk of this dust must be removed, otherwise the boiler and its flues rapidly become choked. If the gas is to be used for burning in large internal combustion (gas) engines then still more complete cleaning from dust is essential. Gas-cleaning appliances are installed in many blast-furnace plants. They either operate by passing the gas at fairly low speeds through a large number of sacks of finely-woven material (Halberg-Beth system) or else the dust is removed by the Lodge-Cottrell method of electrical precipitation. This method of precipitating dust from fumes is used in a number of other metallurgical processes. It depends upon the fact that fine particles of dust or moisture suspended in air, when electrified rapidly coalesce into particles which are heavy enough to settle. Electrification is produced by a high-tension discharge from a point. This requires special appliances, but the process is now widely used. In the case of blast-furnace gas, however, it only appears to become economical where the degree of cleaning which can be achieved by sack filtration is insufficient.

The quality of the pig-iron produced by the blast furnace depends upon the character of the ore with which the furnace is fed and also on the way in which the furnace is run. The pig iron always contains a considerable amount of carbon—of the order of 3 or 4 per cent. and different amounts, according to circumstances, of silicon, sulphur and phosphorus, as well as other impurities. The silicon of the iron is mainly derived from the siliceous "gangue" material which is always present, more or less, in the ore. Sulphur is derived, usually, from pyrites (iron sulphide) in the ore and phosphorus from phosphate minerals in the ore. The coke also contributes to the impurities of the iron, principally to the sulphur and for that reason iron made with wood-charcoal, as fuel in Sweden, is of higher purity than coke-made iron, although the high purity of the Swedish ores has much to do with the result.

The composition of the pig iron determines the uses to which it can be put. These are, broadly, of four kinds:—the production of iron castings in the foundry; the production of wrought iron by the puddling process and the third and fourth are the production of steel by the acid and basic processes respectively, although further distinctions exist between irons suited for Bessemer as distinct from open-hearth steel-making. In iron founding—*i.e.*, the production of iron castings, the requisite composition is obtained by a judicious blending of different varieties of pig-irons of different composition. The cast-iron must have a sufficient content of silicon to render it grey and soft by the formation of graphite, and frequently the presence of a considerable amount of phosphorus is considered desirable in order to render the iron easily fusible and fluid. Formerly the scientific aspects of iron founding were much neglected, but a good deal of research work on the subject has been done recently, particularly in Germany where methods for the production of special and superior qualities of cast iron have been worked out. In England the subject has also received attention from the British Cast Iron Research Association.

Wrought Iron.—The pig iron required for conversion into wrought iron must meet special requirements arising from the nature of that ancient process. The conversion of pig into wrought iron by puddling is one of the oldest of the processes of ferrous metallurgy. It has lost ground to the modern steel-making processes, but appears to hold its own for certain special purposes. For example, the best qualities of welded chain are still made of wrought iron although some degree of competition is now arising from electrically welded mild steel chain. Wrought iron differs from mild steel both in mode of origin and in constitution and structure. Steel is always made by the oxidation of the molten pig iron carried out in furnaces at temperatures high enough to maintain the purified metal in the fully liquid state. In the puddling of wrought iron, on the contrary, although the initial charge of pig iron is molten, as oxidation proceeds by the absorption of oxygen from the air and from the iron oxide with which the furnace is lined, the metal becomes increasingly pasty and, when the elimination of the carbon is nearly complete the resulting iron is fully solid although very soft. It is, however, intimately mingled with the slag or cinder, consisting mainly of iron oxide and silicate, together with a certain proportion of phosphoric compounds, which is produced during the puddling process. Much of this is pressed out during the shingling and forging operations to which the hot, pasty metal is subjected, yet a considerable amount of cinder remains behind in the finished product. The true metallic structure of the iron is thus interrupted frequently by veins of non-metallic matter. This structure gives to the material a pseudo-fibrous texture, but it is well to bear in mind that the individual "fibres" of the iron are, like all other iron and steel, aggregates of minute crystals and not strictly "continuous" fibres.

Steel.—The steel-making processes at present in extensive use for the production of mild steel consist essentially of a process of oxidation by which the carbon and certain of the impurities of pig iron are eliminated. The oxidising process, however, usually leaves the metal in an over-oxidised condition and subsequent reduction of the excess of oxide is necessary. It will be seen that this procedure is analogous to that adopted in the treatment of copper mattes, which are first over-oxidised and then subjected to a reducing treatment by "poling." In the case of steel, reduction by the direct action of carbon or by the equivalent of "poling" is not used, but de-oxidation is effected by the addition to the steel, just before it is tapped from the furnace, or even in the ladle after tapping but before the metal is run into the moulds, of certain "ferro-alloys." These usually contain a considerable amount of carbon to serve for re-carburising the steel to the desired degree, and also either or both manganese and silicon. Sometimes aluminium is also used as a de-oxidant. These substances have a sufficiently strong affinity for oxygen to rob the iron of that element, although this de-oxidation is never complete. The products of this reaction—oxide of manganese

and silica, or—more probably—a silicate of iron and manganese—form more or less fusible slag particles and, if the steel is given time to settle, these rise to the surface and are eliminated. As a rule, however, they remain in suspension in the steel and form undesirable non-metallic enclosures.

Two methods of oxidising the molten pig-iron are employed. In one, known as the Bessemer process, air is blown through or over the molten iron until the character of the resulting flame shows that oxidation has been carried far enough. The burning of the silicon and carbon content of the pig iron generates enough heat to raise the molten metal to a very high temperature, sufficient to allow it to be run out of the converter into a ladle and then into moulds. In the "Open Hearth" process on the other hand, the pig-iron, usually mixed with a considerable amount of steel scrap, is melted on the hearth of a large furnace regeneratively fired so as to maintain a very high temperature. It was, in fact, the invention of the Siemens regenerative furnace which, by making it possible to produce and maintain steel-melting temperatures easily and economically, made this type of process possible. Once the charge is molten it is oxidised by the addition of an iron-oxide ore, the oxygen of this ore combining vigorously with the carbon and silicon of the pig iron in the charge. A slag layer is formed above the layer of molten metal and protects it from direct interaction with the atmosphere of the furnace.

The reactions which occur in both types of oxidation process depend upon the material with which the furnace is lined. At the high temperatures employed the composition of the slag must be adapted to that of the lining, otherwise rapid attack would result. In the "acid" processes the lining of the open-hearth furnace or of the Bessemer converter is siliceous in character: the name "acid" refers to the acidic character of the silica which predominates in these linings and which must, therefore, be kept high in the slag also. Under such a slag it is possible to remove or lower the silicon and the carbon content of the charge, but it is not possible to purify the resulting steel in regard to its content of phosphorus or sulphur. It follows that, for the production of high-class steel in the acid process the pig-iron employed must itself be sufficiently low in sulphur and phosphorus, and this stringent condition—in view of the fact that the finished steel is frequently required to carrry less than 0·05% of these impurities—sets a limit on the range of pig-iron and therefore of ores which can be employed.

Basic Steel.—In the "basic" processes the furnace linings are made of magnesia and lime, bonded together with tar or similar material and containing very little silica. The slags used with these basic linings must also be correspondingly basic, *i.e.*, low in silica. A mixture of lime and magnesia, even with a small amount of iron oxide would not be sufficiently fusible, but the acidic element is provided by phosphoric acid, derived from the phosphorus of the charge. The basic slag is thus a highly basic lime-magnesia phosphate and tends to absorb phosphorus from the iron so long as oxidising conditions are maintained—for instance, by the frequent addition of iron oxide in the form of ore. Under reducing or less strongly oxidising conditions, however, there is a tendency for phosphorus to be reduced by the iron and to be returned from the slag to the charge. In the basic process, any silicon present in the charge rapidly forms silicates with the bases of the slag and would, if present in sufficient amount, attack the furnace lining. It will thus be seen that while in the acid process phosphorus is extremely undesirable, while silicon is needed, the reverse holds for the basic processes where pig-irons can be used which have a high phosphorus content, while high silicon is undesirable. There is one other point of general importance in which the two processes differ; it is much more difficult—on account of the danger of returning phosphorus to the molten steel—to effect thorough de-oxidation in the basic process than in the acid. Badly made basic steel, therefore, is liable to be over-oxidised and unsatisfactory, although when properly operated produces material of excellent quality.

Besides the four main processes various operations are employed in the treatment and production of steel for special purposes. Of particular interest from the comparative point of view are the processes for decarburising and carburising, by which the carbon content of the iron alloy can be changed without actual melting. The treatment of certain types of cast-iron by prolonged heating, generally in oxidising surroundings, leads to a profound change in the condition of the carbon. In the "white" iron as cast for this purpose the carbon is present as the compound Fe_3C—known as "cementite." In this condition the iron is very hard and brittle. If, however, a "white" iron of suitable composition, which has solidified without separation of graphite, is subjected to prolonged heating in oxidising surroundings, part of the carbon is oxidised and removed entirely, while the remainder is deposited in the form of nodules of finely-divided carbon. Unlike the graphite flakes of "grey" cast iron, these do not seriously interfere with the strength or ductility of the metal, and the iron is thus rendered "malleable." It is considerably inferior to true wrought iron or steel, since it still contains the finely divided graphite and the other impurities, but it is sufficiently strong and ductile for many purposes for which untreated iron castings would be too weak and brittle.

Cementation.—The converse of this process is that of carburising or "cementation." If bars of wrought iron or very low-carbon steel are packed in a carbonaceous material, such as a mixture of charcoal and barium carbonate, and are heated for some time at temperatures near 900° C the iron absorbs carbon. If this process is carried to a moderate extent, the iron or mild-steel article is left at the end with an outer layer or case of high-carbon steel. This, unlike the soft low-carbon core, can be hardened by quenching and in this way "case-hardened" articles are produced. Instead of a plain iron or low-carbon steel, a special type of nickel steel can be employed and this allows the final heat treatment to be much simplified. A surface hardening process depending on the formation of iron nitride has recently been worked out in Germany. Prolonged heating in a nitrogenous atmosphere at moderate temperatures is employed, and no final quenching or other heat-treatment is required, the core of the steel retaining its original high quality while no distortion can occur. The process is only applicable to steels of special composition, in which a certain content of aluminium is important.

The simple carbon cementation process has, however, another use which was formerly very important. Before the modern processes of steel-making were developed, high-carbon steel, such as is used for tools and weapons, was for a long time prepared almost exclusively by the cementation of wrought iron. For this purpose the carburising process is prolonged until the entire thickness of the bars is penetrated by the carbon, so that the whole of the material is converted into high-carbon steel. The product is known as "blister steel" and could, to some extent, be used direct in that condition. Preferably, however, the cemented bars were melted in small crucibles and the molten high-carbon steel cast into small ingots or other moulds—the product being "crucible" or "cast" steel. For a long time this product, when prepared from the purest Swedish wrought iron was regarded as the highest grade of steel. In recent times, however, the high degree of purification which can be applied to steel by melting it in a basic-lined electric furnace has made electric steel—when properly prepared—a serious rival to crucible steel.

Electric Steel Processes.—The application of electric processes to iron and steel differs markedly from its use in non-ferrous metallurgy. The electro-deposition of iron in the wet way is possible and yields a product of high purity; the cost, however, is too high to allow the process to compete with the large-scale furnace methods. Fusion electrolysis of iron is also possible, but the process has not been used. The electric furnaces employed in steel making, and—to a much lesser extent—for the reduction of iron from its ores—serve essentially as electrical generators of heat—*i.e.*, they are melting and not electrolytic appliances. As a rule alternating current, usually of the three-phase type, is employed, thus precluding all electrolytic effects. The electric furnace is used mainly for the remelting of scrap steel which can be successfully purified with very little loss. The production of alloy steels of accurately-determined composition is also facilitated in the electric furnace because of the exact control of composition which it per-

mits. On the other hand, the electric furnace has the disadvantage that the source of heat is costly so that in spite of the efficient way in which the heat is generated within the furnace itself, the electrical method of melting proves more costly than the fuel-fired furnace except perhaps in localities where very cheap water-power is available. For this reason the use of the electric furnace has not extended as much as was at one time expected.

"Cast" and "Wrought."—The preparation of the metal in the pure or approximately pure form, generally in the liquid state, is a distinct stage in most processes. It is only the beginning of the series of operations by which the metal is brought into its finished form. Those operations vary widely according to the form in which the metal is to be finally used. Broadly, however, metallic objects may be divided according to their mode of production into two types: "cast" and "wrought." The "cast" material is brought into its final shape, so far as metallurgical operations are concerned, by allowing the molten metal to fill and to solidify in a mould of suitable shape. "Wrought" material, on the other hand, begins its career by solidification in a mould of simple shape and the resulting solid ingot, slab or other shape is then brought into the desired form by working, which may be done either in the cold or at an elevated temperature, by rolling, pressing, forging, stamping, drawing, etc. There are many metals and alloys which cannot be "wrought" because they are, even when hot, too brittle to withstand plastic change of shape. Such materials—of which cast iron is a typical example—can only be used in the cast state. Finally, the finished or nearly finished material may be subjected to certain forms of heating and cooling known as "heat treatment," which improves its properties to a marked extent.

The first step in bringing metal into the desired finished state consists in causing the liquid metal to fill a mould, where it solidifies as a solid casting which has the shape of the interior hollow of the mould. Although superficially simple, this process offers many difficulties. These are greatest where the metal melts at a very high temperature and in those cases where the liquid metal absorbs large volumes of gas which are liberated during solidification.

A large proportion of the liquid metal produced throughout the world is required for future mechanical working, such as rolling or forging and is therefore cast into moulds of very simple shape. The most striking example is the production of steel ingots, which range in size from a small rectangular block weighing a few pounds to huge tapered octagonal masses weighing over a hundred tons. Except in the case of crucible-melted steel, the liquid metal is first run from the refining furnace into a large "ladle"—generally a steel box open at the top and provided with a refractory lining. These ladles are sometimes capable of holding considerably more than 100 tons of liquid steel and are moved about the furnace building by powerful overhead cranes. For filling they are brought in front of the furnace, from which the liquid steel is allowed to escape through a tap-hole at the base. From this hole the liquid steel runs along a gutter or "lander" lined with refractories and falls into the ladle as a cascade from which great showers of sparks arise. A photograph of this striking spectacle, taken at the proper moment, makes a picture at once impressive and inspiring. From the ladle the liquid steel is afterwards allowed to flow into the cast-iron ingot moulds.

The solidification process is comparatively simple in a pure metal free from gas, but as steel is a complex alloy of iron with carbon and other elements, and contains dissolved gas as well as oxides, sulphides and silicates in suspension, the process becomes complex. In spite of an immense amount of laborious investigation the details of the solidification of steel are neither fully understood nor entirely under control. The principal factors which play a part in the process of ingot solidification are briefly as follows:

(a) **Contraction.**—The steel after solidification occupies a smaller volume than in the liquid state. Since the layer of metal next to the wall of the mould solidifies first, and successive layers of solid metal are formed on the solid crust thus initiated, the last liquid portions are left at or near the centre of the ingot. A funnel-shaped contraction cavity or "pipe" is formed which may extend well down the centre of the ingot. This "pipe" must, for most purposes, be eliminated and a large part of the upper portion of the ingot must be cut off and discarded. This can be partly avoided by using containers, usually of fire-clay and known as "sinkhead" or "hot-tops" placed on top of the open end of the mould. The molten steel is allowed to fill these as well as the mould proper, and little or no solidification takes place in these "heads." They consequently provide a reservoir of liquid steel from which the contraction in the ingot proper can be made good. This method confines the pipe more or less to the "feeder head" of the ingot, and the amount which has to be cropped is much reduced.

(b) **Gas Liberation.**—Liquid steel, like most liquid metals, is capable of dissolving large quantities of gas, especially hydrogen. Most of this gas is driven out of solution when the liquid metal crystallizes and then partly escapes to the surface. A considerable amount, however, fails to escape unaided and forms cavities or bubbles in the solidified metal. It is contended that in steel which is to be rolled or forged such gas cavities are harmless because their surfaces, when subsequently pressed together at a high temperature during rolling or forging, unite by welding. Such welding, however, does not always occur; a great many of these cavities can never weld, because their walls become coated with impurities, such as silicates and sulphides, gathered from the adjacent steel during the pasty stage of solidification. These can be traced as long lines of "non-metallic enclosures" in the finished steel. The formation of gas cavities or "blow holes" in steel can be to a great extent regulated by the manner in which the oxidising processes in the steel furnace are conducted. If the reactions between oxide of iron and carbon are allowed to complete themselves so that the agitation or "boiling" of the steel in the furnace ceases, the product is a "dead melted" steel in which gas cavities will be comparatively few. Such steel, however, shows marked "piping" as described above. Even if the process is stopped at a point where there is still some oxide of iron present in the bath, the steel can be "killed" by the addition of a relatively small quantity of aluminium. Steel killed in this way "pipes" like "dead melted" metal. If, on the contrary, the steel is brought into the ingot mould while still actively generating gas—so-called "wild" steel—this process continues to some extent during solidification. A good deal of the gas there liberated is trapped in the solidifying steel which, consequently, contains a large number of "blow holes." The formation of these holes counteracts the effects of the normal contraction of the steel, and the steel does not appear to shrink while solidifying—it may, indeed, appear to rise in the mould. Such steel is called "rising" or "rimming" steel. It is also—perhaps more frankly—described as "unsound" steel. It has, from the point of view of mass-production, the advantage that as there is no definite "pipe" almost the whole of the ingot can be rolled, thus affording a larger yield of finished steel.

(c) **Segregation.**—As steel is a complex substance and the rate of solidification of any but the smallest ingot is necessarily slow the constituents have time to undergo separation or "segregation" which results in non-uniformity of chemical composition in different parts of the ingot. This subject cannot be adequately discussed in a general article but it is important to mention it because segregation plays a very important part in affecting the quality of large steel ingots. It is, of course, a natural process which, under conditions of slow undisturbed cooling in large masses, cannot be prevented except, possibly to some extent, by a careful choice of the composition of the steel itself. At the same time it has to be regarded to some extent as imposing a limitation on the size of the ingot, and consequently of the forgings or plates, which it is desirable to use where high and uniform quality is essential.

(d) **Contraction Stresses.**—Since the outer portions of an ingot necessarily solidify while the inner portions are still liquid, the latter—on subsequent solidification and contraction—exert a powerful inward pull on the outer portions. Masses of large size are therefore apt to be under severe internal stress and may, sometimes, crack spontaneously or when placed in a re-heating furnace. The formation of such cracks or "clinks" can be largely

avoided by correct design of the ingot moulds. Part of the difficulty is also avoided by the practice—adopted also with a view to economy—of drawing the ingots from the moulds while the steel is still very hot, so that the interior may still be partially liquid, and placing them in so-called "soaking pits"—a kind of pit furnace in which the temperature throughout the ingot has the opportunity to become equalized and the steel is, moreover, kept at a temperature suitable for forging or rough rolling.

The production of ingots or slabs of the non-ferrous metals and alloys, while subject to the same general laws and phenomena as steel, differs in regard to the conditions which have to be met. Non-ferrous ingots are never very large so that many of the problems which arise from large size, very slow cooling and extensive segregation, do not enter into the corresponding non-ferrous problem. On the other hand the non-ferrous ingot has frequently to meet special conditions. The quality of the surface of the cast slab is often important. In steel, so long as there are no cracks or foldings, smoothness of the surface is not essential. Brass, on the contrary, has frequently to be rolled out into a finished product with a smooth surface, so that the nature of the ingot or slab surface is very important. In the same way, blow-holes lying just under the ingot skin, which are often regarded as normal in steel, are not permissible in non-ferrous metal which is to be rolled into strip or sheet, since these cavities tend to open out during the annealing process following cold-rolling, and to cause defects known as "spill" and "blister." Much more attention is therefore paid in non-ferrous ingot casting to the details of mould surface, dressing, etc., and also to the method of filling the moulds. In steel practice this is very frequently done by allowing the fluid metal to run into the mould from an opening in the bottom of a large ladle. In non-ferrous practice, where the masses to be handled are much smaller, the molten metal is often poured direct from the crucible, or even from the furnace, pouring being done "over the lip" of the crucible and into the open top of the mould. For certain special purposes a process has recently been developed in France (the Durville process) in which the molten metal is first poured into a ladle or receptacle which is connected by a channel or short "runner" with a number of parallel small ingot or bar moulds. Ladle, runner and moulds are mounted together on trunnions about which the whole assembly is slowly rotated so that the ladle rises and the moulds are lowered. The metal then flows steadily from ladle to moulds. The resulting bars have remarkably perfect surfaces, but the process is readily applicable only to copper alloys containing a small amount of aluminium. Many other processes for filling ingot moulds have been developed, some working by gravity with or without the interposition of funnels or separators of various kinds, others by pressure applied to the liquid metal that forces it into the mould.

In regard to dissolved gases, while non-ferrous metals do not undergo a "boiling" process in which gas is generated during refining and melting, as in steel, they yet absorb considerable quantities of gas from the atmosphere of the furnace and from other sources. In some cases this leads to difficulty in securing soundness whether in ingots or in shaped castings. Copper is an example of this kind, but the phenomenon is encountered to a marked extent also in aluminium and its alloys and in certain kinds of bronze. Two methods have been recently evolved for freeing non-ferrous metals from dissolved gas. The most positive of these is that of "pre-solidification." It consists in allowing the molten metal or alloy to solidify very slowly, preferably in the crucible and in the furnace where it has been melted. During this slow solidification the crystallizing metal expels the gas, which has time to escape to the surface. As soon as solidification is complete the metal is rapidly re-melted and cast.

Another method of gas-expulsion consists in bubbling through the molten metal a more or less inert gas which, by local reduction of the partial pressure of the dissolved gas, leads to the removal of the latter. This method is successful when nitrogen is bubbled through molten aluminium alloys. Nitrogen, however, is itself slightly soluble in many metals, so that this process is not universally applicable. In some alloys, on the other hand, one of the constituent metals is itself volatile and escaping bubbles of its vapour serve to expel other gases in the same manner as bubbles of an inert gas. This is, perhaps, the reason why brass—with its large content of volatile zinc—readily yields sound castings.

The production of shaped castings entails processes and problems widely different from those of ingot production, but it is impossible to discuss them even in outline here. They vary according to the nature of the metal to be cast. Some reference has already been made to cast iron. Steel offers much greater difficulty in regard to casting. The tendency of the metal to liberate gas during solidification is one of these: another is the high temperature of molten steel which makes severe demands on the materials used as moulds. Castings are made in two types of mould—sand moulds and "permanent" or "chill-moulds." The former have to be specially prepared—sometimes by means of machines—from patterns for each casting. The "moulding sand" of which they are made must be carefully adapted to the needs of the metal to be cast. For steel it must be highly refractory so that it may not melt and "burn" on to the steel. Sand for moulding, however, must be sufficiently plastic to form moulds of adequate strength and cohesion, while the mould must remain sufficiently porous to allow the rapid escape of air, steam and other gases.

The use of metal or "permanent" moulds offers many advantages where the process is applicable. The constantly repeated cost of sand moulding is eliminated, but against this must be set the high first cost of the metal mould or "die." The latter is usually only justified where the same casting is required in great numbers. For many metals there is also a distinct advantage in regard to structure and strength which results from the relatively rapid solidification which takes place in a metal or "chill" mould. For steel it is not easy to use metal moulds but they have in recent years found application in regard to certain kinds of cast iron. For the non-ferrous metals chill casting is extensively practised, especially in the case of some aluminium alloys. For the lower-melting non-ferrous metals the process known as "die-casting" has found extensive application on account of the accuracy of dimensions which can be attained. Die-castings can be used for many purposes without subsequent machining and are widely employed in the cheaper kinds of light machinery, domestic and office appliances, etc.

Die-casting consists essentially in producing castings in metal "dies" or moulds, but as a rule the process is carried out by forcing the molten metal into the mould rapidly under pressure. This is done in machines which also open the die and eject the casting, the operation being rapidly repeated. The widest use of this method is made in castings of low-melting alloys of zinc, tin and lead. It has recently been extended to many aluminium alloys and even to certain types of brass and bronze. The difficulties of the process, however, increase rapidly as the melting point of the alloy rises.

Reverting to the ingots in which a great part of the world's metal production is cast, we have to consider briefly the principal processes by which the finished products are produced. In these the metal is forced to assume new shapes by the application of large mechanical forces, which may be applied to the material while it is either hot or cold.

Mechanical Working.—The purpose of subjecting metal to the mechanical working is not merely that of bringing it into a desired shape. Mechanical work affects the structure and properties of most metals and alloys in a markedly favourable manner. When metal solidifies from fusion, especially if it does so in large masses and therefore slowly, it forms a crystalline structure which is relatively coarse—sometimes very coarse indeed. While it is true that, whatever the treatment to which metal may be subjected, it remains essentially crystalline, yet the size or scale of that structure is highly important as affecting physical behaviour. Mechanical working always breaks down the original "cast" structure and replaces it by a much finer and more satisfactory structure. In some metals, of which steel is the most important example, it is possible to produce a "refined" structure, comparable in scale with that of wrought metal, by heat treatment alone, but this is only practicable for pieces of moderate size because larger masses cannot be cooled rapidly enough to bring about the desired changes. In addition, mechanical working, particularly in the case

of steel, serves to close up, and perhaps to bring about welding of cavities existing in the cast material. It also brings about a redistribution of the non-metallic impurities. These become elongated in the direction in which the metal is caused to flow under mechanical treatment and in some cases confer upon the material something which has the appearance of grain or fibre. There is, however, no true fibre in any metal, although "fibrous" fractures are frequently obtained and are often rightly regarded as indications of good quality.

Forging and Rolling.—The process of forging may be carried out under hammers or presses. The former range in size from the hand-sledge of the blacksmith to the largest steam-hammers delivering blows of many foot tons. For much of the heaviest forging great hydraulic presses are used in which the heated metal is quietly pressed or kneaded into the desired shape. Forging, particularly on the large scale, is mainly applied to steel and in that material very large pieces are sometimes handled. The tubes of heavy naval guns are probably the largest of these, but parts of large ships are also very heavy forgings. These very large forgings are always made from the ingot itself, but for much of the smaller work the steel is first brought into the form of bars by rolling and is only then forged. Work of this kind merges into what is known as "drop forging" in which a carefully proportioned piece of steel bar is forged between heavy dies to assume a designed shape. Stamping and pressing may also be regarded as allied to forging, but while true forging is always applied to highly heated metal, stamping and pressing may be done either hot or cold. Here the metal is used in the form of bar or sheet and is forced into the desired shape, usually without much change of section or real flow of metal, but rather by bending accompanied by a certain amount of "drawing." Metal to be used in this way must, of course, possess an ample degree of ductility. The rolling process is used to convert ingots into forms which are small in cross-section in comparison with their length. Bars and sheets, rods and wire, rails and girders and all kinds of structural sections are produced in this way. Rolling is carried out in successive stages. In the early stage the purpose is, while gradually bringing the metal towards the desired shape, to improve its quality—especially its ductility—so that it can better stand the more severe subsequent treatment. Yet for this very purpose it is, in many cases, found necessary to make the first deformations of the metal very drastic. It is found that at almost any stage of mechanical working, if the change of shape or size forced on the material at any one stage is not sufficient to penetrate and affect the entire thickness, there is risk of damage. Accordingly, where an ingot of large size has to be "broken down" very large forces and correspondingly heavy deformations are applied. This occurs mainly in the rolling of steel and is carried out in very powerful machinery. The ingots are so large and heavy that they are handled by automatic appliances which take them from the furnace, feed them backwards and forwards through the great rolls and finally eject the finished billet from the rolling train. Some recently-erected rolling mills of this kind, which are employed for dealing with nickel ingots as well as for steel, are operated electrically and are controlled by two or three men from a control platform—there is no heavy manual labour. For smaller work, however, and in most of the non-ferrous industries, the metal is put through the rolls by hand.

While steel is always "broken down" hot, some of the softer non-ferrous metals and alloys can be safely treated cold. The essential nature of the process does not differ as between hot and cold rolling. The effect of cold rolling, however, is always to produce hardening so that, after a time, the metal has to be "annealed" in order to soften it prior to further cold-rolling. Such annealing usually consists in placing the metal in a suitable furnace and heating it to a temperature correctly chosen for each metal.

The details of rolling practice vary widely according to the metal employed and the purpose for which the product is required. Heavy plates and extremely thin sheets naturally demand entirely different treatment. Strip metal is sometimes rolled in so-called "continuous" mills and these are especially applied to the production of wire. In these mills, which are mainly used for steel, the hot metal is fed into the first set of rolls rotating at a moderate speed. The material emerging from the first rolls is fed directly into a second set which—since the length is increased by the passage through the first rolls—must run at a considerably higher speed. A number of sets of rolls are used in series in this way, the finished product, such as wire, leaving the last rolls at a very high speed. Other types of rolling result in the production of "sections" —*i.e.*, of material having the form of H or I beams, channels, angles, railway rails, etc. These are produced by the action of suitably shaped grooves cut in the rolls, but the differences in the rate of movement at the bottom of such grooves and near the top require careful consideration. Successive passes in such rolls must provide for the easy flow of the metal from one shape to the next.

Extrusion.—Another method of manipulating metals, more especially non-ferrous alloys, for the purpose of bringing them quickly and easily into the form of bars or rods having any desired section or into the form of tubes, is that of extrusion. Here the heated billet of metal, previously produced of the correct size and shape, is placed in a heavy steel cylinder and a steel ram is forced down into the cylinder from one end. At the other end there is an aperture or "die" through which the metal is forced to escape in the desired form. Rods or bars produced by this process are sometimes found to possess an interior defect. This is believed to be due to the manner in which the flow of the metal in entering the die from the chamber causes the outer portions of the billet, including the skin, to flow into the centre of the extruded bar. A means of avoiding this difficulty has been devised recently, by a modification of the extrusion press. It is possible to extrude many alloys which are not sufficiently ductile, in the cast state, to stand rolling. In other cases, rolling is still possible if the internal structure of the metal has first been modified either by previous extrusion or by preliminary forging.

Heat Treatment.—While the great majority of metallic products are put into use in the condition—so far as their inner structure and strength are concerned—in which the final stages of production have left them, an increasing number of articles (more particularly those intended for important engineering uses) are now subjected to some form of heat-treatment for the purpose of improving their internal structure and mechanical properties. In the case of steel castings, for example, annealing is almost universally applied for the purpose of removing some of the impurities from the inter-crystalline boundaries, where they tend to form embrittling cell-walls, and bringing them into the shape of small scattered globules which are comparatively harmless. The treatment breaks up the original coarse casting structure and a further improvement is effected by either "normalizing" or "quenching and tempering" the steel.

Simple annealing is also used for softening metal hardened by cold working, as in rolling, stamping, pressing, wire-drawing, etc. If carried out at a high temperature or for a long time this may result in the formation of a coarse and brittle structure. Fortunately this occurs only rarely in the non-ferrous metals, but in very mild steel it is frequently encountered. In this material, however, it is possible to produce a refining of the structure by "normalising." This consists in raising the steel to a temperature just above the critical range, maintaining it there only long enough to ensure that the whole of the piece has reached the desired temperature and then removing the steel from the furnace and allowing it to cool rapidly in still air. The result is a marked refining of the crystal structure with a corresponding improvement in the mechanical properties. If, however, the steel is of a very soft variety and is required to possess the greatest ductility without much regard to strength, the final heat-treatment may be simply annealing at a much lower temperature, such as 680° C, which is just below the critical range of the steel. This causes the carbide of the steel to become "balled up" into little spherical masses making the material very soft and relatively weak.

The most important forms of heat-treatment applicable to steel, whether a plain carbon steel or an "alloy steel" containing nickel, chromium, manganese, etc., is a double treatment known as "hardening and tempering." In some cases the first stage of this treatment is a true "hardening," but in a great many cases it can only be called "hardening" by analogy. A full discussion of these

transformations could only be given after an explanation of the metallography of steel and especially of the equilibrium diagrams of carbon steels and of alloy steels. Since space will not permit of such treatment, the subject can only be treated in the broadest outline. The general nature of the changes involved in heat-treatment of steel can, however, be explained in an approximate manner if it is realized that the metal iron, which constitutes the great bulk of all steels, even of the more complex alloy steels, can exist in at least two allotropic states, known as the α and γ states respectively. In pure iron, the γ state exists at temperatures between 900° C and 1,450° C. It is a soft non-magnetic substance which crystallizes with the face-centred cubic lattice. Below 900° C. pure iron assumes the α form, which is also relatively soft and ductile, but is—below 750° C—strongly magnetic. The two kinds of iron differ most widely, however, in their power of absorbing carbon in the condition which is known as "solid solution." Gamma iron has a considerable power of holding carbon in solid solution—up to about 1·2 per cent—while in alpha iron carbon is only soluble in very minute amounts. "Soluble" as here used simply means that the metal—in this case iron—can take up a certain proportion of the other element into its own crystal structure without the formation of a second constituent or kind of crystal. Thus a carbon steel at a high temperature consists of γ iron crystals holding carbon in solid solution, while on cooling through the transformation range—if the cooling is slow—the carbon is separated. As the iron itself undergoes transformation into the α form, crystals of iron carbide (Fe_3C) are separated. This is the condition of slowly cooled or annealed steel. By very rapid cooling—chilling or quenching—the transformation can be more or less suppressed or delayed. If certain alloying elements are present, particularly chromium and nickel, the retardation of the transformation is much facilitated and if enough nickel or manganese is present the transformation may be entirely suppressed. In that case the iron retains the γ condition, the steel is non-magnetic and soft. It is in the intermediate condition, where the transformation has been retarded rather than entirely suppressed that the steel becomes hardened.

The capacity of hardening was at one time believed to be a unique property of steel but it is now known in the alloys of other metals also. It was long regarded as mysterious and controversy still turns on its theoretical explanation. Here, however, we are mainly concerned with the fact that by suitable quenching, from a temperature above the "critical range"—*i.e.,* above the temperature at which the $\gamma\,\alpha$ transformation occurs—all but the very softest steels can be more or less strongly hardened. In the high-carbon tool steels hardening is utilized to provide cutting tools, cutlery, etc. Even for these special purposes, however, where the greatest hardness is desirable, it is not possible to use the steel in the fully hardened state produced by direct quenching if that quenching has been drastic, as in water. The steel in that state is too brittle. The steel is therefore slightly heated and thereby becomes "tempered." When quench-hardened steel is gently heated, as the temperature rises the suppressed transformation gradually takes place to a slight but progressive extent. The steel is thereby rendered tougher but at the same time slightly softer. The degree of tempering applied is adjusted to suit the purpose for which the implement is required.

High Speed Steels.—In recent years special alloy steels have been introduced for machine cutting tools which render much better service than ordinary carbon steels. The action of these "high speed steels," which generally contain a considerable amount (sometimes up to 18 or 20 per cent) of tungsten, depends upon the fact that in ordinary carbon steels the hardness is rapidly reduced by rising temperature. When a tool is taking a heavy cut, its temperature rises rapidly and the amount of loading which can be applied to a tool made of carbon steel is limited by the comparatively low temperature which brings about softening. In the "high speed" steels the temperature which must be attained to cause softening is very much higher: the steels are for this reason said to possess "red hardness." They owe this valuable property to the peculiar manner in which the transformation temperatures are altered by the presence of the alloying elements.

In structural steel of lower carbon and alloy content, the purpose of heat-treatment is not to produce a material of high hardness but one possessing high tensile strength combined with reasonable ductility and good behaviour in the notched-bar impact test. For this purpose the steel is first "hardened" by quenching, but this is more frequently done in oil than in water. The subsequent tempering or "drawing" may be carried out at temperatures which usually lie between 400 and 600° C. Two serious difficulties have arisen in applying this heat-treatment particularly to larger masses of steel. Owing to their large heat content and the relative slowness with which heat flows from the interior to the exterior of a mass of steel, it is not possible to secure in the inner portions of a steel forging a rate of cooling sufficiently rapid to bring about hardening. The heat-treatment of large masses—and for this purpose pieces exceeding two inches in thickness must be regarded as "large"—thus presents grave difficulties in simple carbon and nickel steels. By the addition of suitable amounts of chromium, however, the transformations of the steel are rendered more sluggish so that even the moderately rapid rates of cooling which can be attained in large masses are sufficient to bring about hardening. Such steels can, therefore, be hardened and subsequently tempered, in relatively large masses. Here, however, the second difficulty arises. Steels of this type, especially the nickel-chromium steels, exhibit the phenomenon known as "temper brittleness" which makes itself felt most strongly under the notched-bar impact test. When such steel has been tempered to show the desired degree of high ductility, it gives very low values under the impact test. This type of brittleness can be prevented by accelerating the cooling of the steel immediately after it has been tempered. Rapid cooling, however, is difficult or impossible in large masses. Fortunately it has been discovered that the presence of a small percentage of molybdenum in the steel prevents the development of temper-brittleness even if the material is slowly cooled after tempering.

The heat-treatment of non-ferrous metals and alloys was, until quite recently, confined to simple annealing at various temperatures, for the purpose of softening metal hardened by cold working. To this must now be added forms of heat-treatment which, while they differ in detail, are closely analogous in principle to those applied to steel. The first non-ferrous alloy known to undergo hardening by heat-treatment is "duralumin," the well-known aluminium structural alloy discovered by Wilm in Germany about 1913. This alloy is treated by heating it for a short time to 480° C and then quenching it in water. Immediately after quenching, the material is quite soft—slightly softer than in the ordinary untreated condition. In the course of four or five days, however, at room temperature, or in less than an hour at about 190° C, hardening sets in. Although this hardening is not comparable in its results with that of steel, it leads to a doubling of the strength and hardness of the material—a fact which has made the alloy extremely important in practice, particularly as the age-hardening at room temperature is not accompanied by any loss of ductility.

Some years after the first discovery of duralumin, the nature of the age-hardening process was discovered independently in England and in America and subsequently it was further recognized that a similar mechanism for potential hardening might exist in many other non-ferrous alloys. As a result, a series of aluminium alloys capable of hardening by heat-treatment has made its appearance—perhaps the most important of these is the British "Y" alloy which has the valuable property that it will respond to heat-treatment in the cast state. In addition, still more recently, a number of copper alloys have been developed both in America and Germany which undergo marked hardening after quenching from suitable temperatures, but in these cases the subsequent hardening only occurs on moderate heating. The most striking example of this type of copper alloy is that containing about 3% of beryllium. The Brinell hardness of this alloy rises from 80 to 400 with a rise of tensile strength from 14 to over 90 tons per sq. inch as a result of heat-treatment.

In the whole of this wide range of non-ferrous alloys the mechanism of hardening is the same; the discovery of these alloys has, in fact, been based upon a theoretical study of their constitution. The hardening depends in every case upon the fact that the

base metal can, at a high temperature, hold in solid solution a larger proportion of the alloying element than it can hold at lower temperatures. Quenching brings down to the ordinary temperature a solid solution which is, at that temperature, heavily super-saturated. This solid solution is not hard so long as it remains in that super-saturated condition, but becomes hard as soon as break-down or transformation begins, whether at room temperature or on slight heating. There is a close analogy between these phenomena and what we believe to occur in the hardening of steel.

In regard to iron and steel, reference has been made to the "high speed" steels used for cutting tools. To these must be added two types of special alloys which furnish tools of still greater hardness and cutting power than the steels. The "stellite" type of alloy contains chromium, cobalt and tungsten. It can only be brought to the desired shape by casting, as it remains hard and non-ductile at all temperatures. The final shaping of the tool is done by grinding. The tools can be used to cut rapidly and up to higher temperatures than the steels, but are apt to break under a blow. Still harder and capable of resisting still higher temperatures are a group of substances whose most important constituent is tungsten carbide. Only thin strips or plates of these expensive substances are used as facings brazed to the front of a steel "tool" but with these tools it is possible to cut at fairly high speeds materials, such as toughened manganese steel, which resist all steel cutting tools. Even glass has—as a demonstration—been "machined" with one of these tools. The materials themselves are known under a variety of proprietary names such as "thoran," "widia," etc. Important advances have also been made in regard to steel for magnetic purposes. For permanent magnets tungsten steels are most widely used, but a Japanese discovery has shown that cobalt steels are markedly superior and these magnet steels are used where permanent magnets of minimum weight are important. The high cost of cobalt, however, sets a limit to the application of these steels. On the other hand, in the development of very soft magnetic steels, for transformer cores and for the inductive winding of submarine cables, special alloys have also been developed. Steel containing very little carbon with about 4% of silicon has a lower magnetic hysteresis loss combined with a higher electrical resistance than ordinary soft steel, and its extensive use has had wide effects in improving the economy of electric current transformers. For the sheathing of submarine cables a magnetic material having the highest possible permeability under very low magnetic fields is required. A remarkable material for this purpose is the American alloy of iron with about 79% of nickel. This alloy, known as "permalloy" and a British modification known as "mumetal" are, however, highly sensitive to slight plastic deformation and only attain their best properties after careful annealing.

The immense losses caused by corrosion have led to much research on this subject both in regard to ferrous and non-ferrous metals. The addition of small amounts of copper to steel has been found to reduce corrosion in many circumstances, but very great resistance to corrosion has been attained by the addition to steel of considerable amounts of chromium. "Stainless steel" was developed in Sheffield by Brearley; it contains about 13% of chromium and, with a moderate carbon content can be satisfactorily hardened and tempered. When properly hardened, tempered and polished, this steel resists corrosion extremely well, although there are certain conditions, such as prolonged exposure to sea-water, which cause attack. For purposes where softness and ductility are required, "stainless iron" has been developed with a very low carbon content. This is, however, being largely displaced by a type of rust-resisting steel of which "staybrite" and "anka" are typical. These contain still higher proportions of chromium than ordinary "stainless" steel, together with a high proportion of nickel. These steels retain the austenitic structure on cooling, whether fast or slow, and are thus soft, ductile and non-magnetic, but they cannot be hardened by heat-treatment and are difficult to machine. They are extremely resistant to corrosion and chemical attack of all kinds and widely applied in chemical engineering and elsewhere. The cost of these rust-resisting steels is, however, too high to allow of their use for general structural purposes so that methods of preventing or reducing corrosion in ordinary steel are still required. Apart from paints and other organic coatings, protection of steel by coating with another metal, such as zinc and tin, is widely used. Galvanized iron—really steel coated with a thin layer of zinc—is used in immense quantities. Perhaps the most striking development in protective coatings is the application of metallic chromium to this purpose. When properly deposited by electrolysis, this metal furnishes a coating of brilliant bluish-white colour which is incorrodible and untarnishable, while it is also so hard that it cannot be readily scratched. These promising properties have led to wide-spread attempts at immediate industrial application and, while some success has been attained, many difficulties and defects have been encountered. The process is therefore still in course of development but may well be expected to gain ground in the future.

In non-ferrous metals the problems of corrosion, although different, are equally important. In regard to the alloys of copper, the production of condenser tubes immune from failure by pitting still offers a problem although much important progress has been made. In regard to aluminium alloys, the corrosion problem stood for some time in the way of their wider application. The difficulty, has, however, been met by the development of protective coatings. Aluminium owes its natural resistance to corrosion to a thin transparent coating of oxide which forms on the metal immediately it is exposed to the air and to a great extent prevents further attack. As naturally formed, however, this is neither strong enough nor impervious enough to prevent corrosion under more difficult conditions, such as exposure to sea-water, etc. It has, however, been found that the natural oxide coating can be strengthened and thickened by making the metal the anode in a bath containing chromic acid or potassium bichromate and gradually raising the voltage. Aluminium and many of its alloys, when treated in this way, become very resistant to corrosion and this resistance can be further increased by saturating the "anodic oxidation" film with fatty matter such as lanoline. While the value of this process has been very fully demonstrated and recognized in England it is curious that reports upon it both from American and German sources are less satisfactory, but this is perhaps due to inadequate attention to important details.

Among further recent developments in the production and treatment of metals, the great expansion of welding operations in the jointing of steel may be mentioned. The two principal processes are oxy-acetylene and electric welding. An advanced technique for both methods has been developed and welded joints are finding increasing application. While it is admitted that the strength of steel—and especially of heat-treated steel—is locally impaired by the high temperatures applied in welding, yet the great convenience of the process and the saving in weight and labour which it allows as compared with rivetting, outweigh these disadvantages wherever satisfactory allowance for the impaired properties of the steel in the neighbourhood of the weld can be made. It must further be borne in mind that the correct basis of comparison in estimating the value of a welded joint is not the strength of the solid metal but of any alternative joint such as a rivetted seam. The most serious defect of welding is the difficulty of being sure that a given joint is sound. Reliance must be placed on the skill and conscientiousness of the workman. The examination of welds by means of X-rays is slow and costly and not entirely certain of showing up defective places. In England there is still some hesitation in using welded joints in structures exposed to severe stresses. In France the process has been very widely used even for boiler construction, but a few serious failures have occurred.

Important advances have also been made in regard to materials for use at high temperatures. The demand for these arises from the effort to improve the thermal efficiency of heat engines—stimulated by the struggle, which has been in progress for a number of years, between the steam-turbine and the internal combustion engine. The result is a demand for steels and non-ferrous alloys capable of withstanding stress and oxidation at temperatures sometimes as high as 800° C. Ordinary steel becomes too weak to be used at these temperatures, and even materials which show a reasonably high strength under an ordinary tensile test carried

out at the high temperatures have been found to fail under much lower stresses if exposed to them for a sufficiently long time. This has led to the conception of the "limiting creep stress" which is measured by determining the highest stress which the material can bear, at a constantly maintained high temperature, for long periods of time without undergoing measurable changes of length. At 800° C some of the best materials yet available commercially show a creep stress limit of little more than two tons per square inch. For so high a temperature, however, this constitutes a marked achievement and has only been attained by a few special "heat-resisting" steels and by one type of non-ferrous alloy. These steels contain relatively large proportions of nickel, chromium and tungsten, the combined presence of all three being essential. The non-ferrous alloys suitable for high temperature use consist mainly of nickel and chromium. For less extreme conditions, such as those encountered in the construction of high pressure steam boilers, turbine blading, etc., where 400° C is not likely to be exceeded in the near future, less expensive types of material are available.

METALS. It is extremely difficult to find a satisfactory definition for a metal but it is probably best specified as a body which possesses many of the following properties: it is solid at ordinary temperatures; it is opaque; when polished it is a good reflector of light; it is a good, or fairly good conductor of heat and electricity; when melted and allowed to cool, it solidifies as a compact mass of crystals. These crystals are generally invisible as such to the unaided eye, but in suitably prepared specimens can be seen under the microscope (*see* METALLOGRAPHY). It is by no means true to say that every metal possesses all these properties, while many of them, *e.g.*, opacity and crystalline form, are shared with some of the non-metals, and mercury is a liquid.

Metals may be divided into two classes: elemental metals and alloys. The former are chemical elements (*q.v.*), whilst the latter are made by mixing intimately (generally by melting together) two or more elemental metals. (*See* ALLOYS.)

Metals are only rarely found native in the earth; platinum and gold are usually, and silver is frequently found thus, whilst copper and iron occasionally occur in the native state. The majority of metals, however, are found in the form of ores, which are chemical compounds of the metal with one or more elements such as oxygen, sulphur and carbon. These compounds are generally mixed with other minerals known to the miner as gangue (*see* MINING). After separating the ore from the gangue, the metal has to be obtained by breaking up the compound, either by chemical means or, more usually, by heat. Examples of the processes used will be found in the articles dealing with the individual metals.

Density.—The density of a metal is usually expressed in terms of the weight of water. Thus if a metal is three times as heavy as an equal volume of water, it is said to have a density of 3. The heaviest known materials are metals, but on the other hand some metals exist which are among the lightest of solid materials. The densest material is osmium which is 22·5 times heavier than water, whilst at the other end of the scale is lithium which is little more than half the weight of water. Among the more common metals attention may be drawn to aluminium and magnesium which have densities of 2·7 and 1·7 respectively, whilst lead, mercury, gold and platinum have densities of 11·3, 13·5, 19·3 and 21·5. (Col. 3 of the Table gives the densities of most of the known metals.)

The property of density is often used in the commercial world. Thus the high density of mercury (which is the only metal that is liquid at ordinary temperatures) renders possible the mercury barometer. The high density of lead is useful when heavy weights are required. On the other hand the low density of aluminium has given it a considerable value both in the pure state and alloyed with other metals. Its uses range from the construction of airships to manufacture of frying pans.

Colour.—The vast majority of metals are of a greyish colour, varying from the blue grey of lead to the so-called white colour of silver. There are, however, certain exceptions to this, such as gold, which is yellow, and copper, which is reddish in appearance.

The colour of a metal can be seen much better if it is viewed by means of light which has been reflected many times off its surface. Thus, the inside of a smooth gold vase appears much richer in colour than the outside.

Melting and Boiling Points.—Pure metals, being chemical elements, melt at a constant temperature. Mercury is liquid at ordinary climatic temperatures, though arctic explorers have to use spirit thermometers, as the temperature to which they may be exposed is often below that at which mercury freezes (—38·9° C). At the other end of the range we have the metal tungsten, which does not fuse until it reaches a temperature of about 3,380° C. (The temperature of the surface of the sun is calculated to be about 6,000° C.) For this reason tungsten is used in the form of fine wires for the filaments of incandescent electric lamps (Col. 5 of the Table gives the melting points of metals.) All metals will boil if the temperature is high enough. Mercury boils at a temperature of 367° C, not much above the melting point of lead, whilst tungsten is said to boil at 5,900° C.

Many metals have an appreciable vapour pressure at temperatures considerably below their boiling points—a property which is made use of in certain industrial processes. Thus it is possible to coat iron objects with zinc by placing them in a mixture of zinc dust and zinc oxide and heating to a temperature below the melting point of zinc. The zinc condenses onto the iron.

Thermal Expansion.—As the temperature of a metal is raised the metal expands. This expansion with temperature has been used for many purposes; for example, the tyres of locomotives are sometimes shrunk on to the wheels, by making the tyre slightly smaller than the wheel and expanding it by heat till it can just be forced on to the wheel. On cooling it contracts and grips firmly. In the ordinary mercury thermometer use is made of the expansion of a metal with temperature.

On the other hand, a metal with a zero coefficient of expansion would be invaluable for the construction of apparatus which must keep accurately to size, such as standards of length, pendulum rods, etc.; although no pure metal approaches this condition, an alloy of iron and nickel (known as Invar) has an extremely low

coefficient of expansion.

Thermal and Electrical Conductivity.—All metals are more or less good conductors of heat and of electricity and in the case of pure metals these properties are closely related. There is little doubt that it is impossible to raise the electrical conductivity of a metal by alloying it and consequently all the metals used for conductors in industry are as pure as is possible consistent with price and strength. The best conductor is silver, closely followed by the cheaper and much used copper, the resistances respectively being 1·62 and 1·69 microhms per centimetre cube. In a few cases, such as trolley wires for electric trams and trains, a small amount of cadmium is added to the copper, as the increase in tensile strength thus gained more than compensates for the lowering of the conductivity. Next to copper, aluminium is most widely used as a conductor; its resistivity is considerably greater, being about 2·6 microhms per cu.cm., but its low density renders it preferable in certain cases.

The resistivity of metals falls as the temperature is lowered and in the neighbourhood of absolute zero it drops enormously. It has been shown that lead at the temperature of liquid helium has a resistance only 1/1,000,000,000 of that at 0° C. If a current is started in a ring of lead at this temperature it will continue for many hours with but a small decrease in intensity. The resistivity of lead at ordinary temperatures is 22 microhms per cu.cm. (this is the highest value obtained in the more common metals), but by alloying various metals together it is possible to produce material with resistivities very many times this value. (Values for the resistivities of most of the metals are given in the Table, Col. 6.)

Magnetic Properties.—The vast majority of metals are practically non-magnetic; indeed it requires very sensitive apparatus to discover that they have any magnetic properties at all. A few, however, which are known as the ferro-magnetic elements, are strongly magnetic; these are iron, nickel and cobalt. It is, however, a remarkable fact that certain mixtures of the non-magnetic metals copper, aluminium and manganese are also magnetic.

Crystalline Habit.—Most metals crystallize in what is known as the cubic system (*see* CRYSTALLOGRAPHY). This means that the atoms, which may be regarded as the bricks out of which the metal is constructed, are so arranged as to be built up into cubes. There are three varieties of this arrangement known as the simple cube, the body-centred cube and the face-centred cube. In the first case the atoms are arranged so as to occupy the corners of a cube; in the second case there is, in addition, one atom occupying the middle of each cube; whilst the face-centred variety has, in addition to the atom at the corners of the cube, an atom in the middle of each cube face.

No metals are known to crystallize in the simple cubic form, but the majority form either body-centred or face-centred cubes. Several of the metals crystallize in the hexagonal system, which is somewhat more complicated than the cubic, whilst a few assume a tetragonal arrangement which is still more complex. If the metals are arranged in their correct place in the periodic classification (*q.v.*) it will be seen that those in the same sub-group crystallize in the same habit.

The systems in which metals crystallize are given in the Table, Col. 7. It will be noticed that some of the metals are shown as crystallizing in more than one form, so that they are spoken of as having different allotropic modifications. This means that the metal can exist in two or more forms which may differ from each other in their mechanical or physical properties as much as two completely separate metals differ (*see* ALLOTROPY). Allotropic changes in metals may not be quite as pronounced as with the non-metals, but they are often very marked and are accompanied by a change in the crystalline arrangement. Thus pure iron below 900°C is a highly magnetic material which crystallizes in the face-centred cubic form, whilst above 900°C it is non-magnetic and the atoms are arranged in a body-centred cubic "lattice." Another interesting example is to be found in tin which at ordinary temperatures is a soft ductile metal; at low temperatures, however, it changes into a grey material which breaks into a powder.

Mechanical Properties.—Among the most remarkable properties of metals is their power of resisting deformation of various kinds. This is studied under the heading of elasticity, tensile strength, hardness, ductility, etc. In most cases these properties are found to differ considerably between a single crystal of a metal and an aggregate of crystals of the same metal, showing that the crystal boundaries have an appreciable influence.

The hardness of metals—not easy to define—is usually measured either by the pressure required to force a ball or other object to a definite distance into the metal, or by the depth of scratch made in the metal by a diamond point under a given load. Of the ordinary metals of commerce lead is the softest although lithium is the softest metal of all, whereas possibly manganese is the hardest metal. Chromium was long considered to head the list, but it is now known that this hardness is mainly due to the presence of hydrogen.

Closely related to hardness is the property known as tensile strength. This is measured by finding the weight required to break, by means of a straight pull, a rod of metal of known diameter. Probably the strongest pure metal is tungsten, which

Table of Metals

1 Metal	2 Chemical symbol	3 Density	4 Coeff. of expansion	5 Melting point	6 Electrical resistivity	7 Crystalline system

Notes.

Col. 3. Where there are allotropic forms, the density of each is given when possible.

Col. 4. For the expansion for 1° C, these figures must be multiplied by 10^{-6}; *e.g.*, for platinum, 0·0000089.

Col. 5. The melting point is given in degrees Centigrade.

Col. 6. The figure given is the resistance, expressed in millionths of an ohm, of a cube of the metal, each side of which is one centimetre long.

Col. 7. Crystalline system:—C = cubic, whether body- or face-centred unknown; C b = body-centred, C f = face-centred; H = hexagonal; T = tetragonal.

as drawn wire has a tensile strength of over 300kg. per sq.mm.

Many metals possess the property of ductility to a high degree, *i.e.*, when subjected to a tensile load they elongate to a very considerable extent before breaking. Use is made of this property to produce wires, the metal being first rolled into thin rods which are then drawn through holes in a steel plate, known as a die. Each hole through which the wire is drawn reduces its diameter. For very thin wires the dies are made of diamond.

Several metals can also be "extruded," *i.e.*, forced to flow through a hole by means of pressure or they can be rolled or hammered into thin sheets. Gold has been beaten into sheet only 1/3,800mm. thick, whilst, by a very special process platinum has been reduced to a wire 1/20,000mm. in diameter.

BIBLIOGRAPHY.—There are no non-technical books on metals, but these are useful to students or specialists. C. H. Desch, *Metallography;* W. Rosenhain, *Introduction to the Study of Physical Metallurgy;* S. L. Hoyt, *Metallography, Metals & Common Alloys;* F. Robin, *Traité de Metallographie;* Guillet & A. Portevin, *Précis de Metallographie.* (J. L. HA.)

METAL WORK. The processes of working metals are so varied that it has been found necessary to treat them under separate headings. Bronze and brass (*q.v.*) have been handled together, the technique being almost identical. Silversmiths' and goldsmiths' work (*q.v.*) are brought under one heading for similar reasons. Lead (*q.v.*) and pewter (*q.v.*) are handled in separate articles, giving the methods of working each metal and the history of the development of these methods. Related articles are: ARMS AND ARMOUR; ENAMELS; SCULPTURE TECHNIQUE; *Casting and Finishing,* and *Patina.* Discussions of the theory of metalwork technique will be found under TECHNIQUE IN ART and IRON IN ART: *Modern Theory.*

METAMORPHISM, in petrology, denotes the sum of the processes effecting fundamental alterations in composition, mineral or chemical, structural or textural in solid rock masses, the alterations determining completely the character of the rock mass.

The term (from Gr. μετὰ, change of, and μορφή, shape) is now very generally used to exclude those alterations of decomposition, disintegration and cementation taking place in the upper parts of the lithosphere under the influence of the atmosphere and surface waters (weathering, cementation). *See* METASOMATISM and PNEUMATOLYSIS. Metamorphic rock types treated separately include QUARTZITE, SLATE, PHYLLITE, SCHIST (including MICA-SCHIST) and GNEISS (in part)—also AMPHIBOLITE, ECLOGITE (in part), EPIDIORITE, EPIDOSITE, GRANULITE, HORNFELS, MARBLE, MYLONITE and the SCAPOLITE rocks. The original materials upon which metamorphic processes have operated are either sediments, igneous rocks or mixtures of these (as tuffs and other pyroclastic aggregates). Rocks may, however, be subjected to more than one epoch of metamorphism. Such rocks have been termed polymetamorphosed rocks, and the process *polymetamorphism.* Metamorphic rocks are thus to be regarded as a group of rocks of coordinate importance with sedimentary and with igneous rocks; they are formed in the wide temperature and pressure region existing between the region of formation of sedimentary rocks (low temperature, low pressure), and that of igneous rocks (high temperature sometimes accompanied by high pressures).

According as metamorphism takes place without appreciable change in chemical composition, or with addition or exchange of material, two types of metamorphic rock may be broadly distinguished, viz., (*a*) products of *normal* metamorphism, in which the chemical composition remains unchanged except for loss of such volatile constituents as water or carbon dioxide, and (*b*) products of *metasomatic* metamorphism, where fundamental changes are brought about by the introduction of new materials. In normal metamorphism, the chemical analysis of the rock is usually sufficient to determine its origin.

Sandstones yield quartzites and quartz schists, limestones are converted into marbles, shales into mica-schists, without their bulk composition being greatly modified. The simple loss of water or carbon dioxide, as in the conversion of a calcareous sandstone into a rock composed of wollastonite ($CaSiO_3$) is not usually considered a case of metasomatic metamorphism. Metasomatism, in its relation to metamorphism, implies addition of new material, which reacts with the original components of the rock. The formation of skarn rocks from carbonate sediments, whereby iron compounds from magmatic sources react with carbonate to form andradite- and hedenbergite-bearing rocks, is a case of metasomatic metamorphism. Except in the vicinity of igneous intrusions, metamorphism is accomplished without significant change in composition.

Differences of metamorphism can be distinguished, viz., (*a*) *contact* or *thermal* metamorphism, in which the chief factor is temperature. It embraces all those processes which operate on solid rock under the influence of magmatic heat, and from its localized occurrence around igneous intrusions is sometimes referred to as *local* metamorphism; (*b*) *load* metamorphism (Ger. *Belastungsmetamorphose*), affecting rock masses buried deep within the crust. The operating factors are pressure due to the weight of superincumbent material and temperature appropriate to the depth. This type is frequently referred to as *geothermal* metamorphism; and (*c*) *dynamo-thermal* metamorphism, in which the operating factors are stress, uniform pressure and temperature in varying degree.

Contact or Thermal Metamorphism.—Any kind of rock—igneous or sedimentary—which has come into contact with molten magma, is likely to show alteration of this type. Heat is the principal agent of metamorphism and is conveyed from the magma principally by the process of conduction. Other factors, however, are important. Volatile materials, principally water, pass into the surrounding rocks from the magma and assist in the processes of solution and reaction. The medium in which the operative processes take place is the interstitial liquid occupying the capillary pores and fissures in the rocks. A rise in temperature facilitates diffusion and reaction. Chemical reactions which proceed at an infinitesimal rate at low temperatures are enormously accelerated by rise of temperature, a rise of 100° C being sufficient in many cases to increase the rate of reaction a thousandfold. The net result of these processes is eventually a recrystallization of the whole rock, which is now built up of a mineral assemblage adjusted to, or approaching adjustment to, the new temperature conditions. The extent and intensity of the alteration effected depends chiefly on two factors—(*a*) the nature of the rock, and (*b*) the magnitude of the igneous mass.

A great granite batholith, which may be many miles in diameter, is often surrounded by a wide aureole of contact alteration, varying from a few hundred yards to two miles in breadth. This variation may have structural causes dependent on the underground contour of the intrusion.

Crystalline schists which are already recrystallized may show little sign of alteration, or are affected only at the immediate contact, and the same remark applies to fresh igneous rocks which have consolidated at high temperatures. If, however, they have been subject to alteration by weathering, or contain amygdales filled with hydrated minerals such as zeolites, chlorite, etc., fundamental changes may be produced. The altered rocks of such aureoles are known as hornfelses (*q.v.*), and are typically fine-grained compact rocks devoid of fissility and cleavage. Argillaceous sediments give rise to dark lustrous hornfelses full of minute scales of red-brown biotite and cordierite, limestones to marbles; impure limestones become grey, yellow or green calc-silicate hornfelses rich in diopside, grossular garnet, wollastonite and vesuvianite; while dolerites, basalts and andesites are transformed into dark granular hornfelses with a large development of new pyroxene, hornblende, biotite and recrystallized felspar. Cherts, flints and fine sandstones are converted into quartzites, consisting of small close-fitting grains of quartz.

The progressive changes that take place in an aureole may be determined by studying the effects observed at the outer edge of the aureole, and tracing these changes inwards to the contact. Argillaceous rocks are very suitable for this purpose on account of their common occurrence and homogeneity. In most aureoles the first signs of alterations in shales or slates is seen in an induration or hardening of the rock, accompanied by the development of minute spots, which consist either of new-formed minerals or a new distribution of minerals. Considerable alteration may be

effected without deleting other structures. Fossils may be in part preserved and are not destroyed till the whole rock has been recrystallized. This variation in the nature of the incipient changes is probably to be ascribed to the mineralogical nature of the argillaceous rocks themselves. All shales and slates are built up of varying amounts of quartz, sericite, chlorite, iron oxides, kaolin or other hydrated aluminium silicates. Where the last named minerals are abundant, an early formation of andalusite and cordierite is to be expected. Where they are scarce or absent, the first signs of change are seen in the rearrangement of the original minerals or the development of new-formed biotite.

Regarding a metamorphic rock as a mineral assemblage formed within a given temperature and pressure range, it is clear from physico-chemical principles that the number of co-existing mineral phases in equilibrium must be limited by the number of components. It is to the completely recrystallized products of the hornfels zone that the phase rule of Willard Gibbs may be applied. The measure of success obtained by its application to metamorphic mineral assemblages, and so the utility of an ideal classification of metamorphic rocks developed with its aid, are largely dependent on the approach towards equilibrium of the final products. Actual experience, indeed, has afforded a very considerable degree of confirmation of the results to be expected.

Briefly, the phase rule states that the number of phases plus the number of degrees of freedom exceeds the number of components by 2, $p+f=c+2$. For example: if one takes into consideration a three-component system, five solid phases can at most co-exist. Under such conditions both temperature and pressure are fixed. Metamorphic processes, however, take place over a range of temperatures and pressures, and the random conditions attendant upon particular examples of metamorphism imply a divariant system, so that the maximum number of solid phases in a three component system will not exceed three. As expressed by Goldschmidt, the phase rule applied to mineralogical systems can be stated as "the maximum number of solid minerals that can co-exist in stable equilibrium is equal to the number of individual components that are contained in the minerals if the singular temperatures of transition points are excluded." This important rule has been a very useful guide in the study and classification of metamorphic rocks, and it will be of interest to note its application to some simplified rock systems.

Consider the system built up of the four components—CaO, MgO, Al_2O_3, SiO_2. Apart from their polymorphic modifications the number of possible minerals constituted of these oxides or their combinations approximate 20. The phase rule simply states that the maximum number of phases found together is limited at equilibrium, but gives no information as to the particular mineral associations. In the case before us, the maximum number is four. This system is of great importance in metamorphic petrology, for the group of sediments ranging from pure shales to limestones is largely constituted of these four oxides. A study of the hornfelses derived from shale-limestone sediments shows that a number of well defined assemblages can be recognized as constantly recurring types. Pure shales give rise to andalusite-cordierite hornfelses, certain marls to diopside-plagioclase hornfelses, etc. Apart from the alkali minerals, orthoclase, albite and biotite, limefree shale hornfelses have the composition andalusite-cordierite-quartz, a three phase assemblage built up of three components (MgO, Al_2O_3,SiO_2). If now, to this system lime is added, a fourth phase enters, namely, anorthite, and we have the combination andalusite-anorthite-cordierite-quartz. By successive increments of lime a series of mineralogical combinations can be derived which correspond to the hornfelses formed from the continuous shale-limestone series of sediments. As first recognized from the aureoles of the Devonian intrusions of the Oslo region, these mineral assemblages are as follows, quartz and orthoclase being possible phases in all:—

1. Andalusite cordierite albite (biotite)
2. Andalusite cordierite plagioclase (biotite)
3. Andalusite cordierite plagioclase (biotite)
4. Andalusite cordierite plagioclase (biotite) enstatite
5. Andalusite cordierite plagioclase (biotite) enstatite
6. Andalusite cordierite plagioclase (biotite) enstatite, diopside
7. Andalusite cordierite plagioclase (biotite) enstatite, diopside
8. Andalusite cordierite plagioclase (biotite) enstatite, diopside grossular
9. Andalusite cordierite plagioclase (biotite) enstatite, diopside grossular
10. Andalusite cordierite plagioclase (biotite) enstatite, diopside grossular wollastonite.

The composition of these assemblages may be represented in a triangular diagram. Such a diagram (fig. 1) represents the quartz-bearing hornfelses of the four-component system lime-magnesia-alumina-silica. Each of the classes is represented by the numerals within or on the sides of the triangles, any point representing a mineral assemblage composed of the minerals represented at the apices of the individual triangles. In a similar way fig. 2 represents the three-phase mineral assemblages of the three-component system $MgO-Al_2O_3-SiO_2$. The various associations are characteristic of thermally altered sediments, periclase-spinel-forsterite, of metamorphosed dolomites and the remainder (with the exception of the assemblage forsterite-enstatite-spinel) of argillaceous sediments, those rich in enstatite corresponding to magnesia-rich types, those rich in corundum or spinel to silica-poor types. The dotted area represents the bulk compositions of shales whose constituent minerals are indicated by the points for quartz, kaolin and chlorite. The foregoing assemblages are characteristic of the highest grades of thermal metamorphism and are presumably those stable at the highest temperatures to which the rocks are subjected. Other components such as H_2O, Na_2O, Cl, B, F, introduce new phases such as biotite, orthoclase, and albite among argillaceous sediments, scapolite, vesuvianite, chondrodite and axinite among carbonate rocks. That we are able to study at ordinary temperatures such systems formed at high temperatures, naturally implies that a great lag effect accompanies the cooling of the rock. Reactions of adjustment to the conditions of lower temperature are, however, by no means altogether absent. The process of retrograde metamorphism is known as *diaphthoresis*. In contact aureoles it is commonly seen in the conversion of diopside or augite to tremolite or hornblende and the formation of epidote or clinozoisite from anorthite. Hornfelses bearing amphibole in place of pyroxene are also commonly met with in the outer portions of contact aureoles. Clearly, here the amphibole is developed under the conditions of lower temperature. On the other hand, certain assemblages are characteristic of the highest temperatures. They are commonly met with as inclusions or xenoliths in the igneous mass itself or at the immediate contact. Mullite ($3Al_2O_3{\cdot}2SiO_2$) appears in place of sillimanite as in buchites, sanidine in place of orthoclase tridymite, or cristobalite in place of quartz, and the combination wollastonite-anorthite in place of grossular garnet. Such high temperature assemblages are known as *pyrometamorphic* rocks. An intense metasomatic action often accompanies the formation of such rocks. They are typically represented in the xenolithic assemblages of volcanic centres such as the Eifel, Vesuvius, etc.

FIG. 2

Load Metamorphism.—The metamorphism incident upon the deep burial of rocks in geosynclines, where the operating factors are vertical stress due to the weight of superincumbent material, and the temperature appropriate to the depth, is referred to as *load* metamorphism or *static* metamorphism, in contrast to *dynamic* metamorphism, in which tangential stresses are operative.

The geothermic gradient may be taken as 3° C for every 100 metres of covering strata. Consider a series of strata accumulated

to a depth of 13,000 metres; the temperature at the base would approximate 400° and the pressure 3,500 atmospheres. Some geologists, as Milch, Dawson, Daly and others, have attributed great powers of metamorphism to geothermal agencies of this kind and the common parallelism between stratification and schistosity seen in some terranes is attributed to superincumbent load. Oceanic salt deposits undoubtedly have suffered profound metamorphism in this way, for they contain hydrated minerals which are stable only over a narrow temperature and pressure interval. For silicate rocks, however, a very great cover of sediment would be necessary to induce reaction and recrystallization, principally for the reason that such reactions proceed with great tardiness at these temperatures and pressures; indeed, clear evidence that deep burial is insufficient to produce notable metamorphic effects in detrital sediments is provided in the great Palaeozoic geosynclines where the underlying strata can be studied in an almost unaltered condition.

The metamorphism of salt deposits is beyond the scope of this article, but reference may be made to E. Jänecke, *Die Entstehung der deutschen Kalisalzlager* (1915), and F. Rinne, *Die geothermische Metamorphosen und die Dislokationen der deutschen Kalisalzlagerstätten. Fortschritte der Mineralogie* . . . vol. vi. (1920), where the subject is discussed at length.

Dynamo-thermal Metamorphism.—Unlike contact metamorphism, *dynamo-thermal* or *regional* metamorphism is not directly connected with the intrusion of igneous magma. While the breadth of a contact zone seldom exceeds 2 m. the effects of regional metamorphism may be traced over hundreds or thousands of square miles.

Metamorphic rocks of this type constitute the greater part of continental shields (Fennoscandia, North America, West Australia, etc.). Where such rocks occur there is generally much evidence of earth movement, accompanied by crushing and folding. They are very characteristic of the central axes of great mountain chains, especially when these have been denuded and their deeper cores exposed. Most geologists believe that this connection is causal, holding that the contraction of the outer layers of the earth's crust, due to shrinkage of the outer shell upon a cooling and contracting interior, has bent and folded the rocks, and at the same time has crushed and largely recrystallized them.

In extreme cases where dynamic action is localized, the ultimate stage of intense crushing and pulverization is the production of flinty crush rocks or pseudotachylytes, in which mylonization is accompanied by an incipient fusion of the rock mass, due to the generation of great heat by friction. Analogous effects are sometimes obtained in rock drills, where the cores are found to contain slag-like masses, produced by the heat of friction. In these cases it is shown that the temperature attained may approximate 1,100° C, sufficient to fuse arkoses or felspathic sandstones. Flinty crush rocks have now been recognized from a number of areas from the north-west Highlands of Scotland, the Outer Hebrides, and the Vredefort area of the Southern Transvaal. The trap shotten gneisses of southern India are similar rocks. In Eriskay and South Uist (Outer Hebrides), the flinty crush rocks are extensively developed along great thrust planes in the Archaean gneiss, while in the Vredefort area rocks of this character occur on a grander scale than elsewhere.

In areas of regional metamorphism, whole complexes consisting of intermixed sediments, tuffs and igneous extrusions and intrusions may be converted into a great series of schists and gneisses. Although recrystallization may be complete the original masses still retain their identity in their new state, though their structural relations may be rendered excessively complex by intense folding and overthrusting. The effects of stress in regionally metamorphosed rocks are revealed in their foliated or schistose textures. This consists in a definite arrangement of the minerals, so that such as are platy, prismatic or fibrous (*e.g.*, mica hornblende or sillimanite) have their longest axes arranged parallel to one another. For that reason many of these rocks split readily in one direction. Contortion or crumpling of the foliation is by no means uncommon, and the splitting faces are then undulose or puckered. Recrystallization under the influence of stress gives rise to the very characteristic *crystallization-schistosity*. On solid minerals at low temperatures the effects of stress are seen in crushing and shearing, and the development of glide planes or secondary twinning (as seen in calcite, diallage, kyanite, etc.), but at higher temperatures in the presence of interstitial liquid such as pervades all rocks, the most important effect is the raising of the solubility of the material stressed. Wherever an appropriate stress is reached, material is dissolved at the points of greatest stress, and redeposited at points where the stress is less. This principle (sometimes referred to as Riecke's principle) is obviously of fundamental importance in explaining the foliated textures of crystalline schists. Not only so, the material dissolved is capable of reaction and may be redeposited as new minerals. Stress thus facilitates chemical reactions and may be considered as a kind of catalyst, promoting reactions but also having influence on the nature of the products formed. Stress may thus influence fundamentally the stability range of a given compound; on the one hand, the range may be extended or contracted; on the other, reactions which can proceed only very slowly under uniform pressure may be greatly facilitated under stress. The possibility that thereby *new* phases may be precipitated in stressed systems while others are totally excluded is now to be envisaged. It is consequently not surprising that we find among the minerals of crystalline schists types which are unknown amongst contact rocks or are not synthesized in ordinary melts at uniform pressure. Minerals such as kyanite, chloritoid, lawsonite, glaucophane and staurolite are almost wholly restricted to stressed rocks, and are conveniently styled stress minerals. On the other hand, minerals such as orthoclase anorthite, andalusite and olivine are restricted to systems formed under uniform pressures and are referred to as *anti-stress* minerals. In contradistinction to thermal metamorphism, where many of the minerals are characteristically anhydrous, the lower grades of regional metamorphism are characterized by the hydroxyl-containing minerals like sericite, chlorite, some amphiboles, and the epidote-zoisite group.

The effects of stress on reactions accompanied by a gas or vapour phase are very great. The mere grinding of calcium carbonate in a mortar leads to the evolution of some carbon dioxide. Reactions which are inappreciable in the absence of stress may thus be greatly facilitated by application of stress. The reaction $CaCO_3 + SiO_2 \rightleftarrows CaSiO_3 + CO_2$ is an important one in rock metamorphism. Under high uniform pressure the left side of the equation represents the stable assemblage, and calcite and quartz are found together. On the other hand, at high temperatures the reaction proceeds with the formation of wollastonite. The approximate equilibrium curve for this reaction has been calculated on the basis of the Nernst heat theorem. From the standpoint of the phase rule, a mixture of calcium carbonate and silica represents a three-component system and therefore under the conditions of metamorphism only three phases are possible. Below the transformation curve the possible three phase assemblages are $SiO_2 - CaCO_3 - CO_2$ and $SiO_2 - CaCO_3 - CaSiO_3$. Above the transformation curve the assemblages are $CaSiO_3 - CaCO_3 - CO_2$ and $CaSiO_3 - SiO_2 - CO_2$ (fig. 3). The occurrence together of calcite and quartz might therefore be used to indicate that the rock assemblage had not been heated above the transformation temperature, and in this way the mineral constitution of such a rock might be used as a geological thermometer. The effects of shearing stress are of a different order if the vapour phase is allowed to escape, for the reaction is driven in one definite direction leading to the production of wollastonite. In the choice of transition points adapted for the purposes of a geological thermometer it is clear that much care is necessary and the conditions of metamorphism realized.

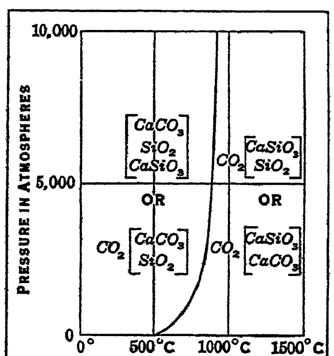

FIG. 3

The effects of temperature on reversible reactions are usually of a different order of magnitude from those of pressure. A large increase of pressure may be less effective in displacing equilibrium than a small increase of temperature. Nevertheless the effects of pressure are by no means negligible. In such reactions increase of pressure tends to displace the equilibrium in the direction in which the reaction is accompanied by decrease of volume. Thus, in a reacting system, high pressure favours the production of phases of greater density. This well known law of Le Chatelier (1885) was first applied to metamorphic processes by Lepsius (1893), but its importance was first clearly enunciated by Becke, whence it is frequently referred to as Becke's volume law. The knowledge of the specific volumes of minerals is largely gleaned from observations at ordinary temperatures, and under the conditions of reaction the change in volume is not necessarily the same in magnitude, nor even in sign; moreover some of the reactions to which the law is applied are not definitely known to be reversible. Its application to mineralogical systems requires the exercise of considerable caution. Undoubtedly it is in the rocks of higher grades of metamorphism where enormous pressures are involved that the volume law is operative. Such minerals as jadeite, pyrope, almandine, grossular, kyanite and staurolite are dense minerals represented only in rocks formed at high pressures, and arise under the operation of the volume law. The combination wollastonite-anorthite appearing in limestone xenoliths at volcanic centres, under the conditions of contact metamorphism or deep-seated alteration, appears as a grossular-quartz assemblage:

$$2CaSiO_3+CaAl_2Si_2O_8 \rightleftarrows Ca_3Al_2(SiO_4)_3+SiO_2.$$

In dry melts, a system of the bulk composition of grossular consolidates as a mixture of the phases anorthite, wollastonite and gehlenite. Regarded as a reversible action:

$$\underset{\text{Grossular}}{2Ca_3Al_2(SiO_4)_3} \leftrightarrows \underset{\text{anorthite}}{CaAl_2Si_2O_8}+\underset{\text{gehlenite}}{Ca_2Al_2SiO_7}+\underset{\text{wollastonite}}{3CaSiO_3}$$

the formation of grossular is accompanied by a large decrease of volume. The sum of the molecular volumes of the phases of the right hand side of the equation is 310, the molecular volume of grossular 260. Clearly, pressure favours the formation of the garnet mineral.

Again glaucophane or jadeite appears in place of nepheline and albite under high pressure:

$$\underbrace{NaAlSiO_4+NaAlSi_3O_8}_{\text{molec. vol.}=156} \rightleftarrows \underbrace{2NaAlSi_2O_6}_{\text{molec. vol.}=123.}$$

Similarly, olivine and anorthite are represented by garnet:

$$Mg_2SiO_4+CaAl_2Si_2O_8 \rightleftarrows CaMg_2Al_2(SiO_4)_3,$$

the formation of garnet being accompanied by a diminution in volume of 17%.

In the more deep-seated regions metamorphism is effected under the influence of widespread magmatic activity. An intimate commingling of igneous and metamorphic rock is therefore characteristic of these regions. Injection gneisses are produced by the *lit par lit* intrusion of igneous magma between the foliation planes of metamorphic rocks. The process is not always limited to a mechanical injection of material, but may be accompanied by an intense metasomatic action, in which solutions emanating from the magma react with the country rock to produce metasomatic schists and gneisses.

Recrystallization processes in metamorphic rocks take place in an essentially solid environment, and in distinction from igneous rocks no definite sequence or order of separation of crystals is to be traced. The characteristic structures and textures of metamorphic rocks have, therefore, a distinct significance. The term "structure" is used to express the genetic relationship of the component minerals, while "texture" refers more explicitly to their stereometric arrangement. The typical structure produced by the growth of crystals in a solid environment is known as the *crystalloblastic structure* (Gr. *βλαστάνειν*, to sprout). Since each grain grows in intimate contact with its neighbours, the form-development of the individual crystals tends in general to be poor. Rounded crystals are thus very common. Different minerals, however, possess varying crystallization force, and some are able to assert their proper crystalline form against the resistance of their solid environment. The experiments of Becke and Day on the growth of crystals of alum under load, show that the force of crystallization may be very great, and indicate that the internal stresses set up during growth are of the same order of magnitude as the crushing strength of crystals themselves, and, indeed, as the forces brought into play during orogenic movements.

For the common metamorphic minerals the series is as follows: Titanite, rutile, hematite, ilmenite, garnet, tourmaline, staurolite, kyanite, epidote, zoisite, pyroxene, hornblende, dolomite, albite, mica, chlorite, talc-calcite-quartz, plagioclase, orthoclase, microcline. In general, this order is one of increasing molecular volume and decreasing density. Any particular member of this series is able to assert its own crystal form against that of any other member following it in the series. Where crystal form is developed, only facies with simple crystallographic indices are developed, and these are commonly cleavage facies. Hornblendes have prominent development of (110) faces, garnet (110), kyanite (100) and (010). Crystals showing a well developed form are known as *idioblasts,* and those characterized by absence of crystal form—*xenoblasts.* Where the stresses developed by the growth of crystals in a solid rock are not offset by stresses imposed from without, being in random directions they tend to be neutralized by mutual compensation. The directionless hornfels structure of contact rocks is produced in this way, but the various schistose and foliated structures are the result of the imposition of shearing stress from without by which the internal stresses are reduced.

It is to be expected, therefore, that those minerals which occur as idioblasts in metamorphic rocks are members high in the crystalloblastic series—as rutile, garnet, etc. They are known as strong minerals, in contradistinction to weak minerals, such as quartz and the potash felspars. The structures given by inclusions, relative form, development and size of crystals, have thus no direct analogy with the apparently similar features observed in igneous rocks. Whereas, in the latter, inclusions are older and tend to have better crystal shape than their host, in metamorphic rocks both host and inclusion may be developed simultaneously, and not infrequently inclusions are xenoblastic and the host idioblastic. The porphyritic crystals of igneous rocks are an early generation, but in metamorphic rocks the corresponding large crystals are pseudo-porphyritic. They are known as *porphyroblasts.* Frequently they are strong minerals, as garnet, ilmenite, hornblende, etc., and though formed at the same time as the ground mass minerals, they are not infrequently aligned across the common schistosity or foliation planes. Many porphyroblasts are characterized by multiple twinning (kyanite, chloritoid, cordierite), or show the typical sieve structure, being crowded with the ground-mass constituents (cordierite, chloritoid, staurolite, chiastolite); again, many of them are unrepresented among the ground-mass minerals. The large size of porphyroblasts is, doubtless, in large measure to be accounted for by their relatively greater crystallization force and crystallization velocity. Indeed, it is not improbable that many of them grow rapidly from supersaturated solutions; their twinning inclusions and orientation point to rapid growth. While for the elements of the ground-mass, nuclei are usually originally present, with porphyroblasts it is frequently otherwise; garnet, staurolite and chloritoid are new phases developing in a medium free from the crystal nuclei of these minerals. In the absence of the latter, spontaneous crystallization from supersaturated solutions is rendered possible. In the highest grades of metamorphism porphyroblast structure is less in evidence than in medium grades, owing to a tendency towards equalization of the size maxima of different minerals under very high temperatures and pressures. At the same time sieve structures tend to be abolished. Where the structures of the original rocks are incompletely effaced during metamorphism, they are known as relict or palimpsest structures. Some amphibolites may thus preserve the porphyritic or ophitic structures of the dolerites from which they are derived, conglomerate-schists or quartzites the psephitic or psammitic structures of sediments. These relict features are usually referred to by prefixing the term

"blasto" to the specific structure, as blastophitic, blastopsephitic, etc.

CLASSIFICATION OF METAMORPHIC ROCKS

Metamorphism being the response to change of condition in respect of temperature and pressure, the diversity in mineral composition of metamorphic rocks can be regarded as the resultant of two independent variables, viz., (*a*) the ultimate composition of the rocks, and (*b*) the physical conditions operating during metamorphism. These two variables may well form the basis of a classification of the products of metamorphism.

In Grubenmann's well known classification of the crystalline schists these two variables occupy the dominant positions, and are the foundation upon which the classification is erected. The composition variable is expressed in the 12 groups recognized, six of which correspond to sedimentary types, these being the shales, sandstones, limestones, marls and the weathering residuals represented by laterites and bauxites, and six corresponding to igneous rocks, granites, diorites, gabbros, ultrabasic and alkali rocks, the latter including the syenites, nepheline syenites, theralites, lamprophyres, etc. The physical factors of pressure and temperature are recognized as a threefold division into zones, *epi, meso* and *kata.* In a general way the factors temperature and pressure are a function of depth and the divisions *epi, meso* and *kata* thus correspond to bathymetric zones, each with its distinctive types of mineral paragenesis.

In the uppermost or epi zone, temperatures are low, hydrostatic pressure is low, while shearing stress may be high. The mineral products of this zone are those rich in H_2O, OH or H, and are characteristically those of low density, such as chlorite, zoisite, sericite, hornblende, chloritoid, etc.

The rock products are those of mechanical deformation with little recrystallization, cataclastic rocks of all types and the rocks of a low grade metamorphism such as phyllites, chlorite and talc schist, epidote schists, etc. In the second or meso zone the temperatures are higher, while stress probably reaches the maximum value. Owing to the increase of temperature the imposition of shearing stress results in recrystallization without mechanical rupture. Hydroxyl-containing minerals are now less prominent. The type minerals are kyanite, staurolite, almandine, anthophyllite, muscovite, biotite, etc., while the assemblages appear in such rocks as biotite, garnet, staurolite, kyanite and actinolite schists, marbles and quartzites. In the deepest, or kata zone, the high stress of the meso zone under the influence of the very high temperature, is replaced by high uniform pressure. Reactions take place pre-eminently in response to the volume law leading to the generation of anhydrous minerals of high density. Pyroxenes, olivine, pyrope, sillimanite, spinel, anorthite, jadeite, potash felspar, etc., are the type minerals, while the resulting rocks are gneisses, granulites, eclogites, etc., characterized by these minerals.

It is not to be concluded that natural assemblages can be fitted into such a simple scheme without serious difficulties. The factors of temperature and pressure are not dependent simply on depth below the surface, but may be subject to wide variation locally. These physical factors include among themselves at least two independent variables: the intrusion of igneous magma brings into play the factor of high temperature without the incidence of pressure and local intense orogenic movement, the factor of high stress without necessarily the incidence of temperature. Thus in this system we find no well-defined place for assemblages of contact metamorphic origin. The range of possibilities thus opened up is, however, to a large extent diminished by the fact that the maximum value of shearing stress is a function of the temperature, and the possible range of stress is therefore decreased as the temperature rises. Where metamorphism is of the regional type, it may be expected that stresses are maintained close to their maximum value, and to this degree the changes effected are in response to a single variable. The ease with which the rock assemblages originating under higher temperatures can be fitted into the meso and kata zones, finds its explanation in this dependent relationship between maximum stress and temperature. In rocks of the epi zone, the great variety of rock products is a direct reflection of the widely variable stress maxima of different materials. The peripheral areas of a mountain tract that has undergone metamorphism are usually of a low grade of metamorphism, and as zones of weakness are prone to be cut off from observation by subsequent dislocation, or covered by the overlap of later sediments. Frequently, therefore, the metamorphism over a wide tract may be of nearly uniform (but high) intensity. In some areas of regional metamorphism, however, these marginal zones are preserved for observation, and a continuous passage from unaltered sediments to schists and gneisses of high metamorphic grade can be traced.

Such areas are of paramount importance in metamorphic studies, for the gradational changes in structure, texture and mineral composition which their rocks spatially display are the resultant of the imposition of continuously varying temperatures and pressures. Two such model metamorphic regions are the Highlands of Scotland and the Caledonian mountain chain of southern Norway.

The detailed examination of such regions reveals a progression of metamorphism in which—selecting one particular sedimentary type—a series of zones can be mapped out according to the entry of new-formed metamorphic minerals. Successive zones are thus characterized by special index minerals. Study along these lines was first carried out by Barrow (1893) in the south-east highlands of Scotland. Argillaceous rocks, owing to their ubiquity, are the foremost types in which such zones can be recognized. In them, successive zones of increasing metamorphism are characterized by the index minerals, chlorite, biotite, almandine, staurolite, kyanite and sillimanite. The boundary surfaces of these zones are at once isothermals and isodynamics, and as referred to the grade of metamorphism imposed, their intersections with the earth's surface have been termed *isograds.* Other sediments show corresponding zones, limestones for example have as index, minerals, zoisite, tremolite, diopside and wollastonite.

A complete study of such a metamorphic region would include the laying down upon the map of all the zones distinguishable among the varied sediments, and it is clear that from studies of this kind the data for the development of an ideal classification should be realized. In place of the three depth zones of Grubenmann's classification, we should recognize many zones. In this sense the *facies* classification suggested by Eskola is a refinement of the existing classificatory scheme. A facies is defined to designate a group of rocks characterized by a definite set of minerals which, under the conditions obtaining during their formation, were in perfect equilibrium with each other. The quantitative and qualitative mineral composition in the rocks of a given facies varies gradually in correspondence with variation in the chemical composition of the rocks. The number of facies expresses the variable physical environment under which rocks have been formed and any given facies may include assemblages (isofaciel) of widely different bulk composition. A distinctive facies is the hornfels facies characteristic of the inner zones of thermal aureoles. Other facies are recognized by the name of some important constituent assemblage, as green schist, amphibolite, eclogite or sanidinite facies. The number of facies is not limited by *a priori* considerations, and may be increased as advancement of knowledge may require. The elucidation of the different zones in a region of progressive metamorphism is clearly a first step towards the determination of the facies of metamorphic rocks, and thus a guide—apart altogether from experimental study—to the goal of deeper understanding of metamorphic processes.

BIBLIOGRAPHY.—The subject of metamorphism is treated in most elementary text books of petrology. (*See* PETROLOGY: *Bibliography.*) The principal detailed treatises are C. R. Van Hise, *A Treatise on Metamorphism,* Monograph U.S. Geol. Survey, No. 47 (1904); U. Grubenmann, *Die Kristallinen Schiefer* (2nd ed., 1910); C. K. Leith and W. J. Mead, *Metamorphic Geology* (1915). The more recent advances are incorporated in U. Grubenmann and P. Niggli, *Die Gesteinsmetamorphose,* vol. i. (1924). Reference may also be made to R. A. Daly, "Metamorphism and its Phases," *Bull. Geol. Soc., America,* vol. xxviii. (1917); A. Harker, *Presid. Address Geol. Soc., London,* vol. lxxiv. (1918). (C. E. T.)

METAMORPHOSIS, a Greek word meaning change of shape, is applied in zoology. (*See* INVERTEBRATE EMBRYOLOGY.) All animals begin their existence as undifferentiated cells and attain their characteristic features by growth which entails changes of shape. If we were to magnify the model of a baby to the size of a man we should discover how striking are the changes in the proportions of the human figure as manhood is attained and yet these changes are not regarded as metamorphosis. The best definition of metamorphosis is "a conspicuous change in shape and mode of life in an animal occurring in a comparatively short time without any increase in size or even with a decrease in size." In the common English frog, the tadpole stage lasts from two to four months, during which the animal increases very much in size but retains the same general appearance and proportions. The rudiments of the hind limbs gradually increase in length whilst the fore-limbs break through the skin of the breast region. The creature then ceases to feed and begins to crawl out of the water, though it remains within reach and takes to it if alarmed. In about four days the tail is reduced to a vestige and finally disappears and the young frog takes up land life. The froglet is smaller than the completely grown tadpole and requires four years to attain sexual ripeness and full size.

In the development of the butterfly, the caterpillar, like the tadpole, requires about two months to grow to full size. Then in a day or so it constructs its cocoon and changes into a chrysalis or pupa. The pupal stage may last as long as the entire growth of the caterpillar, or longer, for a whole winter may be passed in this state, but the emergence of the perfect insect from the pupal skin only occupies an hour or two. The adult life may last only about three weeks.

The term metamorphosis is not applied to embryos, only to larvae. Since the change in shape is accomplished without increase in size, it always involves the casting off or absorption of certain larval tissues. In the case of the tadpole's tail, wandering cells (phagocytes) carried by the blood-stream attack and devour the contained muscles, nerve-cord and notochord, the skin is thrown into internal folds and these folds in turn are attacked by phagocytes and so the whole skin area shrinks in size, till the tail is reduced to a stump.

Metamorphosis is found only in those life-histories where the larva and the adult have very different habits. Among vertebrates it only occurs in Cyclostomes in certain groups of fish and in Amphibia (frogs, toads and newts). Below the level of vertebrates, however, it is found in every great division of the animal kingdom. The newt is especially interesting. This creature differs from a frog in having the fore- and hind-limbs of approximately equal size and in retaining the tail throughout life. The larva differs from the tadpole in retaining during the whole of its aquatic existence the external feather-like gills which the tadpole at first possesses but later casts off when they have been covered by the growth of the gill cover. This cover in the tadpole hides the fore-limbs which are only revealed a short time before the little frog leaves the water, but in the newt larva this cover is rudimentary and the fore-limbs appear in development first, to be followed later by the hind-limbs so that in the older larvae all four limbs are obvious and fully formed. Now in certain species of newt such as the Mexican axolotl the habit has been acquired of spending the whole life in water. In normal circumstances the larvae of these newts never metamorphose but develop their genital organs and eventually lay eggs. For reasons discussed below it is possible to induce metamorphosis in these newts by feeding them with thyroid gland. No more startling phenomenon can be witnessed than this. In a week or two in the writer's laboratory a large fat axolotl lost its gills, closed up its gill slits, lost the blade-like fin on its tail, darkened in colour, shrunk considerably in size and emerged from the water as a rather small black newt.

Among fishes metamorphosis is comparatively rare, because both young and adult swim in the water and get their food in much the same way. The best examples are the flatfishes (Heterosomata), in which the adult swims lying on one side. The eye belonging to this side is twisted on to the upper side; and the mouth is distorted towards the lower side, for the fish feeds on the animals (worms and molluscs) which burrow in the sand and mud beneath it. The young fry swim upright in the water and the eyes are on opposite sides of the head. When they have reached a certain size they fall to the bottom and rest on one side. Darwin, quoting Malm, says that they make violent effort to twist the lower eye on to the upper side and that as the skull is soft these efforts meet with considerable success. In a comparatively short time both eyes are on the upper side and the metamorphosis has been accomplished.

The lamprey (*q.v.*) (*Petromyzon*), is separated by such a deep gap from all fish that it is placed in a different class, Cyclostomata (*q.v.*). No true jaws exist; the mouth is surrounded by a circular cartilage and the animal lives by attaching itself by suctional action to a larger animal and then rasping a hole in its victim's flesh by means of horny teeth which are developed on a piston like tongue. The larval form, known as ammocoetes, lives in a totally different manner. The mouth is overhung by a hood-like upper lip separated by a lateral cleft from a small straight underlip. The gill-sacs open directly into the oesophagus instead of into a special tube as in the adult. But the greatest peculiarity of the ammocoetes is that the organ from which the lamprey's thyroid gland is later developed is a sac-like structure with a permanent opening into the throat, through which the mucous secretion escapes in the form of a cord. This entangles any minute organisms in the water which the animal swallows. The mucus with its contained food is passed back into the oesophagus whilst the surplus water escapes through the gill openings.

After living like this for two or three years the ammocoetes undergoes a rapid transformation into the adult form. In 1912 the writer received a consignment of "young lampreys" from the Severn. They were about six in. long and half of them were full grown ammocoetes larvae and half young fully metamorphosed lampreys. They were equal in size.

The animals known as Tunicata (*q.v.*) are also primitive members of the phylum Vertebrata. The egg develops into a tadpole-like larva with a hollow spinal cord expanding into a brain-vesicle in front. There is a notochord in the tail and the alimentary canal consists of a pharynx, opening above by a mouth in front of the brain, and at the side by a pair of gill-pouches. The pharynx is succeeded by a loop of intestine leading to an anus high up on the left side. This larva after swimming for some hours attaches itself to the substratum by three adhesive papillae on the chin beneath the mouth. Metamorphosis occurs within a few minutes. The tail and notochord are cast off. The spinal cord shrivels and the brain vesicle is replaced by a little solid ganglion, whilst the mouth by the elongation of the chin is elevated above the substratum.

When we descend to Invertebrata, we find the classical example of metamorphosis in the life-histories of the Echinodermata. In this phylum the larva and the adult are so unlike each other that the change from one stage to the other was formerly supposed to be an alternation of generations. To render our ideas more definite consider the case of the common British sea-urchin *Echinus miliaris*. The larva is a beautiful transparent free-swimming form with outwardly perfect bilateral symmetry. It has a scoop-like mouth leading into a narrow gullet. This is followed by a globular stomach from which a short straight intestine leads back towards the mouth to end in the anus. The alimentary canal forms a loop in the median plane. The skin is drawn out into four symmetrical pairs of long arms supported by transparent calcareous rods. These arms are covered by cilia—are in fact prolongations of a lobed, ciliated band which crosses in front of the mouth, passes down the sides and then crosses on the under-surface in front of the anus. Behind the ciliated band the larva has a circle of four crescents carrying powerful cilia.

This general form characterizes larval life for six weeks, gradually increasing in elaboration as the larva grows older. The arms are at first four, then six, and finally eight, and the ciliated

crescents are cut off from the ciliated band. Then the larva sinks to the bottom and extends from its left side the first adult tentacles or "tube-feet" which have been formed under a screen of skin. As soon as the larva has thus come to anchor a marvellous and rapid change supervenes, which, in the case of another species, the writer has seen completed in about half an hour. The long ciliated arms literally melt away, the protoplasm of the skin covering them seems to gather up into drops and flow backwards off the spines into the body. A large part of the fluid in the primary body-cavity is expelled by osmosis into the stomach, and the globular body of the larva becomes compressed into a flat disc which then crawls away as the young sea-urchin. The mouth becomes cut off from the gullet, shallows out and disappears and a new mouth is formed on the left side in the middle of the circle of tentacles. Similar rapid changes accompanied by shrinkage in size and loss of larval tissues characterize the life-histories of other echinoderms, but in no case are these changes accomplished in so short a time as in the case of the sea-urchin. Consider, for example, the life history of the common starfish *Asterias rubens*. Its larva shows a general similarity to the larva of the sea-urchin. But this larva, the bipinnaria, differs from the sea-urchin larva in two important points: first, its paired arms are more numerous and are unsupported by calcareous rods, and secondly it possesses a long forehead or preoral lobe in front of the mouth, over which a loop of the ciliated band bends back. When its free-swimming life terminates it attaches itself to the substratum not by the adult tentacles but by a sucker which is developed at the apex of this preoral lobe. This lobe is thus converted into a stalk and this attached stage lasts a week or ten days, during which the adult organs are developing at the hinder end of the larva, and the stalk is reduced to a mere knob. The starfish then wrenches itself loose and walks away.

The larva of *Asterias* must find firm rock or at any rate seaweed to which to attach itself, but there is another British starfish, *Astropecten*, which habitually lives on sandy ground. When the bipinnaria of this starfish reaches the age at which it should attach itself, this is impossible; so it continues to swim until the locomotor organs of the future starfish are so far developed that they are capable of functioning. Then the great ciliated preoral lobe is suddenly amputated; the hinder part of the body falls to the bottom and crawls away as the young starfish.

The comparison of the development of *Asterias* and *Astropecten* gives the clue to the meaning of metamorphosis; it is always a period of rapid change of structure during which the animal does not feed, which bridges over the transition from one set of habits to another. Always this involves the casting off of organs required by the earlier set of habits—and this casting off is the principal element in the change of structure. For in most cases the structures required for the second set of habits have already begun to form whilst the first set of habits persists, but these new structures are, as it were, sketched out in embryonic tissue and packed away under a fold. Metamorphosis is therefore a secondary falsification of the ancestral record embedded in a life-history. *See* INVERTEBRATE EMBRYOLOGY. (E. W. MACB.)

EXPERIMENTAL WORK

The crisis of metamorphosis, by which an organism wholly changes its structure and mode of life, is not only of great interest as a phenomenon of general biology, but offers the most interesting opportunities of research in the field of developmental physiology. Gudernatsch in 1911 demonstrated that tadpoles could be caused to metamorphose precociously by feeding them with thyroid gland. He thus showed that amphibian metamorphosis was due to a hormone (*q.v.*) circulating in the blood, which would explain the synchronization of all the numerous changes which occur together at metamorphosis. Since then a number of important facts have been elicited. All Amphibia which normally metamorphose can be made to do so precociously by the thyroid of any vertebrate, whether fresh or dried, given as food or injected. The effect is a quantitative one up to a point. The greater the dose, the more rapid and abrupt the metamorphosis; after a certain threshold value has been reached, however, increase of dose has no further effect. The rapidity of thyroid-induced as of normal metamorphosis is also affected by external factors. A protein-rich diet accelerates it, one rich in fat slows it down. Heat hastens, while cold may actually inhibit it.

Further experiment showed that larvae whose thyroids were removed never metamorphosed, but continued to grow as tadpoles. It is now certain that the secretion of the animal's own thyroid is the main agency in producing normal metamorphosis.

As the thyroid secretion is exceptionally rich in iodine, the natural supply of this element must constitute a limiting factor, and in waters exceptionally poor in iodine, we should expect a retardation or suppression of metamorphosis. There are certain lakes where newts never metamorphose: it is probable that these will be found to lack iodine. Iodine will also induce precocious metamorphosis, but only in frog and toad tadpoles, not in those of tailed Amphibia. The metamorphosis due to iodine is much more gradual than that induced by thyroid since what is provided is not so much ready-made metamorphosis-producing substance, but raw material which enables the animal's own thyroid to grow more quickly. Iodine even causes thyroidless frog tadpoles to metamorphose, but much more slowly than unoperated animals. Some at least of the body-cells of frog tadpoles must thus have some power of synthesizing the metamorphosis-producing substance.

In tailless amphibia (Anura) the thyroid is passing secretion into the blood throughout larval life. In tailed amphibians (Urodela), the thyroid appears to be entirely devoted to storage during larval life; when a certain stage of development is reached, the gland suddenly begins secreting its stored substance into the blood, so inducing metamorphosis. It would be of great physiological interest to discover what is the "releasing factor" which brings about this change in the thyroid.

This difference between anuran and urodele is correlated with another. The growth of limbs is not affected by thyroid in urodele tadpoles, but is in Anura. In frog tadpoles whose thyroids have been removed, limb-growth, though not absent, is very slow; in thyroid-treated specimens it is more rapid than normal, the rapidity varying with the dose.

This introduces us to an important general principle—the specific reactivity of tissues to hormones. Thyroid from any vertebrate will act upon Amphibia; but corresponding tissues in frog and newt will react differently to the same thyroid. The same is true of the tail; in Anura thyroid causes its total resorption, in Urodela only that of its fin-membrane. The tail of Amphibia also illustrates the principle of differential susceptibility. The limbs of frog tadpoles begin excess growth when the least trace of thyroid extract is to be found in the blood: the tail is not resorbed until a considerable threshold-concentration is attained.

Specific reactivity is also illustrated by the neotenous Amphibia, *i.e.*, those which normally live their whole lives and reproduce while retaining larval form and aquatic habit. Most of these cannot be artificially metamorphosed even by the heaviest doses of thyroid: their tissues no longer react to the hormone. In Amblystoma matters are different. Most species metamorphose normally. The well-known axolotl of Old Mexico, however, is neotenous. It has now been shown that thyroid will always metamorphose axolotls. There is, however, a threshold dose below which only minor, reversible changes occur. A dose just near the threshold causes metamorphosis to advance rather more than half-way and then stop, leaving the animal neither aquatic nor terrestrial. Metamorphosis is thus not an "all-or-nothing" phenomenon. Neoteny here is apparently due to three co-operating factors: (1) failure of the thyroid's "release mechanism," (2) reduced thyroid-size, (3) reduced tissue-sensitivity.

The thyroid, however, is not the only ductless gland concerned in metamorphosis. The pituitary also plays an important, if secondary, role. Its secretion is indeed necessary for the development of the thyroid; tadpoles with pituitary removed never metamorphose, and their thyroid-size is less than $\frac{1}{20}$ of normal. Its own secretion can also produce metamorphosis, in axolotls as well as tadpoles, even in animals deprived of their own thyroid and pituitary. However, the hormone is not so potent as that of

the thyroid. These effects are all due to the anterior lobe. The posterior lobe produces a hormone which if injected in sufficient quantity will antagonize small doses of thyroid or moderate doses of anterior pituitary, and so prevent metamorphosis.

We must briefly mention some points concerning the time-relations of metamorphosis. The common European frog, *Rana temporaria,* normally takes about four months to metamorphose; some toads only four to six weeks; the American leopard-frog over a year; and several bull-frogs over two years. The thyroid of leopard-frog or bull-frog tadpoles contains the metamorphosis-hormone, since if engrafted into tadpoles of other species it induces rapid metamorphosis. Apparently the prolongation of larval life in these animals is due to an alteration in the relative rates of thyroid-growth and body-growth. A definite concentration of thyroid hormone in the blood must be reached before metamorphosis can occur. If the thyroid grows relatively more slowly, metamorphosis will be postponed. The same postponement could equally well be effected by diminished sensitivity of the tissues to thyroid. Thus the relative rate of thyroid-growth and the absolute degree of tissue sensitivity between them decide the date of metamorphosis.

The compensatory reactions of the thyroid are interesting. At high temperatures, a tadpole's thyroid diminishes in size and activity, at low temperatures it increases. Similarly, after a small dose of thyroid, the animal's own gland is not called upon, and shrinks. Interesting results have been obtained by utilizing these facts. If tadpoles are kept at high temperatures till half-grown, and then placed at low temperature, they fail to metamorphose. This is because their thyroids, first much reduced by heat, are unable to respond to the extreme demands made on them by cold, and can only react by forming a goitre which vainly tries to compensate by quantity of tissue for lack of quality of secretion.

Again, if half-grown normal tadpoles are put at very low and very high temperatures after receiving a small dose of thyroid, those at high temperature will metamorphose in under 48 hours, but those at low will proceed half-way with metamorphosis, and remain thus even if put at medium temperature. The dose of thyroid was sufficient to cause their own thyroid to shut down its activity, but not sufficient to counteract the cold.

It should be mentioned that Romeis claims to have achieved a definite influence on the date of metamorphosis by immersing frog eggs or sperm in thyroid solutions.

Little work has been done on metamorphosis in other animals. In caterpillars the brain produces some chemical substance necessary for pupation (Kopec). Certain treatments will cause the meal-worm beetle to develop large wing-rudiments while still in the grub stage; apparently the relative growth-rate of the wings has been altered. In sea-urchins J. S. Huxley has secured precocious metamorphosis by immersing moderately-advanced larvae in very dilute poisons for some hours. The larval tissues are much more affected by the poison, undergo dedifferentiation (*q.v.*) and can then be absorbed by the urchin-rudiment. Here it is probable that no hormone is concerned with metamorphosis. Ascidian larvae metamorphose precociously under thyroid treatment (Weiss), but lamprey larvae do not. Metamorphosis is thus accomplished in different ways in different animals. (J. S. H.)

METAPHOR, a figure of speech, which consists in the transference to one object of an attribute or name which strictly and literally is not applicable to it, but only figuratively and by analogy. It is thus in essence an emphatic comparison, which if expressed formally is a "simile"; thus it is a metaphor to speak of a ship ploughing her way through the waves, but a simile when it takes the form of "the ship, like a plough, moves," etc.

METAPHYSICS. The systematic study of the fundamental problems relating to the ultimate nature of reality and of human knowledge. It naturally falls into two divisions, namely, Ontology or the systematic study of the ultimate problems of Being or Reality, and Epistemology, or Theory of Knowledge, the systematic study of the ultimate problems of human knowledge. These constitute between them the principal departments of Philosophy, which, however, also includes certain other branches of inquiry which are commonly known as philosophical studies or sciences (Ethics, Logic, etc.). (*See* PHILOSOPHY.) Few systems of philosophy do even justice to both departments of Metaphysics. With rare exceptions, like Plato, the Sceptics, Descartes and Locke, philosophers before the time of Kant's *Critique of Pure Reason* (1781) were mainly interested in ontology. Since the time of Kant, however, metaphysical interest has shifted to a very large extent to Epistemology. For sceptics and agnostics of course, there can be no such thing as ontology, and even Kant and his school are essentially agnostic in relation to ontology, except as a matter of faith based on moral postulates. These facts may help to explain the vacillating use of the term Metaphysics. Some writers use it as synonymous with Ontology, others make it synonymous with Epistemology. But if due regard is paid to the whole history of the subject there can be no reasonable doubt that the correct use of the term is to make it include both Ontology and Epistemology, or Theory of Being and Theory of Knowledge, as its two intimately related branches. Metaphysical speculations are the outcome of what is called sometimes a "religious impulse" and sometimes a "metaphysical craving" to find something permanent behind or beyond the changing appearances of daily observation, and to acquire a knowledge that shall be better founded than the shifting opinions usually encountered.

The first introduction of the term Metaphysics was a mere accident. When the writings of Aristotle were first collected and arranged by Andronicus of Rhodes (in Rome, about 70 B.C.), or possibly by some earlier Peripatetic already, the treatises on what Aristotle had called "First Philosophy" (also "Theology") were placed after the treatises on physics, and so came to be known as "the treatises after the physical treatises" (τὰ μετὰ τὰ φυσικά). In course of time this designation was applied to the subject matter of these treatises, and so the Scholastics used the term *transphysica* for studies which come after the ordinary physical studies of natural phenomena. The term *Metaphysica* occurs already in Boetius (A.D. 480–525). To some people the term "metaphysical" rather suggests the "supernatural." This is partly responsible for the growing unpopularity of the term, and for the increasing tendency to use the wider terms "philosophy" and "philosophical" in place of "metaphysics" and "metaphysical."

As the principal types of epistemological theory are dealt with in the article on KNOWLEDGE, THEORY OF, it is only necessary to set out here the main types of ontological theory (*see* ONTOLOGY). Briefly, these are:—

(1) One of the first questions, probably the first question, raised in the history of Western philosophy was, Is there anything permanent at the basis of the changing phenomena of Nature? The earliest Greek philosophers (Thales, Anaximander, etc.) assumed that there is; so did many subsequent philosophers (the Eclectics, Plato, Aristotle, Spinoza, etc.). On the other hand, Heraclitus, among the ancients, and Bergson and James, among the moderns, maintain that there is nothing permanent, that the "ever rolling stream" of changing phenomena or of experiences is the only and ultimate reality. We may call a philosophy of the former type *Ontological Substantivalism;* one of the latter type *Ontological Phenomenalism.* The latter view implies *epistemological phenomenalism,* but is not necessarily implied by it.

(2) The second question is as old as the first, and may be put in this way. Is there only one ultimate reality or more than one? The possible answers to this are obvious. They may be expressed by the familiar terms, *Monism* and *Pluralism,* corresponding respectively to the views that ultimate reality is just one, or more than one. Thales, the Eclectics, Plato, Spinoza may be classed as Monists. Democritus and the Atomists, Descartes and Leibniz may be classed as Pluralists. To avoid confusion with the other uses of these terms, it may be advisable to call these views *Substantival Monism,* and *Substantival Pluralism* respectively.

(3) The third problem, also old, is whether ultimate reality is all of one *kind* only or of more kinds than one. Here, too, the possible answers are obvious. Moreover, Substantival Monism clearly implies the former alternative. On the other hand, Substantival Pluralism may or may not adopt the same alternative. Leibniz, *e.g.*, was a pluralist, but the monads in which he believed

were all supposed by him to be of the same (spiritual) kind, only different in degree. Similarly with the Atomists. On the other hand, Descartes (if one can really be sure about his views) believed in a plurality of material substances, and a plurality of souls or mental substances entirely different from the material substances, and in God besides. To name these distinctions suitably is not easy. Since they affect Pluralism only, one might distinguish between *uniform pluralism* (like that of Leibniz) and *multiform pluralism* (like that of Descartes); Substantival Monism being necessarily *uniform*.

(4) The fourth question relates to the number of fundamental or irreducible attributes which pertain to the real or reals. To this question likewise the answer may be "one," or it may be "more than one." If "one," we have *Attributive Monism* (Leibniz, on the one hand, the Materialists, on the other, also the Voluntarists); if "more than one" then we have either *Attributive Pluralism* (Spinoza, for instance) which recognizes a multiplicity or even an infinity of such attributes, or *Attributive Dualism or Natural Realism* (like that of Descartes and of some modern realists) which recognizes only two such attributes, and may associate each of them with a different kind of substance. Attributive Monism is known as Materialism, if materiality or extension or some form of physical energy is the only irreducible character admitted; it is called *Ontological Idealism* or Intellectualism or Spiritualism if thought or reason or some sort of intelligence is the only irreducible attribute that is acknowledged; it is called *Voluntarism* if the irreducible attribute is identified with will (*e.g.*, Schopenhauer and Nietzsche); it is known as *Neutral Monism* if the ultimate attribute is regarded as different from both mentality and materiality, but as the source of the emergence of both (*e.g.*, W. James, B. Russell and some of the New Realists). E. von Hartmann's philosophy of the unconscious must probably be classed as a form of Attributive Dualism because the "Unconscious" is conceived by him apparently as a combination of will and unconscious or subconscious cognition. Materialism usually regards mentality (or consciousness in the widest sense of the term) as a mere epiphenomenon or by-product of matter or physical energy; and Ontological Idealism as commonly treats so-called material objects and events as mere appearances to, or creative images of, some consciousness or other. It should be remarked, however, that there is a very modern type of Idealism which is not primarily epistemological nor ontological, but axiological, maintaining simply that it is the "ideal" or rational part of reality which is the most valuable. Such a view is, of course, compatible with most ontological theories.

(5) The next ontological problem concerns the mode of interrelation between the various parts or modes or units of reality. Is each in turn absolutely determined by the others, or is there room in this universe for a measure of what is variously called spontaneity, novelty, originality, freedom or self-determination? The Mechanistic theory, or simply "Mechanism," is the view that the world is a "block-universe," in which everything is once for all causally predetermined, so that a sufficiently clever demon could accurately read the future and the past from the present condition of things. Such a view is usually linked with Materialism, though it may also be found in conjunction with other ontological theories. The opposed views are variously named according to the different points which are especially stressed. The philosophy of *Creative Evolution* (Bergson) and the theory of *Emergence* (Lloyd Morgan and Alexander) lay stress on the originality of natural events and on the utter impossibility of anticipating the character of most results from a mere knowledge of the laws of matter and motion—especially so in the case of vital phenomena and the higher activities of human beings. *Teleology* vindicates the reality of purposiveness in Nature—the direction of processes to the realization of certain ends in front of them, as distinguished from their determination entirely by mechanical forces behind them, and *Libertarianism* is the view which vindicates more particularly the freedom of man's will. An extreme form of anti-Mechanism is known as *Tychism*, according to which everything just happens by chance. The view which upholds "Necessity" in Nature is in one of its forms at least (Spinoza, for example) essentially a denial of Tychism and a defence of the prevalence of law and order throughout the universe, without, however, denying the reality of freedom as self-determination. Such *"Necessitarianism"* must be distinguished from Mechanism and its offspring, Determinism.

(6) Lastly, there is the question whether there is anything in the universe which may be called divine. *Atheism* gives a negative answer to this question. The principal forms which the affirmative answers assume are known as Theism, Deism and Pantheism respectively; there are also less articulate forms. *Theism* is the belief in a personal God, the Creator in some sense of Nature and Man, distinct from both yet in some ways in or near them. *Deism* and *Pantheism* endeavour to avoid the anthropomorphic tendencies of Theism by conceiving God as impersonal or, more correctly, as supra-personal. But whereas Deism, like Theism, separates God from the world, Pantheism identifies them—"the One and All" is at once God and the universe. All the historic churches are theistic; many of the so-called freethinkers of the 17th and 18th centuries were deists; the leading Stoics, in ancient times, and Spinoza, in modern times, are among the classical pantheists. Materialism is usually associated with Atheism. Other forms of Monism usually tend towards Pantheism. Idealistic Pluralism is usually associated with Theism. Other forms of Pluralism may be either theistic or deistic, but as a matter of fact are mostly theistic.

METAPONTUM, ancient city, Magna Graecia (Gr. Μεταπόντιον, mod. Metaponto), on the Gulf of Tarentum, near the mouth of the river Bradanus, about 24 m. from Tarentum and 13 m. from Heraclea. It was founded by an Achaean colony from Sybaris and Croton about 700 B.C. At Metapontum Pythagoras died in 497 B.C. His tomb was still shown in the time of Cicero.

Its support of the Athenian expedition to Sicily (415 B.C) was trifling. In 332 B.C. it allied itself with Alexander of Epirus. After the battle of Cannae (216 B.C.) it declared in favour of Hannibal, and became his headquarters. After the defeat of Hasdrubal at the Metaurus (207 B.C.), the inhabitants of Metapontum followed him in his retreat. From this time the city sank; Pausanias says that a theatre and the walls alone remained.

Metapontum has the remains of two temples, both of 510–480 B.C. One of them, which was probably dedicated to Apollo Lycius, was a peripteros, decorated with finely painted terra-cottas, measuring 186 by 91¾ ft., of which only the foundations are left. The capitals were 3⅓ ft. in diameter. Of the other temple, the so-called Tavole Paladine, outside the area of the ancient city, a peripteros with 6 columns, 3⅓ ft. in diameter, in front, and 12 at the sides; 15 columns are standing, with the lower portion of the epistyle. It measured 105 ft. by 49 ft. without the steps. There are also traces of the town walls. An archaic treasure-house dedicated at Olympia by the people of Metapontum has been discovered there. The railway station is the junction of the line from Battipaglia (and Naples) with that from Taranto to Reggio.

METASOMATISM, in petrology a process of alteration of rocks which involves enrichment of the rock by new substances introduced from without (μετά, change, σῶμα, body). Substances originally present are partly or wholly removed in solution, the newly introduced material entering as gas or in aqueous solution. Usually the enrichment takes place by definite chemical reactions, but this is not always so; the conversion of limestone into siliceous chert though recognized as a metasomatic process is not directly governed by any definite chemical reaction. Precipitation of material may result from changes in solution rendering insoluble a substance foreign to the mineral acted upon. Replacement may be partial or complete, with or without preservation of original structures and textures. Metasomatic processes take place over a wide range of temperatures and pressures and may be accompanied by a volume change; in general they obey the law of mass action, and in order to effect replacement the

introduced solutions must attain a minimum concentration.

This minimum concentration of solutions or minimum vapour pressure in the case of gas reactions varies both with different reactions and the temperatures and pressures at which the replacement is effected. Among the common examples of metasomatism may be noted the dolomitization and conversion into siderite of iron oxides of limestones. Phosphatization of limestones is a further example. These replacements probably take place at low temperatures, as do also the metasomatic changes in salt deposits, such as the conversion of anhydrite into glauberite or polyphalite (*see* PNEUMATOLYSIS).

Metasomatism is widespread in silicate rocks and is especially characteristic of contact zones of igneous intrusions. These replacements affect, however, not only the intruded rocks but also the crystallized magma from which the emanations are derived. Metasomatism involving addition of alkalis is represented by such processes as albitization, analcitization and the formation of felspar in certain contact zones of injected rocks.

The production of tourmaline, topaz and lithra-mica as seen in tourmaline and topaz-hornfelses, greisens, etc., is a metasomatic process involving enrichment of the rocks in boron, fluorine and lithium. Similarly the formation of chloride-marialite (scapolite) at the expense of felspars, serpentine from olivine, sericitization of felspars and felspathoid minerals are common examples of metasomatism occurring around igneous intrusions.

Many ore deposits and the regions in their vicinity show evidences of widespread chemical replacement leading to enrichment, as in sulphide deposits.

Limestones are particularly prone to metasomatic alteration. Their conversion to dolomite, siderite and iron oxide has already been referred to. Around igneous contacts they are not infrequently locally changed to andradite garnet or hedenbergite rocks, processes involving great enrichment in iron and silica. These garnet and pyroxene rocks are known as "skarns." Probably iron is introduced in the gaseous form as fluoride or chloride.

Valuable ore deposits are frequently associated with rocks of this character. In many parts of western North America (Nevada, Arizona, etc.), great deposits of copper, lead and silver ores are worked in crystalline limestones and are often clearly replacement products of the limestones themselves. The constant presence of igneous rocks in their vicinity indicates that they are connected with the introduction of the metals, and the deposits are often of such a kind as to show that post-volcanic discharges or magmatic gases and water were the mineralizing agents.

(C. E. T.)

METASTASIO (1698–1782). Pietro Trapassi, Italian poet, better known by his assumed name of Metastasio, was born in Rome on Jan. 13, 1698. His father, Felice Trapassi, a native of Assisi, who had served in the Corsican regiment of the papal forces, kept a grocer's shop in the Via dei Cappellari.

In 1709, Gian Vincenzo Gravina and Lorenzini, a critic of some note, heard the boy improvising verse to a crowd in the street. Gravina adopted him, hellenized his name into Metastasio; and gave him a good education. Metastasio soon found himself competing with the most celebrated improvvisatori of his time in Italy, and almost wrecked his health. Gravina had the good sense to place the boy in a quiet seaside place in Calabria.

At the age of twelve Metastasio translated the *Iliad* into octave stanzas; and two years later he composed a tragedy in the manner of Seneca upon a subject chosen from Trissino's *Italia liberata*—Gravina's favourite epic. In 1718 Gravina died leaving his protégé a fortune. Metastasio was now twenty and an abbé. In two years, having spent his money, he apprenticed himself to a lawyer in Naples. He composed an epithalamium, and his first musical serenade, *Endimione*, on the occasion (1721) of the marriage of his patroness the Princess Pinelli di Sangro to the Marchese Belmonte Pignatelli. In 1722 the viceroy asked Metastasio to compose a serenata for the empress's birthday. He produced *Gli orti esperidi*. It was set to music by Porpora, and the great Roman prima donna, Marianna Bulgarelli, called La Romanina from her birthplace, played the part of Venus. La Romanina forthwith took possession of Metastasio, and in her house he became acquainted with the greatest composers of the day—with Porpora, from whom he took lessons in music; with Hasse, Pergolese, Scarlatti, Vinci, Leo, Durante, Marcello, all of whom were destined in the future to set his plays to melody. Here too he studied the art of singing, and won the friendship of the great singer Carlo Broschi (*see* FARINELLI). His plays, while beautiful in themselves, judged merely as works of literary art, became masterpieces as soon as their words were set to music which justified the conventionality of his plots, the absurdities of his situations, the violence he does to history in the persons of some leading characters and his "damnable iteration" of the theme of love in all its phases.

Metastasio resided with La Romanina and her husband in Rome. The generous woman took the whole Trapassi family—father, mother, brother, sisters—into her own house. She fostered the poet's genius and pampered his caprices. Under her influence he wrote from 1721 onwards in rapid succession the *Didone abbandonata Catone in Utica, Ezio, Alessandro nell' Indie, Semiramide riconosciuta, Siroe* and *Artaserse*. But she was growing older; she had ceased to sing in public; and the poet felt himself more and more dependent in an irksome sense upon her kindness. He gained 300 scudi (about £60) for each opera; this pay, though good, was precarious, and in Sept. 1729 he accepted the offer of the post of court poet to the theatre at Vienna, with a stipend of 3000 florins. La Romanina took charge of his family in Rome, and in the summer of 1730 Metastasio settled at Vienna in the house of a Spanish Neapolitan, Niccolò Martinez, where he resided until his death. Between the years 1730 and 1740 his finest dramas, *Adriano, Demetrio, Issipile, Demofoonte, Olimpiade, Clemenza di Tito, Achille in Sciro, Temistocle* and *Attilio Regolo*, which he himself considered his masterpiece, were produced for the imperial theatre. Poet, composer, musical copyist and singer did their work together in frantic haste. Metastasio understood the technique of his peculiar art in its minutest details. Metastasio's *liaison* with the Countess Althann, sister-in-law of his old patroness the Princess Belmonte Pignatelli, became so close that it was even believed they had been privately married. In 1734 La Romanina asked Metastasio to get her an engagement at the court theatre, but he did not want her in Vienna. The tone of his letters alarmed and irritated her. It is probable that she set out from Rome, but died suddenly upon the road. She left him her fortune after her husband's life interest in it had expired, but Metastasio renounced the legacy.

Metastasio's later cantatas and the canzonet *Ecco quel fiero istante*, which he sent to his friend Farinelli, rank among his popular productions. In 1755 the Countess Althann died, and Metastasio was more than ever reduced to the society which gathered round him in the bourgeois house of the Martinez. He died on April 12, 1782. During the long period of 40 years in which Metastasio outlived his originality and creative powers his fame went on increasing. In his library he counted as many as 40 editions of his own works. They had been translated into French, English, German, Spanish, even into modern Greek. But with the changes effected by Gluck and Mozart, with the development of orchestration and the rapid growth of the German manner, a new type of libretto came into request. Metastasio's plays fell into undeserved neglect. Farinelli, whom he styled "twin-brother," was the true exponent of his poetry; and, with the disappearance of the school to which Farinelli belonged, Metastasio's libretti suffered eclipse. Collected editions of Metastasio's works published at Genoa (1802) and Padua (1811) will probably be found most useful by the general student. An edition of the letters, by Carducci, was published at Bologna in 1883. Metastasio's life was written by Aluigi (Assisi, 1783); by Charles Burney (1796); and by others; but the most vivid sketch is in Vernon Lee's *Studies of the 18th Century in Italy* (1880).

METAURUS (Mod. Metauro), a river of Italy which flows into the Adriatic a little south-east of Fanum Fortunae (mod. Fano). In 207 B.C. (*see* PUNIC WARS and HANNIBAL) Hasdrubal had marched from Placentia to the aid of his brother Hannibal, and, on reaching the Cesano, the next stream south of the Metaurus, halted and encamped. The forces of Livius Salinator and the praetor Porcius Licinus, the latter of whom had previously

been watching his movements, were encamped near Sena Gallica (mod. Sinigaglia) only about half a mile away from him (no doubt on the opposite bank of the Cesano). He was about to attack them, when he discovered that the other consul, Nero, who had been watching Hannibal's movements at Canusium had brought his army to swell the Roman forces, having, as a fact, intercepted Hasdrubal's message to Hannibal that he would meet him "in Umbria" *i.e.* at this very place—for the name Umbria extended to the coast before the time of Augustus. Hasdrubal then attempted to retreat to the Metaurus and cross it, but his guides deserted him, and he was unable to hit on the ford without them; he then marched up the tortuous stream to find another, but had only reached the hills of Sant Angelo, some two or three miles from the coast, where he tried to pitch his camp, when he found the Romans, who had started their pursuit at dawn, too close on his heels, and was obliged to halt and give battle. His left wing was protected by the terrain, but there was room for fighting on the right, where he drew up his Spanish troops in deep formation, with his ten elephants in front of them, taking position himself in the centre. He then attacked the advancing Romans and the clash was a violent one; but the fighting was indecisive, until Nero, who at first remained inactive on the right wing, with a deep streambed in front of him, decided to pass behind Livius' position and advance on his left, thus taking the enemy on their right flank; the distance he had to traverse was less than a mile, and the move was a decisive one. Hasdrubal, who had seen that he must win or perish, sought and found the death of a hero. Livy's statement that 56,000 of his army fell and only 5,400 prisoners were taken, is probably an exaggeration; and if we reckon his whole force very roughly at 30,000, we may accept Polybius' figure of 10,000 killed, and assume 10,000 prisoners; while the other third of the army, the Gauls and Ligurians, who had either taken no part in the battle or escaped, was allowed to make off undisturbed. The defeat ended Hannibal's hopes of success in Italy.

See Kromayer, *Antike Schlachtfelder* iii. 1. (1912) 424 *sqq.* for an authoritative treatment of the whole question. (T. A.)

METAXAS, ANDREAS (1786–1860), Greek politician, was born in the island of Cephalonia. When Capo d'Istria was murdered in 1831 Metaxas, who had been war minister, became a member of the provisional government which held office till the accession of King Otho in 1833. He subsequently represented Greece at Madrid, Lisbon and Constantinople, with an interval (1843–44) in which he was premier. He died at Athens on Sept. 19, 1860.

METAYAGE SYSTEM. The cultivation of land for a proprietor by one who receives a proportion of the produce. The system has never existed in England and has no English name, but in certain provinces of Italy and France it was once almost universal, and is still very common. It is also practised in the United States, in Portugal, in Greece, and in the countries bordering on the Danube. In Italy and France, respectively, it is called *mezzeria* and *metayage,* or halving—the halving, that is, of the produce of the soil between landowner and landholder. These expressions merely signify that the produce is divisible in certain definite proportions, which must obviously vary with the varying fertility of the soil and other circumstances. Sometimes the landlord supplies all the stock, and sometimes only part—the cattle and seed perhaps, while the farmer provides the implements; or perhaps only half the seed and half the cattle, the farmer finding the other halves—taxes too being paid wholly by one or the other, or jointly by both.

English writers were unanimous, until J. S. Mill adopted a different tone, in condemning the metayer system. They judged it by France where under the *ancien régime* all direct taxes were paid by the metayer, the noble landowner being exempt, which taxes, being assessed according to the visible produce of the soil, operated as penalties upon all endeavours to increase output. Also, there was no fixity of tenure without which metayage cannot prosper. French metayers in Arthur Young's time were "removable at pleasure, and obliged to conform in all things to the will of their landlords," and so in general they are still. Yet even in France, although metayage and extreme rural poverty usually coincide, there are provinces where the contrary is the fact, as it is also in Italy. Indeed, Lombardy is a triumphant vindication of metayage in the abstract. The contrasts may be explained. Metayage, to be a success, must be a genuine partnership, one in which there is no sleeping partner, but in the affairs of which the landlord, as well as the tenant, takes an active part.

In France there is also a system termed *metayage par groupes,* which consists in letting a considerable farm, not to one metayer, but to an association of several, who work together for the general good, under the supervision either of the landlord himself, or of his bailiff. This arrangement avoids the difficulty of finding tenants possessed of capital enough for any but very small farms.

See further LAND TENURE and the section *Agriculture* in the articles FRANCE, GREECE, ITALY, etc.; and consult J. Cruveilhier, *Étude sur le metayage* (Paris, 1894).

METAZOA, a zoological term, the equivalent of the old Enterozoa (*q.v.*) for all animals other than Protozoa (*q.v.*). The sponges are also sometimes separated from this group and termed Parazoa. Metazoa are multicellular animals with at least two cell-layers and one or more body-cavities. (*See* ZOOLOGY).

METCALF, WILLARD LEROY (1858–1925), American artist, was born in Lowell (Mass.), on July 1, 1858. He was a pupil of the Boston Normal Art school, of the Boston Art Museum school, and of the Académie Julien, Paris. After early figure painting and illustration, he became prominent as a landscape painter. He was one of the "Ten American Painters" who in 1897 seceded from the Society of American Artists. For some years he was an instructor in the Woman's Art school, Cooper Union, New York, and in the Art Students' League, New York. He died in New York city on March 9, 1925.

METCALFE, CHARLES THEOPHILUS METCALFE, BARON (1785–1846), Indian and colonial administrator, was born at Calcutta on Jan. 30, 1785. Having been educated at Eton, in 1800 he sailed for India as a writer in the service of the East India Company. Four years later, he was appointed political assistant to General Lake, who was conducting the final campaign of the Mahratta war against Holkar. In 1808 he became envoy to the court of Ranjit Singh at Lahore, where in April 1809, he concluded the treaty securing the independence of the Sikh states between the Sutlej and the Jumna. Four years afterwards he was made resident at Delhi, and in 1819 appointed secretary in the secret and political department. In 1822 he succeeded his brother in the baronetcy, and in 1827 obtained a seat in the supreme council. In March 1835, after he had acted as the first governor of the proposed new presidency of Agra, he provisionally succeeded Lord William Bentinck in the governor-generalship. His liberation of the press so complicated his relations with the directors that he resigned the service of the Company in 1838. In the following year he became governor of Jamaica, where the difficulties created by the recent passing of the Negro Emancipation Act called for tact. Ill health compelled him to return to England in 1842, but six months afterwards he was appointed governor-general of Canada. He was raised to the peerage in 1845. He died at Malshanger, near Basingstoke, on Sept. 5, 1846.

See J. W. Kaye, *Life and Correspondence of Charles Lord Metcalfe* (1854), and *Selections from Lord Metcalfe's Papers* (1855); also Wakefield's paper, *Sir Charles Metcalfe in Canada,* reprinted in E. M. Wrong's *Charles Butler and Responsible Government* (Oxford 1926).

METCHNIKOV, ILYA: *see* MECHNIKOV, ILYA.

METELLUS, the name of a distinguished family of the Caecilian (plebeian) gens at Rome. The most important individuals are given separate notices below. For their history *see* M. Wende, *De Caeciliis Metellis* (Bonn, 1875); P. Gröbe's edition of Drumann's *Geschichte Roms,* ii.; and the article "Caecilius" in Pauly-Wissowa's *Realencyklopädie.*

METELLUS, LUCIUS CAECILIUS, general during the first Punic War. Consul in 251 B.C., he was sent to Sicily, and gained a decisive victory over Hasdrubal, who had the larger force. Metellus's victory was in great measure due to a panic caused amongst the Carthaginian elephants by his clever manoeuvring. A number of them figured in his triumph, and from this time the elephant frequently occurs on the coins of the Metelli. The story

that in 241 he rescued the Palladium from a fire in the temple of Vesta at the cost of his eyesight is not to be found in the extract from his funeral oration in Pliny (*Nat. Hist.* vii. 43 [45]).

METELLUS, QUINTUS CAECILIUS, son of Lucius Caecilius Metellus, became consul in 206 B.C. as a reward for his services at the Metaurus. In 205 he was dictator for holding the comitia; in 201 one of the commissioners for dividing the public land in Samnium and Apulia amongst the Roman veterans; in 186 he conducted an embassy to Macedonia, afterwards proceeding to Peloponnesus to investigate the quarrel between Sparta and the Achaeans. He is the Metellus who caused the poet Naevius (*q.v.*) to be imprisoned and exiled for having attacked him on the stage.

METELLUS CELER, QUINTUS CAECILIUS, legate of Pompey in Asia 65 B.C., praetor 63, was despatched to cut off the retreat of Catiline to the north by blocking the passes, and in 62 went into the province of Cisalpine Gaul with the title of proconsul, although he did not become consul till 60. A supporter of the optimates and an enemy of Pompey, he successfully opposed the agrarian law that was to provide for Pompey's veterans. He also tried, though fruitlessly, to obstruct Caesar's agrarian law in 59. He died suddenly in the same year—it was usually supposed from poison administered by his wife Clodia.

METELLUS CRETICUS, QUINTUS CAECILIUS, Roman general. Consul in 69 B.C., he was appointed to the command of the war against Crete, the headquarters of the pirates of the Mediterranean. In 67 Pompey demanded the control of the campaign under the Gabinian Law. The Cretans offered to surrender to Pompey, who instructed Metellus to cease operations. Metellus refused, and himself annexed the island. His triumph was delayed by Pompey's partisans, and he joined the opposition in the Senate and helped to defeat the ratification of Pompey's Asiatic settlement. He was one of a commission of three sent (60) to investigate the state of affairs in Gaul where disturbances were apprehended. He appears to have been alive in 54.

METELLUS MACEDONICUS, QUINTUS CAECILIUS (d. 115 B.C.), praetor 148 B.C., defeated the usurper Andriscus (*q.v.*) in Macedonia and forced him to surrender. Under his superintendence the country was made a Roman province. In 146, he attacked the Achaeans to avenge an insult offered to a Roman embassy at Corinth. He was superseded during a successful campaign by L. Mummius. On his return to Italy he received a triumph and the title of *Macedonicus.* Consul in 143, he subdued the Celtiberians in northern Spain. In 131, when censor with Q. Pompeius (they were the first two plebeian censors), he proposed that all citizens should be compelled to marry. He was an opponent of the Gracchi, although not averse from moderate reform. He built a colonnade in the Campus Martius, and two temples dedicated to Iuppiter Stator and Juno.

METELLUS NUMIDICUS, QUINTUS CAECILIUS, consul 109 B.C. and commander in the Jugurthine War, defeated Jugurtha (*q.v.*) by the river Muthul, and after a difficult march through the desert took his stronghold, Thala. Marius had him superseded, and himself received the command for the next year. Metellus received a triumph and the title of *Numidicus.* Saturninus, whom as a censor he tried to remove from the senate, passed in 100 B.C. an agrarian law, inserting a provision that all senators should swear to it within five days. All complied but Metellus, who retired to Asia. After Saturninus was killed he returned, and died (probably in 91). He was one of the chief leaders of the aristocratic party. Cicero speaks highly of him as an orator.

METELLUS PIUS, QUINTUS CAECILIUS, son of Numidicus, was one of the commanders in the Social War, and defeated Q. Pompaedius Silo, the Marsian leader (88 B.C.). Sulla, on his departure for Asia, gave him proconsular command over south Italy. When Marius returned to Italy and joined Cinna, the soldiers wished Metellus to take command, but he refused. The soldiers deserted in large numbers, and Metellus retired to Africa and afterwards to Liguria, resuming his proconsular command on Sulla's return. In the war against Marius he gained several important successes, and after his victory over C. Norbanus at Faventia (82) he subdued the whole of upper Italy. Consul in 80 with Sulla, he went to Spain next year against Sertorius, who pressed him hard till the arrival of Pompey in 76. Next year Metellus defeated Sertorius's lieutenant Hirtuleius at Italica and Segovia, and joining Pompey rescued him from the consequences of a check at Sucro. In 71 Metellus returned to Rome and triumphed. He became pontifex maximus, and died probably at the end of 64.

METELLUS PIUS SCIPIO, QUINTUS CAECILIUS, son of P. Scipio Nasica, was adopted by Metellus Celer. He was accused of bribery in 60 B.C., and defended by Cicero. In August 52, he became consul through the influence of Pompey, who had married his daughter Cornelia. In 49 he proposed that Caesar should disband his army within a definite time, under pain of being declared an enemy of the state. His first command during the civil war was the province of Syria. He commanded the centre at Pharsalus, and afterwards went to Africa, where by Cato's influence he received the command. In 46 he was defeated at Thapsus; while endeavouring to escape to Spain he fell into the hands of P. Sittius, and put himself to death.

METEMPSYCHOSIS. The theory of the transmigration of souls is usually associated with the ancient Egyptians, who are said to have practised embalming to prevent or delay reincarnation; with the teaching of Pythagoras and the Buddha (*q.v.*); and was also held by a sect of early Christian heretics spoken of by Jeremy Collier as "Metempsychi." The idea, however, much older than any of these creeds, exists throughout the world. Where the passage of the soul, or the vital essence, into some particular form is associated, as by the Garos of Assam, with ideas of retribution for the sins or accidents of this life, the influence of Buddhism or Hinduism has probably been at work. The primitive idea, independent of moral teaching, is bound up with the conception of an objective soul, and often with ideas as to a plurality of souls in a single individual, one of which is separable and able to go in and out through the mouth or nostrils. Thus the Poso-Alfures of Celebes believe in three souls, the *inosa* or vital principle, the *angga,* or intellectual, and the *tanoana* or divine element which leaves during sleep, and which is of the same nature in many plants and animals. This separable soul is clearly a conception based on the phenomena of dreams taken to be actual experiences undergone during sleep, and postulating some sort of embodiment able to roam while the body sleeps. This soul must be small enough to leave by the mouth, and it appears as a manikin in India and in Celebes, as a snake, a weasel or a mouse, in Germany, or as an insect in further India. Thus the soul is commonly spoken of as "flying" in Greek, and represented as a butterfly, as, indeed, all over Europe, from Ireland to Lithuania, in China, Assam, Burma, Japan, and the Pacific. So, too, the soul appears as a bird—in Europe the dove is the commonest and poles bearing pigeons were erected over Lombard graves; but the soul also appears in the form of ducks, ravens, owls or hawks, and as a hawk again it appears in Egypt and in Assam.

This belief in a separable soul with an insect or other form must obviously influence beliefs in the eschatology of the soul. We find accordingly that the soul is believed to pass into an insect on the decease of the body. Thus the Angami Naga credits the soul with a number of subsequent existences in insect form, while the Chang holds that the souls of those who can sing become cicadas, but the souls of others dung beetles. Thus the Bakongs of Borneo believe that their dead are reincarnated in the bear-cats which frequent their raised coffins; wood-boring wasps and hornets take up their abode in the wooden soul figures put up by some tribes of Assam, and we find Nagas and Lusheis regarding wasps and hornets (among other insects) as souls.

If the soul can leave an individual during sleep and re-enter him, it should be able to enter and be reborn in another individual. In Germany, a dying man's heart passes into his brother, whose courage is doubled; in the Garo hills the soul, after a sojourn in the abode of the dead, returns for another incarnation. The range of this conception of reincarnation is indicated by the frequency of tabu on giving children names already borne by living members of the family. (*See* NAMES.) The notion is that identity of name implies identity of personality and that one of

the two bearers would die. Hence the Lhotas, for instance, never give the child the name of a living relative. A belief in reincarnation within the family would naturally be strengthened by the recurrence of marked family resemblances. In any case a belief in the reincarnation of human souls is indicated by such rites as those of the Akikuyu women of East Africa, who, in order to have children, worship at a *ficus* tree inhabited by the souls of the dead, or of the Konyak Nagas of Assam, who perform ceremonies over phallic cists containing skulls of deceased persons, in order to secure a birth of corresponding sex to that of the skull.

Reincarnation is not confined to animal forms. The stories of trees that grow up from the graves of lovers, such as Tristram and Iseult, and twine themselves together are familiar in Europe; and the human soul also reappears in a flower growing on the grave. In the case of flowers springing from drops of blood, as from that of Ajax, the soul is possibly regarded as located actually in the blood itself. In further Asia and elsewhere the soul goes into the crops, and by preserving the corpse, which is smoke-dried, funeral ceremonies are accommodated to the agricultural year, so as to afford the crop the full benefit of the soul matter from those who have died recently; and in the case of the Karens of Burma a specific theory is evolved of a cycle of life on these lines. (*See* HEAD-HUNTING.) The Lushei theory that the soul takes the form of dew and is reincarnated in the body on which it descends, may be a version of the Karen theory.

The idea of transmigration has been influenced and inevitably confused by ideas as to the external soul, generally associated with magicians, where the vital principle depends on a soul kept in an animal in the forest, or in an egg below the sea, etc., which has to be secured before the magician can be killed, by ideas as to totemism and lycanthropy (*qq.v.*), and beliefs in the reincarnation of the soul in predatory forms such as tigers (India and Sumatra), sharks (Melanesia), or alligators (Africa), have perhaps arisen in connection with those ideas.

HISTORICAL ASPECT

Metempsychosis is also important to philosophic thought. Apparently, Greece did not borrow the doctrine from Egypt or India but used savage ideas for religious and philosophic purposes. The Orphic religion, which held it, first appeared in Thrace upon the semi-barbarous north-eastern frontier. Orpheus, its legendary founder, is said to have taught that "soul and body are united by a compact unequally binding on either; the soul is divine, immortal and aspires to freedom, while the body holds it in fetters as a prisoner. Death dissolves this compact, but only to re-imprison the liberated soul after a short time: for the wheel of birth revolves inexorably. Thus the soul continues its journey, alternating between a separate unrestrained existence and fresh reincarnation, round the wide circle of necessity, as the companion of many bodies of men and animals. To these unfortunate prisoners Orpheus proclaims the message of liberation, that they stand in need of the grace of redeeming gods and of Dionysus in particular, and calls them to turn to God by ascetic piety of life and self-purification: the purer their lives the higher will be their next reincarnation, until the soul has completed the spiral ascent of destiny to live for ever as God from whom it comes." Such teaching appeared in Greece about the 6th century B.C., organized itself into mysteries at Eleusis and elsewhere, and produced a copious literature.

The earliest Greek thinker with whom metempsychosis is connected is Pherecydes; but Pythagoras, who is said to have been his pupil, is its first famous philosophic exponent. Pythagoras probably made his reputation by bringing Orphic doctrine from North-eastern Hellas to Magna Graecia.

The importance of metempsychosis is due to Plato. In the eschatological myth which closes the *Republic* he tells the story how Er, the son of Armenius, miraculously returned to life on the twelfth day after death and recounted the secrets of the other world. There are theories to the same effect in other dialogues, the *Phaedrus, Meno, Phaedo, Timaeus* and *Laws*. In Plato's view the number of souls was fixed; birth therefore is never the creation of a soul, but only a transmigration from one body to another. Plato's acceptance of the doctrine is characteristic of his sympathy with popular beliefs and desire to incorporate them in a purified form into his system. Aristotle, a far less emotional and sympathetic mind, has a doctrine of immortality totally inconsistent with it. In later Greek literature the doctrine appears from time to time; it is mentioned in a fragment of Menander (the *Inspired Woman*) and satirized by Lucian (Gallus § 18 *seq.*). In Roman literature it is found as early as Ennius, who in his Calabrian home must have been familiar with the Greek teachings which had descended to his times from the cities of Magna Graecia. In a lost passage of his *Annals*, a Roman history in verse, Ennius told how he had seen Homer in a dream, who had assured him that the same soul which had animated both the poets had once belonged to a peacock. Persius in one of his satires (vi. 9) laughs at Ennius for this: it is referred to also by Lucretius (i. 124) and by Horace (*Epist. II.* i. 52). Virgil works the idea into his account of the Underworld in the sixth book of the *Aeneid* (vv. 724 *sqq.*). It persists in antiquity down to the latest classic thinkers, Plotinus and the other Neoplatonists.

Attempts have been made with little success to find metempsychosis in early Jewish literature. But there are traces of it in Philo, and it is definitely adopted in the Kabbala. Within the Christian Church it was held during the first centuries by isolated Gnostic sects, and by the Manichaeans in the 4th and 5th centuries, but was invariably repudiated by orthodox theologians. In the middle ages these traditions were continued by the numerous sects known collectively as Cathari. At the Renaissance we find the doctrine in Giordano Bruno, and in the 17th century in the theosophist van Helmont. A modified form of it was adopted by Swedenborg. During the classical period of German literature metempsychosis attracted much attention: Goethe played with the idea, and it was taken up more seriously by Lessing, who borrowed it from Charles Bonnet, and by Herder. It has been mentioned with respect by Hume and by Schopenhauer. Modern theosophy, which draws its inspiration from India, has taken metempsychosis as a cardinal tenet; it is, says a recent theosophical writer, "the master-key to modern problems," and among them to the problem of heredity. (H. ST.)

BIBLIOGRAPHY.—A. Bertholet, *The Transmigration of Souls* (trans. from the German by H. J. Chaytor); E. Rohde, *Psyche*.

METEOR, a term used by the Greeks to denote atmospheric phenomena in general, such as clouds, halos, rainbows, etc., as well as shooting stars (Gr. μετέωρα, literally "things in the air," from μετά, beyond, and ἀείρειν, to lift up). This usage survived even into older English literature. To-day the term meteor is restricted to those cosmical bodies which, entering the earth's atmosphere from without and shooting across the sky, give the appearance of a star in rapid motion, often leaving a bright train behind. (*See* METEORITE.)

As indicated by the name, in ancient times meteors were considered to be atmospheric in origin and hence not cosmical bodies. It is true that accounts of the fall of stones from the sky are found in Chinese and classical literature, running back 2,600 years. The Chinese also recorded single brilliant meteors as well as showers of shooting stars. In Europe many of these latter have also been recorded for the past 1,500 or more years. But not until 1803 were contemporary scientists convinced that meteorites came from space, and not until 1833 was it proved that ordinary meteors or shooting stars also had a cosmical origin. From then on they have been considered true astronomical bodies. In ancient and mediaeval times the passage of a brilliant fireball or fall of a meteorite was considered an omen, and viewed with superstitious dread. Great meteoric showers filled mankind with terrible fear, and in 1833 it is certain that the ignorant thought the end of the world had come. To-day such phenomena are viewed with keen delight and every effort is made to observe them in the interest of science.

Beginning of Systematic Study.—The study of meteors started in 1833. On Nov. 13 of that year there occurred a meteoric shower of the greatest brilliance that was seen from all parts of

eastern North America. It was estimated that more than 200,000 shooting stars were seen at one place between midnight and dawn. Many of the meteors were very bright, leaving persistent trains, yet there was no record of one of them having reached the earth.

Several men who observed this shower noted that the meteors seemed all to shoot out or radiate from a certain fixed point, that happened to be in the constellation Leo. This point is known as the radiant, and the meteors as Leonids. It was soon proved that the radiant was merely the direction in space from which the Leonids came, and, as this radiant was in the same position as seen from many widely separated places, the Leonids must come from without our atmosphere. The radiant is an effect of perspective, due to the meteors actually moving in practically parallel straight lines when they meet the earth. An excellent illustration is the effect when the sun's rays are seen shining through spaces between clouds. The rays are parallel, yet they appear to radiate.

Early Theories.—These discoveries were the foundation of meteoric astronomy. It was later found that the Leonids revolved around the sun in a period of 33 years, and a search of ancient documents showed records of brilliant showers coming in October or November extending back to A.D. 902. In 1866 the further notable discovery was made that the orbit of the Leonids was practically coincident with that of Tempel's Comet. A similar connection between the Perseid meteors, which come to a maximum in every August, and Tuttle's Comet had just been shown. One case might be a coincidence, two could hardly be. The intimate connection between comets and meteor streams was thus established. Soon after similar connections were found between the Lyrids of April and Comet 1861 I, and the Andromedes of late November and Biela's Comet. In recent years a few more have been found, the most notable being those between Halley's Comet and the May Aquarids, and Pons-Winnecke's Comet and a shower that came to a maximum late in June, 1916.

For many years the discovery of these intimate connections led astronomers to believe that most, if not all, meteors were merely the débris of comets, and hence originated in our Solar System. Strong evidence has, however, been accumulating that this view is only partially correct, and that a very large percentage of all classes of meteors must come to us from the depths of space and hence have originated elsewhere. It has been proved that a body, falling from rest at an infinite distance from the sun towards it, would move with a velocity of 26m. per second as it passed the earth's orbit. This is called the parabolic velocity. In general if a meteor has a heliocentric velocity of less than this value, then it originated in our system; if a greater, then in some other stellar system. The observing of such velocities, with a high degree of accuracy, is a most difficult problem, and the whole future of meteoric astronomy must rest largely upon its successful solution. The difficulty is due to the visible life of the average meteor lasting much less than one second. Velocities in our atmosphere as low as 8m. per second and as high as 50m. per second have been observed.

The Leonids.—The Leonids being the best known of all meteor streams, their history will be briefly traced. The following table gives the dates of appearances of bright showers:

902 Oct. 13	1101 Oct. 17	1602 Oct. 27	1833 Nov. 13
931 Oct. 14	1202 Oct. 19	1698 Nov. 9	1866 Nov. 14
934 Oct. 14	1366 Oct. 23	1799 Nov. 12	1867 Nov. 14
1002 Oct. 14	1533 Oct. 24	1832 Nov. 13	1868 Nov. 14
			1901 Nov. 15

It is apparent that while the showers certainly come at intervals of about 33 years, still there are long gaps. These may be explained in two ways; first that no record survives due to mere chance, second that the meteor stream missed the earth in these years. A fine return was hoped for in 1899, but very few Leonids were seen. It was, however, proved that the main group of Leonids, which normally would have met the earth in November 1899, had passed near the giant planet Jupiter *en route* towards us, and so had been switched aside somewhat by its attraction. This caused them to miss the earth. By the time the part of the stream that met us in 1901 passed Jupiter's orbit, the planet had passed on too far to disturb appreciably these meteors, so they appeared in considerable numbers. Indeed a few Leonids are met every November, so some must be scattered all around their orbit, but the dense part that can give us a really fine shower is condensed into a relatively small part of the whole circumference.

That the Leonids are not yet uniformly distributed, but are mostly included in a small group, seems to prove that they were comparatively recently turned into their present orbit. Uranus has been credited with having accomplished this in A.D. 126. It is impossible as yet to predict the chances for another great shower in 1932–34.

Biela's Comet suddenly divided into two parts in 1845. On its next return in 1852 the two parts were seen to be about equally bright and were a million miles apart. The comet was not found at the predicted return of 1859 or 1866, but on Nov. 27, 1872, a splendid display of meteors was seen. Calculation showed that these Andromedes, as they are now called, followed the same orbit as the lost comet which had had a period of $6\frac{2}{3}$ years. Another fine display, notable in that during it a piece of meteoric iron fell at Mazapil in Mexico, occurred on Nov. 27, 1885, and another lesser one on Nov. 23, 1892. On Nov. 24, 1899, a fair shower was seen, but, from then on, the earth has never encountered any considerable number of these meteors. Nor has Biela's Comet reappeared. Older records show showers that were probably due to this group on Dec. 6, 1741, Dec. 7, 1798 and Dec. 7, 1838. The main groups have either been broken up or switched so far from the earth's orbit that we no longer meet them.

Lyrids, Perseids and Others.—There is an annual shower of Lyrids, with a radiant near the star Vega, which in most years is inconspicuous, but occasionally abundant. For instance, on April 20, 1803, it furnished a very brilliant display, and a fair one on April 21, 1922. Ancient annals give us nine other great showers on corresponding dates, the earliest being in 687 B.C. The best known stream that is practically sure to give us a good annual display is the Perseid. These meteors, which are seen late in July and through the first half of August, have been extensively observed for the past hundred years. Their maximum comes on Aug. 11 or 12, when as many as 120 per hour sometimes may be counted. Definite daily motion of a radiant point was first proved for the Perseids. Many of these meteors leave persistent trains, and owing to their appearing in the summer for northern observers, they may be specially recommended to the amateur.

The Orionids which appear during the last half of every October, and the Geminids which appear the first half of every December, complete the list of really conspicuous meteor streams. The Orionids have been the subject of much controversy as to whether their radiant was in motion or stationary. The preponderance of evidence now points to daily motion. For the Geminids motion of the radiant has been generally conceded. At the maxima of both of these streams from 20 to 40 meteors per hour may be expected when conditions are favourable. Others worthy of mention are the Quadrantids, Jan. 1–3; the Eta Aquarids, May 1–11; and the Delta Aquarids, July 27–31. The Eta Aquarids, connected as they are with Halley's Comet, are the most important of the three.

Orbits and Perturbations.—Meteor showers cannot be expected to return an indefinite number of times. From their very nature they are not permanent, and we have already noted the case of the Andromedes, which, after furnishing several fine showers, seem to have died out, as it were. There are several known reasons for this; the most obvious that the stream misses the earth entirely, owing to its having been pulled aside by the attraction of some planet, the second that being at best a very loose aggregation of solid particles, their mutual gravitation is small. Hence when a group passes near a planet those nearest are more pulled aside by its attraction than those farther off, and as this must continually recur, eventually the group is widely scattered.

Meteor Radiants.—The possibility of a radiant remaining fixed in the same apparent place in the heavens has been seriously investigated. The existence of numerous so-called "stationary radiants" has been insisted upon by several experienced observers, and as firmly denied by many others. The reason why a radi-

ant should shift daily is, that even if all meteors from it for many days or weeks are moving in practically parallel paths, yet the earth in its orbital motion around the Sun changes its direction about 1° daily. The position of the apparent radiant depends upon the directions of motion of both earth and meteors. Hence if either changes, in general the radiant must shift. It has been proved, indeed, that a radiant, which lies near the ecliptic, can remain nearly stationary for some weeks.

The Numbers of Meteors.—It is hence impossible at present to give even an approximate estimate of how many meteor streams have so far been observed, more than to say that the number is large. Better data can be given as to hourly or monthly numbers of all meteors visible to the eye. It is found that nearly twice as many are seen per hour during the second half of the night as in the first half. Also meteors are twice as numerous from July to January as from January to July. The second phenomenon is due simply to the earth meeting more meteor streams in that part of its orbit; the first to the fact that in the evening hours the meteors must overtake the earth to become visible, while in the morning hours the meteors meet the earth head-on. Of necessity, therefore, we see more after midnight than before. From January to July, for the whole night, an hourly average of six or seven should be seen by one observer with a clear, moonless sky; from July to January an average of 12 to 15. Excluding telescopic meteors, of which there must be tens of millions, it is estimated that 20 million meteors enter our atmosphere daily, and a minimum of one meteorite per day reaches the earth's surface.

Fireballs and Bolides.—These bodies, which are merely super-meteors, owing to their larger mass, are able to penetrate lower before destruction. Also when they overtake the earth before midnight with low velocity, they sometimes have paths many hundred miles long in our atmosphere, which often do not make large angles with its surface. These circumstances permit them a relatively longer survival. Such bodies may give every variety of phenomenon mentioned above. When they come quite near the earth's surface their passage is frequently accompanied by very loud sounds, which are sometimes said to be like explosions but more properly may be compared to the "shock-wave" of a great projectile. Many compare them also to distant thunder. Such fireballs of very long paths may actually cross from horizon to horizon for one observer and pass far beyond.

The most remarkable example of this type of phenomenon is furnished by the "Meteoric Procession" of Feb. 9, 1913. This wonderful group of bright meteors or fireballs was first seen over Canada, and having travelled about 5,700 miles was last seen over the Atlantic, but still going towards the south-east. It consisted of four or five groups of 40 to 60 members each. Along the observed part of their path their height was only about 35 miles. At many of the Canadian stations their passage produced sounds like thunder, and at eight stations even houses were shaken. A similar phenomenon was seen at Cairo, in 1029 A.D., although unhappily the record is brief.

The brightness of most fireballs will vary greatly, generally increasing towards the end of their path. Minor explosions are often seen before the great final outburst that ends the career of so many of them. It is not unusual for such objects to have an apparent diameter equal to that of the moon, and to give about as much light as that body. Occasionally one has been reported as making the night as bright as day, but we may well consider this an exaggeration. As such bodies are never expected, all observers suffer the serious disadvantage of surprise.

Heights and Velocities.—The heights of meteors in the atmosphere may be determined by observation and calculation, following well-known rules. The same object must have the coordination of its end points observed from at least two places whose distance apart is known. How a meteor is actually observed is described later. With the data mentioned it is relatively a simple matter to calculate the heights at which it began and ended as well as its length of path. During the last century and a quarter this has been done for many hundred such objects, varying from the smallest meteor observable to the naked eye to the largest fireballs. The following table gives the average results:

No.	Beginning.	Ending.	Notes.
109	67·4m	53·6m	Magns. 1–5
121	86·1		Large meteors and
213	..	30·9	meteorites
147	..	37·4	Fireballs
57	..	19·3	Detonating meteors
16	..	13·7	Meteorites
49	71·4	54·7	Perseids by Weiss
			Authority: von Niessl
39	69·8	56·0	Perseids in 1863
78	96·3	60·7	Leonids in 1863
			Authority: Newton
107	73·6	45·3	Misc. meteors and fireballs
			Authority: Denning (1896)

If it is asked why the Leonids appear at higher altitudes than the Perseids, it is due to the fact that they strike the earth more nearly head-on. This gives them a greater relative velocity and hence they can begin to glow in a less dense part of our atmosphere.

Luminosity, Mass and Size.—It is obviously impossible that dust, gas or solid particles could continue to glow, merely from having been heated, in the intensely cold upper air for periods of many minutes. The part of a meteor's path that seems to give long enduring trains is from 60 to 50m. above the earth's surface. Study with the telescope has shown them to be tubular in shape. Suggested explanations are that the trains are due to phosphorescence, possibly connected with electric discharges; or that part of the energy being stored up in the molecules is later released as a gradual emission of light.

All reliable calculations of the masses and diameters of meteors lead to surprisingly small values. Meteors of the first and second magnitude are thought to be not more than one- or two-tenths of an inch in diameter, nor weigh more than a few milligrams. All such bodies undoubtedly appear larger owing to the envelope of heated and glowing gas that surrounds them in their flight, as well as to irradiation. There appears no sound reason for thinking small meteors different in constitution from their larger brothers, the meteorites. Analyses of the latter give us the usual elements, iron and nickel being very prominent in the metallic ones. But many are wholly composed of stone. We may safely infer that smaller meteors have a similar constitution and are merely smaller fragments. That different elements predominate in individual meteors is further proved by their different colours. In a few cases the spectra of meteors have been photographed. These spectra also show familiar elements, such as hydrogen, calcium, magnesium, carbon, helium and sodium, but this analysis gives no conclusive evidence as to their source.

Meteor Observing.—The actual observation of meteors forms one of the branches of astronomy best suited to amateurs. The only equipment needed is a star chart on which to plot the paths, a notebook and watch. Observations are made by noting carefully the points among the stars at which the meteor begins and ends, and plotting this path upon the map. Records of the time, colour, magnitude, etc., are made in the notebook at the same time. Societies for this work, largely composed of amateurs, now exist in several countries. Such work is of real scientific value and is the basis for advances in meteoric astronomy.

For more than 30 years attempts have been made to apply photography, but progress has been slow. It has been proved, however, that only short-focus instruments of considerable light-gathering power are of real service. Lenses four to six inches in diameter with a focal ratio of about 1:4 have been most used. Even with these only bright or very slow-moving meteors register themselves, and as no great shower has come of late the total number of trains photographed has not exceeded a few hundred. In some cases enough have been photographed on one night to give a radiant, but most are isolated. Attempts to obtain heights and velocities by photography have met with some success, but progress has been painfully slow. Nevertheless this method holds out great promise for the future. Some of the few radiants so derived were found with gratifying exactness.

Theories of Origin.—The question of the origin of meteors

carries us inevitably to that of the origin not only of our Solar System, but to that of other similar systems in space. It has been shown that there is an intimate connection between orbits of comets and some meteor streams, and it is inferred on sound grounds that the nuclei of comets consist of solid masses—*i.e.*, meteors of various sizes.

Accepting the Planetesimal Hypothesis, or some modification of it, as the true one, we may look upon all meteoric bodies as the débris of evolution—as fragments left over, or as parts of planetesimals that were destroyed before achieving full growth. But a study of the orbits and velocities of numerous fireballs and meteorites proves that they originated outside the Solar System. Analyses of some such meteorites prove beyond controversy that they once formed part of larger solid bodies of planetary dimensions. Hence we must infer an origin for these similar to those we know originated here. This brings us to one of the most important results of recent meteoric astronomy: if a catastrophic origin must be assumed for our Solar System, similar origins must be assumed for innumerable others, and hence we must admit that many other stars have systems of planets which were evolved in a manner similar to our own.

Bibliography.—O. C. Farrington, *Meteorites* (1915), Chas. P. Olivier, *Meteors* (1925). (C. P. O.)

METEORA, a group of monasteries in Thessaly, north of the Peneius valley, near the village of Kalabaka (the ancient Aeginium, mediaeval Stagus or Stagoi), not quite 20 m. N.E. of Trikkala. From the Cambunian hills two masses of rock project southward into the plain, eroded into isolated columns 85 to 300 ft. high, "some like gigantic tusks, some like sugar-loaves, and some like vast stalagmites," all of iron-grey or reddish-brown conglomerate of gneiss, mica-slate, syenite and greenstone. The monasteries stand on the summit of these pinnacles; accessible only by rope and net worked by a windlass from the top, or by a series of almost perpendicular ladders. The peak on which St. Stephen's is built does not rise higher than the ground behind, and the deep, narrow chasm is spanned by a drawbridge. Owing to the confined area, the buildings are closely packed, but each monastery contains beside the monks' cells and water-cisterns, at least one church and a refectory, and some also a library. At one time they were 14 in number, but now not more than four (the Great Monastery, Holy Trinity, St. Barlaam's and St. Stephen's) are inhabited by more than two or three monks. The present church of the Great Monastery was erected, according to Leake's reading of the local inscription, in 1388 (Björnståhl, the Swedish traveller, had given 1371), and it is one of the largest and handsomest in Greece. A number of the mss. from these monasteries are now in the National Library at Athens. Aeginium is described by Livy as a strong place and Stagus appears in Byzantine writers.

See W. M. Leake, *Northern Greece* (4 vols., 1835); Prof. Kriegk in *Zeitschr. f. allg. Erdk.* (1858); H. F. Tozer, *Researches in the Highlands of Turkey* (1869); L. Heuzey and H. Daumet, *Mission archéologique de Macédoine* (1876), where there is a map of the monasteries and their surroundings; *Guide-Joanne; Grèce*, vol. ii. (1891).

METEORITE, a mass of matter from outer space, which has fallen upon the earth's surface. These masses are made up usually of stony matter with varying amounts of metallic iron containing nickel; more rarely of nickeliferous iron alone; and much more rarely of stony matter with little or no metal.

Before coming in contact with the earth, these bodies have been travelling through space with planetary velocities of many miles a second. It is not surprising, therefore, that their arrival in the earth's atmosphere is heralded by very startling phenomena of light and sound. Owing to the resistance of the air, the meteorite becomes incandescent and is then seen as a scintillating ball of fire, sometimes with an apparent diameter greater than that of the moon. The fireball leaves behind it a trail of luminous matter, like a gigantic shooting-star of which the duration of flight has been much prolonged. The period of incandescence, however, is still only a matter of seconds for, as a result probably of the sudden condensation of the air in front of the moving mass and the accumulating pressure, the meteorite soon loses its planetary speed and eventually bursts into fragments. As a consequence partly of this shattering, but mainly of the sudden explosive shock and rise of temperature given to the air by the rapid passage of the meteorite, a short time after the disappearance of the fireball, loud detonations like thunder are heard, and these are generally followed by weird sounds which have been likened to the bellowing of oxen, the roaring of a fire in a chimney, the tearing of calico, etc. Owing to the rapid reduction in speed of the meteorite, the fragments reach the ground like ordinary falling bodies with velocities not greater than a few hundred feet a second. They, therefore, penetrate the soil to a depth of only a few feet, and in one particular fall, which took place in 1869 at Hessle in Sweden, stones which fell upon ice only a few inches thick rebounded from the surface. Moreover, in spite of the fact that the original mass had been rendered incandescent, the time of flight is too short for any real penetration of heat beneath the surface. Accordingly, the stones, when they reach the ground, are generally only slightly warm to the touch, and the sole evidence of the intense heat to which they had been subjected is a black fused crust which covers them (occasionally only partially), but is rarely more than a millimetre thick. The characteristic feature of most stony meteorites is this black crust, contrasting so remarkably with the white to grey interior scattered through which can usually be seen bright specks of metallic iron and often curious rounded bodies known as chondrules. In these respects meteoric stones are very different from the rounded nodules of sulphide of iron which weather out of the chalk on the S.E. coast of England and are often called "thunderbolts" and mistaken for meteorites. The term "thunderbolt" indeed as applied to meteorites is a misnomer since they have no connection with thunderstorms, and reports of the fall of "thunderbolts" during storms really refer to lightning-strokes. It is only under favourable conditions that such phenomena have been observed in their entirety. At the actual place of fall often only detonations have been heard, although the fireball may have been seen at places miles away, and when on March 9, 1923, a small stone of about 3 lb. fell a few yards from a labourer at Ashdon, Essex, only the whizzing of its flight was heard.

Occurrence of Falls.—That the advent of these bodies is an event of somewhat rare occurrence is evident from the fact that the number of falls of which specimens have been preserved is only about 1,000, and that of these no more than 15 have taken place in the British Isles. The number of new falls recorded for the whole world in any one year is generally less than ten, though doubtless others occur in sparsely populated regions and escape human observation. One of the earliest falls to be recorded took place about 644 B.C., strange to say, in China, for until quite recently no meteorite in that country appears to have been preserved. Other ancient falls of stones, some of which were made objects of worship, are recorded by Plutarch and Pliny. The stone referred to in the Acts as the image of Diana of the Ephesians "which fell down from Jupiter" was probably a meteoric stone, as is also doubtless the sacred stone built into the Kaaba at Mecca. The earliest known meteoric stone still preserved and of which details were placed on record is that weighing about 260 lb. which, after a loud crash like thunder, fell at Ensisheim in Alsace about noon on Nov. 16, 1492, and was seen by a child to strike the ground, where it buried itself to a depth of 5 ft. In later years several other falls were as definitely recorded, including that of a 56 lb. stone (now in the Natural History Museum) which fell within 10 yd. of a labourer at Wold Cottage in Yorkshire in 1795. Nevertheless it was not until after the publication of the detailed report made by the French physicist Biot on the marvellous fall of about 2,000 stones which took place at L'Aigle in France on April 26, 1803, that the fact of solid bodies falling from outer space was finally accepted by scientists.

Many years before this, however, the German philosopher Chladni had collected all the evidence for such events then available, and had laid particular stress, curiously enough, upon the occurrence in various parts of the world of masses of iron which had not actually been seen to fall but had been found in places where their presence could not be accounted for except on the supposition of an extra-terrestrial origin. One of these masses

weighing over 1,500 lb. was found on the top of a mountain 145 m. south of Krasnoyarsk in Siberia and was seen by the traveller Pallas in 1772; while other masses, of which one weighing 1,400 lb. is now in the Natural History Museum, had been found in the desert of the Gran Chaco, Argentina. Since Chladni's time, many other masses of iron meteorites, some of enormous size, have been recorded from different localities. One of the largest is the 36½ ton mass brought from Cape York, Greenland to New York by the Arctic Explorer R. E. Peary and now in the American Museum of Natural History. It is the largest meteorite preserved in a Museum, though in size it may perhaps be rivalled by the mass about 13 ft. long which is still lying where it fell on the farm El Ranchito near Bacubirito in Mexico, and also by a mass found in 1921 near Cinquetti in the desert of Adrar, Mauretania, although the original statement that it measured 100 metres in length still lacks confirmation. All these masses, however, would fall into insignificance beside the mass the impact of which it has been maintained by some must have given rise to that curious crater-like depression near Cañon Diablo in Arizona known as Coon Butte which is 4,000 ft. across and some 550 ft. deep, with walls of limestone and sandstone rising over 100 ft. above the plain. Several tons of meteoric iron have been found in the neighbourhood of the "crater," but borings have failed hitherto to locate any large mass within it. The largest mass of meteoric iron in the British Natural History Museum is the 3½ ton mass which was found in 1854 at Cranbourne near Melbourne, Australia.

Although specimens of iron meteorites bulk largely in museum collections and have resulted from as many as about 250 distinct falls, of only about 20 has the fall been actually witnessed. On the other hand, the great majority of stony meteorites (some 600) have been seen to fall, for if not recovered soon after they reach the ground they are more liable to suffer disintegration and escape notice than large masses of iron. Of these no specimens compare in size with the iron meteorites. The largest mass known was a 1,200 lb. stone found in fragments at Long Island, Kansas. The largest unbroken stone preserved in a museum (the Natural History Museum, Vienna) is one weighing 645 lb. which fell at Knyahinya in Czechoslovakia and is said to have made a hole in the ground 11 ft. deep. This was the largest stone of a shower of about 1,000 which fell near that place on June 9, 1866. The number of stones which fall at any one time and place is usually small and occasionally, as in 12 of the 15 falls recorded in the British Isles, only a single stone is recovered. In some falls, however, as in that of Knyahinya and that of L'Aigle already referred to there are showers of hundreds and thousands of stones. Besides these two showers, the most remarkable are the fall of some 100,000 stones near Pultusk, Poland, on Jan. 30, 1868, of 3,000 at Mocs, Transylvania, on Feb. 3, 1882, of 500 at Hessle, Sweden, on Jan. 1, 1869, 100 near Homestead, Iowa, on Feb. 12, 1875, and 14,000 near Holbrook, Arizona, on July 19, 1912. The stones of such showers are distributed over elliptic areas up to 16 m. in length and the largest stones of greatest momentum travel the farthest before reaching the ground. In the Holbrook shower thousands of the individuals were very small, some not much larger than grape seeds, but each one was covered with the characteristic thin black fused crust.

General Appearance.—Besides the crust, which is usually dull black but in stones containing little metal often glossy, other distinguishing features of meteoric stones are lines of flow, on the crust, of molten material which was directed from the front to the back of the stone as it flew through the air; and also curious pittings, up to 1 in. in diameter, which have been likened to "thumbmarks." In shape meteorites are generally irregular, indicating that they are only fragments of the larger masses from which they have been torn. A roughly pointed conical form is the most common. One of the large iron masses, that weighing about 1,500 lb. found at Tucson in Arizona and now preserved in the National Museum in Washington, is remarkable as being ring-shaped, while jaw-shaped masses like that found at Kokstad in South Africa are supposed to be parts of original ring-shaped masses.

There are few if any really authentic records of death or injury to man being inflicted by meteoric stones, but several—as at Benares, Kilbourn, Pillistfer, etc.—have struck buildings or fallen through roofs. Of these occurrences the most startling, perhaps, was the fall of a mass of iron at Braunau, Bohemia on July 14, 1847, which penetrated the roof of a house and covered with debris the bed in which three children were sleeping; one of the most recent is the crashing through the roof of a house of one of the four stones which fell on Dec. 3, 1917, in the Strathmore district, Scotland.

Composition.—As these bodies come from beyond the skies, it is naturally of interest to see how far they resemble and in what respects they differ from the rocks which compose the earth's crust. Stony meteorites certainly have the character of igneous and not of sedimentary rocks, and as they consist largely of pyroxene and olivine they approach in mineral composition basaltic rocks and more particularly, since felspar is in subordinate amount, the ultra-basic group of peridotites and pyroxenites. As compared with terrestrial rocks, however, they differ in various ways, suggesting that they were formed under conditions of lower oxidation than obtain on the earth's surface. Thus, whereas native iron is of the rarest occurrence in terrestrial rocks, it is an almost invariable constituent of meteorites. Both iron and stony meteorites also contain occasionally minerals such as the sulphide of calcium, *oldhamite,* and the phosphide of iron and nickel, *schreibersite,* which are unknown as minerals of the earth's crust since they could not exist for long in the presence of oxygen and moisture.

No new element has been found up to the present in meteorites, and, on the other hand, some common elements, including the strongly radioactive ones, have not yet been detected in them. The elements of which they are mainly composed are those of low atomic weight such as occur commonly in the earth's crust, viz.:—in approximately their order of abundance (according to W. A. Wahl) iron, oxygen, silicon, magnesium, aluminium, calcium, nickel, sodium and sulphur. In smaller amounts occur potassium, cobalt, phosphorus, carbon, hydrogen, chlorine, chromium, manganese, titanium, nitrogen, platinum metals and copper; while traces of iodine, bromine, argon, helium and radium, and doubtfully gold, tin and vanadium have been recorded. Carbon in meteorites is mostly in the form of graphite, but from the Cañon Diablo iron and the Novo-Urei stone chips having the hardness of diamond are recorded to have been isolated, and in the Youndegin iron was found a cubic form of graphite which has been called cliftonite. A few meteoric stones, including those of the small shower which fell at Cold Bokkeveld, South Africa, on October 13, 1838, are remarkable as containing small amounts of solid hydrocarbons which can be extracted from them by alcohol and ether. According to the relative amounts of nickeliferous iron and stony matter, meteorites have been grouped into three main divisions, viz:—*meteoric irons* or *siderites,* consisting almost wholly of nickeliferous iron; *meteoric stony-irons* or *siderolites,* of metal and stony matter in about equal amounts; and *meteoric stones* or *aerolites,* of stony matter, usually with nickeliferous iron scattered through it in small grains.

The metallic constituent of meteorites (both irons and stones) is not uniform in composition, for the percentage of nickel in it varies widely (from about 3 to 40) in different falls. In by far the greatest number of meteoric irons, however, the percentage of nickel lies between about 7 and 15. These irons are made up mainly of two different alloys of iron and nickel, and are characterized by a peculiar structure which is revealed upon polished surfaces by the etching action of dilute nitric acid or bromine water. These structures, which are known as Widmanstätten figures from their discoverer, consist of bands of a nickel-poor alloy, called *kamacite* and containing about 7% of nickel, bordered by narrower and more brilliantly reflecting bands of another alloy called *taenite* which is much richer in nickel (from 14% to nearly 50%) and less soluble than kamacite. These bands are the edges of plates which are arranged parallel to the faces of an octahedron. Hence these irons are known as *octahedrites* and where the bands are "medium" and "fine," there is usually a third material called *plessite* which is probably an intimate mixture of the same two alloys.

Classification of Meteorites

Group→		1	2	3	4
Class ↓	Nickel-iron→ Magnesium silicates→ Felspar→	Fe: Ni=13 and over. Enstatite (and Clinoenstatite). MgO : FeO very high to ∞. Oligoclase.	Fe: Ni=13−8. Bronzite (and Clinobronzite) and Olivine. MgO : FeO over 4. Oligoclase.	Fe: Ni=8−2. Hypersthene (and Clinohypersthene) and Olivine. MgO : FeO=4−2. Oligoclase.	. . Pyroxene (mostly monoclinic) and Olivine. MgO : FeO less than 2. Anorthite.
Irons 1	SIDERITES→ Mainly nickel-iron.	Nickel-poor Ataxites. Hexahedrites. Coarsest Octahedrites. Coarse Octahedrites.	Medium Octahedrites to Finest Octahedrites.	Nickel-rich Ataxites.	
Stony-Irons 2	SIDEROLITES→ Nickel-iron in large amount.		Most Pallasites. Siderophyre. Lodranite. Mesosiderites.*	A few Pallasites.	
3	CHONDRITES→ Nickel-iron generally in decreasing amount from left to right.	*Enstatite-chondrites.* Daniel's Kuil (Hvittis) type.	*Bronzite-olivine-chondrites.* Cronstad type.	*Hypersthene-olivine-chondrites.* Baroti and Soko-Banja types.	
Stones (Aerolites) 4	ACHONDRITES→ (Non-chondritic stones.) Nickel-iron in small amount or absent.	*Enstatite-achondrites.* Aubrites. (Aubres, Bishopville, and Bustee.)	*Clinobronzite-olivine-achondrites.* Ureilites.	*Hypersthene-olivine-achondrites.* (dites). Amphoterites (& Ro- *Hypersthene-achondrites.* Diogenites (Shalka, etc.). *Olivine-achondrites.* Chassignite.	*Calcium-rich Achondrites.* Angrite, Nakhlite. Eucrites, Sherghottite, Howardites.

*As regards the felspar and the pyroxene, mesosiderites conform to Group 4.

Meteoric irons often contain nodules and crystals of various minerals scattered through them. Of most common occurrence is *troilite,* the monosulphide of iron similar to, if not identical with, the terrestrial pyrrhotite. Frequently associated with the troilite nodules are inclusions of schreibersite and of graphite. Other minerals less frequently found in irons are *daubreelite,* a sulphide of iron and chromium, the sulphur analogue of chromite; *cohenite,* a carbide of iron and nickel similar to the cemenoite of steel; and *moissanite,* a silicide of carbon similar to the artificial carborundum. Chromite is present in small amount in most irons, while in some the presence of the deliquescent chloride of iron called *lawrencite* is the cause of their liability to quick rusting and disintegration.

Gases included in small amount in meteorites have been found to consist mainly of hydrogen, carbon monoxide, carbon dioxide, nitrogen and marsh gas; carbon dioxide predominating in the stones, and hydrogen and carbon monoxide in the irons.

The stony-irons, of which about 30 are known, form a distinct group and are only intermediate between irons and stones as regards the amount of nickel-iron. In many of them (*pallasites*) the stony matter consists of olivine alone as rounded or fragmental crystals. In most of the other stony-irons (*mesosiderites*) the stony matter consists mainly of pyroxene with fragmental anorthite-felspar and only little olivine. Of exceptional composition is the stony-iron which was found at Steinbach in Saxony in which the stony matter consists of bronzite and tridymite (asmanite), for it is the only meteorite known containing an appreciable amount of free silica.

The great majority (about 90%) of meteoric stones are known as *chondrites* since they consist largely of curious rounded bodies (chondrules) which are embedded in a fragmental groundmass made up of irregular grains of pyroxene and olivine with scattered particles of nickel-iron and troilite. Chondrules are mostly of the size of millet seeds though occasionally as large as a walnut. They are formed of the same minerals, pyroxene and olivine with sometimes felspar and glass, as the rest of the stone. Some are of pyroxene alone in fibrous form, with the fibres often radiating from the edge and not from the centre.

The above tabular classification gives the names and mineral composition of the different kinds of meteorites. This classification is based on the hypothesis that meteorites have been derived from a single magma which has passed through successive stages of progressive oxidation.

The following is a list of the meteorites known to have fallen in the British Isles:—

Place	Date	Weight
England		
Wold Cottage, Yorkshire .	Dec. 13, 1795	One stone 56 lb.
Launton, Oxfordshire . .	Feb. 15, 1830	„ „ $2\frac{1}{2}$ lb.
Aldsworth, Glos. . . .	Aug. 4, 1835	„ „ $1\frac{1}{2}$ lb.
Rowton, Shropshire . .	April 20, 1876	„ „ $7\frac{3}{4}$ lb.
Middlesboro, Yorks. . .	March 14, 1881	„ „ $3\frac{1}{2}$ lb.
Appley Bridge, Lancs. . .	Oct. 13, 1914	„ „ 33 lb.
Ashdon, Essex . . .	March 9, 1923	„ „ $2\frac{3}{4}$ lb.
Scotland		
High Possil, Glasgow . .	April 5, 1804	„ „ 10 lb.
Perth	May 17, 1830	„ „ $7\frac{1}{2}$ in. in diameter, mostly lost.
Strathmore, Perthshire .	Dec. 3, 1917	Four stones of $22\frac{1}{4}$, $2\frac{1}{2}$, $2\frac{3}{8}$, $2\frac{1}{4}$ lb.
Ireland		
Mooresfort, Tipperary .	Aug., 1810	One stone of $7\frac{3}{4}$ lb.
Limerick (Adare) . . .	Sep. 10, 1813	A small shower of stones, the largest 65 lb.
Killeter, Tyrone . . .	April 29, 1844	A small shower of stones, only a few fragments preserved.
Dundrum, Tipperary . .	Aug. 12, 1865	One stone of 5 lb.
Crumlin, Antrim . . .	Sep. 13, 1902	„ „ of $9\frac{1}{2}$ lb.

Origin.—Little can be said of a definite character concerning this. The prevailing and orthodox view which dates from the time of Chladni is that the detonating meteoritic fireball and the ordinary shooting star or meteor (*q.v.*) are only variations of one phenomenon. According to this theory meteorites are large enough to survive their fiery transit through the air, meteors are not; and moreover, since the orbits of some comets have been shown to be the same as those of some star-showers, meteorites are supposed to be identical with the material of comets and in that case to be moving through space in swarms having definite orbits. It has been objected to this theory that meteorites, with one exception, have not been known to fall during displays of star-showers and do not fall most frequently during that period of the year when shooting stars are prevalent. The general similarity of meteorites in chemical composition, and the

evidence they afford of consanguinity or derivation by progressive oxidation from a common type, certainly indicate that they belonged originally to a single celestial body. Such a body may have suffered some catastrophic disruption, and if so, it has been argued, this must have taken place in fairly recent geological time since, with the one exception of a meteoric iron found in Pliocene gravels in Klondike, "fossil" meteorites are unknown.

No meteorite which has been seen to fall approaches in chemical composition the acid granitic rocks which occur so plentifully on the earth's surface. In various parts of the world, however, namely in Bohemia and Moravia, the East Indies and Australia, have been found peculiar small glassy bodies resembling obsidian and containing as high a percentage of silica. As these curious bodies, which have been called *tektites*, occur in no obvious connection with recent volcanoes or with ancient volcanic rock, a meteoritic origin has been suggested.

The most important collections of meteorites are in the Natural History Museums of Chicago, London, Vienna and Paris. The number of falls represented in the British Museum (Natural History) collection is about 710, and the weight of the specimens amounts to just over 6 tons.

METEOROLOGY, the science of the atmosphere (Gr. μετέωρα and λόγος, the science of things in the air). In its widest sense the term includes the study of weather, climate, optical phenomena in the atmosphere and atmospheric electricity.

HISTORY

The beginnings of the study of weather are lost in antiquity. Some of the earliest writings extant contain fragmentary references to weather phenomena, but the earliest known effort at systematic discussion was the *Meteorologica* of Aristotle (384–322 B.C.). Theophrastus, a pupil of Aristotle, wrote treatises on winds and on weather signs. Then for two thousand years meteorology stood still.

The Beginning of Meteorology as an Exact Science.—Advances were made with the invention of the thermometer (*see* HEAT) by Galileo in 1607, the invention of the barometer (*q.v.*) by Torricelli in 1643, the discovery of Boyle's law (*q.v.*) in 1659, and the invention of the wheel barometer by Hooke about 1670. Halley (1656–1742) attempted to explain the trade winds as a direct consequence of the distribution of solar radiation over the earth, but the true explanation was given by George Hadley in 1735, in a paper in which for the first time allowance was made for the effect of the rotation of the earth. In 1742 Celsius invented a Centigrade thermometer. Later de Saussure (1740–1799) perfected the thermometer and hygrometer, and showed that damp air is lighter than dry air at the same temperature and pressure. The true nature of atmospheric air was established by Lavoisier in 1783, and the laws of pressure of water-vapour in air were given by Dalton in 1800. Dalton also wrote an epoch-making paper on the effects of rarefaction and condensation, which laid the foundation of modern physical meteorology.

The First Weather Charts and Systematic Observations.—The Chevalier de Lamarck (1774–1829) working with Laplace, Lavoisier, and others established a réseau of observing stations, and published a series of *Annuaires Météorologiques* from 1800 to 1815. In 1820 Brandes produced a series of daily weather charts, one for each day of the year 1783, and later published charts of the great storms of 1820, 1821 and 1823. He explained these storms as due to barometric depressions advancing from west to east over the earth's surface. In America, Espy (1785–1860) carried out similar researches, and published a book *Philosophy of Storms* (Boston 1841). Espy established a service of daily synchronous observations and studied in detail the behaviour of depressions. The work of Lamarck, Brandes, Espy, Loomis, and others led to the establishment of networks of stations in several countries within the years 1850–56, the Meteorological Office in London being established in 1854. International co-operation was first established by an international conference held in Brussels in 1853, and was put on a sound basis by an international congress in Vienna in 1873. The exchange of information was at first by telegraph, later by wireless telegraphy.

The Study of the Upper Air.—A classification of clouds was made by Luke Howard in 1803. Temperatures in the upper air were first measured by Dr. Alexander Wilson at Glasgow in 1749, by means of thermometers sent up on kites. Later observations in manned balloons by Jeffries and Blanchard in 1784, Roberts in 1803–4, Biot and Gay-Lussac in 1804, and by John Welsh at Vauxhall in 1852, the last of these attaining a height of 23,000 feet. Self-recording thermometers were first used on kites by Rev. George Fisher and Sir Edward Parry in the Arctic in 1822–23.

Small free rubber balloons carrying self recording instruments (Sounding balloons) were first used by Hermite and Besançon in 1893, and in 1899–1902 Teisserenc de Bort and Assmann established the fact that above a height varying from 18 km. at the Equator to about 11 km. in latitude 50°, and to 6 km. or less at the poles, the temperature remained sensibly constant with height. (*See* section on Vertical Distribution of Meteorological Elements.) Upper air temperatures and humidities are now obtained daily from wet and dry bulb thermometers placed on the wing struts of aeroplanes.

THE COMPOSITION AND SOME PHYSICAL PROPERTIES OF THE ATMOSPHERE

General Composition.—The atmosphere is a simple mixture of gases, of which nitrogen and oxygen account for a little more than 99%. The proportions of the usual constituents of dry air are given in a table in the article ATMOSPHERE.

Constitution at High Altitudes.—In view of its bearing on theories of the origin of aurorae, magnetic storms and other phenomena, considerable interest attaches to the constitution of the atmosphere at higher levels, say from 20 km. to 200 km. Computation of the constitution of the atmosphere at these levels is based on the effects of diffusion, the convective mixing which is effective in producing constancy of composition in the lower layers having no effect at the higher levels. Each constituent is assumed to follow its own law of variation of density independently of the others, in accordance with Dalton's law. (*See* CHEMISTRY: *Physical.*) The lighter constituents will therefore tend to predominate more and more with increasing height. Hence it is of the utmost importance to ascertain what are the normal constituents of the atmosphere. If hydrogen is assumed to form a normal constituent of the atmosphere, then at great heights hydrogen will be the predominating constituent of the atmosphere.

In Wegener's scheme nitrogen ceases to be measurable at about 100 km. and beyond this level the composition of air by volume is

about 5% helium, and 95% hydrogen and geocoronium. Chapman and Milne (*Q.J.R. Met. Soc.* vol. xlvi.) regard the hydrogen observed at low levels as accidental, so that the lightest normal constituent of the atmosphere is helium. Experimental data are insufficient to decide between the different schemes of constitution of the high level atmosphere. According to Dobson (*Q.J.R. Met. Soc.*, 1923) meteors indicate that oxygen and nitrogen are the chief constituents up to about 160 km. McLennan attributes the green auroral line, of wave-length $\lambda = 5577{\cdot}35$ A.U. ($5{\cdot}57735 \times 10^{-5}$ cm., or $\cdot 557735\ \mu$) to *atomic* oxygen. These results appear to conflict with those derived from the assumption of Dalton's law.

Aqueous Vapour in the Atmosphere. Humidity.—The amount of aqueous vapour present in unit volume of air varies within wide limits from place to place, and from time to time in a given place. It may account for anything from 0 to 2·5% of the weight of a specimen of air. The saturation vapour pressure of air depends only on the temperature of the air, and is independent of the total pressure. If e is the saturation vapour pressure at temperature $t°$ C, then it should be possible to represent e as a function of t. No general formula has ever been discovered, though a large number of empirical formulae have been proposed by various writers. (*See* T. Preston *Theory of Heat*, v., 3rd ed. 1919.)

The relative humidity, vapour pressure, etc., are normally determined by observations of wet and dry bulb thermometers. If t and t' are the readings of the dry and wet bulb thermometers respectively, p the pressure, e' the saturation vapour pressure at the temperature of the wet bulb t', and e is the vapour pressure of the air under observation, these quantities are related by the formula

$$e - e' = Ap\ (t - t').$$

where A is a constant. The value of A depends upon the degree of ventilation of the thermometers, and care must be exercised to use the value of A appropriate to the conditions.

Tables will be found in Jelinek's *Psycrometer Tafeln*, in the *Smithsonian Meteorological Tables*, and in the *Humidity Tables* published by the Meteorological Office, London (M.O. 265).

Physical Constants for Air.—*The density of dry air* containing no CO_2, as determined by Regnault at the Collège de France, is 1·29321 kg. per cubic metre, at 0° C and at a pressure of 760 mm. At a pressure of 1,000 millibars and 0° C, the corresponding figure is 1·27590. Dry atmospheric air at a temperature of 0° C and 1,000 mb. has a density of 1·27617. The ratio of the density of water vapour to that of dry air at the same temperature and pressure is 0·6221, approximately $\frac{5}{8}$.

The Gas Constant, R.—The equation of condition for gases is

$$pv = RT,$$

where p is the pressure, v the volume of unit mass, T the absolute temperature, and R is a constant. If the pressure is expressed in millibars, and v is in cubic metres per kilogram the value of R for dry air is 2·8703.

The Density of Damp Air. Virtual Temperature.—For damp air at a total pressure p and vapour pressure e, the total density is the sum of the densities of the dry air and water vapour. The density is therefore

$$\frac{1}{RT}(p-e) + \frac{0{\cdot}6221}{RT}e \quad \text{or} \quad \frac{0{\cdot}34839}{T}(p - 0{\cdot}378e)$$

$$= \frac{0{\cdot}34839}{T}(p - \tfrac{3}{8}e) \text{ approximately.}$$

This is equal to the density of dry air at the same pressure p and a temperature T^v, where T^v is defined by

$$T^v = \frac{T}{1 - \frac{3}{8}\frac{e}{p}},$$

T^v is called the "virtual temperature." Tables of virtual temperature will be found in Bjerknes' *Dynamical Meteorology and Hydrography*, vol. ii. (Smithsonian Institution).

Absorption and Radiation.—In discussing meteorological processes we have to take account of (a) radiation from the sun, of relatively short wave-length, and of (b) radiation from the earth and portions of the atmosphere itself, of longer wave-length, having a maximum intensity at about 10 μ. (a) The amount of absorption of short wave solar radiation by "dry air" is so slight as to be almost negligible, but there is an appreciable absorption by water vapour, sufficient according to Abbot and Fowle to diminish the solar beam by one-tenth in its passage through the atmosphere. (b) Long wave radiation is not absorbed by oxygen or nitrogen, which, according to Burmeister (*Berlin Verh. Phys. Ges.* 1913) have no absorption bands at wave-lengths longer than 1 μ. Carbon dioxide shows absorption bands at 2·4 to 3·0 μ, at 4·2 to 4·5 μ and at 12·5 to 16 μ; and Schlaefer concluded that the amount of carbon dioxide in the atmosphere was sufficient to produce complete absorption within the bands mentioned. Water vapour absorbs long wave radiation in bands which are distributed through a considerable range of wave-length. The most exhaustive study of water vapour absorption is that of Hettner (*Ann. d. Phys.* 1905), who found that there is very marked absorption between 4·4 μ and 8 μ and above 12 μ, while there is a band from 8 μ to 11 μ within which there is only slight absorption by water vapour. Radiation from the earth at normal temperatures has a maximum intensity at about 10 μ, and so the existence of the band of relative transparency from 8 μ to 11 μ is of fundamental importance. The elementary gases absorb no radiation at atmospheric temperatures.

Thermodynamical Constants for Air.—*The potential temperature* of a mass of dry air is defined as the temperature which it would attain by adiabatic expansion or compression to a standard pressure, usually taken as 1,000 millibars.

The concept of potential temperature is particularly useful in dealing with conditions of vertical stability in the atmosphere. It was first introduced by von Bezold (*Sitz. Ber. Akad*, 1888).

Entropy.—A definition of entropy will be found in the article THERMODYNAMICS. If a small amount of heat dQ is communicated isothermally (*i.e.*, without changing the temperature) at a temperature T to a mass of air, then the ratio $\frac{dQ}{T}$ represents a small change of entropy, and is denoted by $d\phi$ (ϕ being the symbol for entropy). Thus, in an isothermal process, the gain or loss of heat is represented by $Td\phi$. Entropy remains constant for any adiabatic changes (*i.e.*, changes where heat is neither lost nor absorbed by the system). If we take zero of ϕ as corresponding to a potential temperature of 100° on the absolute scale,

$$\phi = 2{\cdot}30 \times 10^7 \times \log_{10} \frac{\theta}{100} \text{ ergs per degree per gram}$$

$$= 2{,}300 \log_{10} \frac{\theta}{100} \text{ joules per degree per kilogram.}$$

Geopotential.—It has been suggested that the height of a point above the surface of the earth should be defined by the geopotential, or the potential energy of unit mass at that height due to its elevation above the surface of the geoid. Surfaces of equal geopotential are "level surfaces" and are horizontal in the technical sense.

The geopotential being the potential energy of unit mass, has the dimensions of (velocity)^2. On the c.g.s. system the unit is 1 cm.^{2}/sec.^{2} A convenient unit for ordinary working purposes is the dynamic metre, equal to 10^5 cm.^{2}/sec.^{2} The approximate relation of the dynamic metre to the metre for latitude 50° is 1 dynamic metre = 1·0209 metre. Tables of geopotential are given in Bjerknes, *Dynamical Meteorology and Hydrography.*

INSTRUMENTAL OBSERVATIONS

For full details of the types of instrument which are in normal use in meteorological observations, reference should be made to the *Meteorological Observers Handbook* of the Meteorological

Office, or any standard textbook on the subject. (*See* also BAROMETRY, THERMOMETRY, etc.)

Air temperature does not readily permit of accurate determination. Difficulties arise through the necessity for ventilation of the instruments, combined with adequate protection from direct radiation from the sun or surrounding objects, combined with the variability of temperature between adjacent masses of air. The accuracy of determination of air temperature is therefore much inferior to the accuracy of the determination of the temperature of a liquid in the laboratory. This is but one example of the very real difficulties of accurate meteorological observation, and the existence of these difficulties must be borne in mind in what follows.

The methods which have hitherto been developed for upper air observations are only applicable in relatively fine weather, and so little is known from actual observation of the conditions at high levels above cyclones. This is probably the main reason for the slow advance made in meteorology during the last half-century.

GEOGRAPHICAL DISTRIBUTION OF METEOROLOGICAL FACTORS

The standard observations carried out at any meteorological station consist of measurements of: (1) Pressure at the time of observation, and the change in pressure during the past three hours if a barograph is available. (2) Temperature of dry bulb and wet bulb thermometers, so that both temperature and humidity can be derived from the readings. (3) Wind direction and velocity, the latter being estimated on the Beaufort scale, or read from an instrument in some convenient unit such as metres per second, miles per hour, or feet per second. (4) Weather and state of sky; *i.e.*, number of tenths of the sky clouded, and nature of the cloud; whether rain or snow, hail, etc., is falling or not, whether there is fog, or mist present. (5) Visibility, usually given a numerical value by noting the most distant object visible among a number of previously selected standard objects at known distances from the observing point. (6) Maximum day temperature noted in the evening, and minimum night temperature noted in the morning. (7) Amount of precipitation since previous time of observation. (8) Amount of bright sunshine during the day. (9) Motion of cloud.

All these observations are carried out at most meteorological stations reporting by telegraph, telephone or wireless to a central meteorological office. For details of the use of such data for forecasting, *see* the standard textbooks on the subject.

In addition to the above observations, some or all of the following observations are made at a restricted number of stations in practically all countries of the world: (10) Upper wind measured by means of pilot balloons. (11) Upper air temperatures and humidities observed by means of instruments suspended on wing struts of aeroplanes. (12) Upper air temperatures and humidities at different heights by means of self-recording instruments carried by free balloons. (13) Amount of atmospheric pollution. (14) Electric potential gradient in the atmosphere. (15) Various magnetic factors. When observations are made on board ship, to these are added: (16) Temperature of the sea surface, and state of the sea.

Diurnal Variations.—The most fundamental cycles in the atmosphere are those associated with the differences between day and night, and the differences between summer and winter. We shall consider these only briefly, dealing first with the former.

Temperature.—The factor which is most obviously related to solar radiation is the temperature of the air. In fig. 1, (a) gives the curve for diurnal variation of temperature at Aberdeen for August. This curve is typical of the curves obtained over the whole world at levels not much above mean sea level. This curve is definitely only the average over the month, and any one individual interval of 24 hours may give widely differing forms for the curve of temperature, since the phenomenon may be complicated by changes in wind direction, bringing up supplies of air from widely varying altitudes.

The effect of height upon the form of the variation of temperature is shown by curves (b) for Parc St. Maur, Paris, 50 metres above sea level, and (c) for Eiffel tower, 335 metres above sea level, both for the month of July. The low-level station has a mean diurnal variation of over 9° C, while the higher station has a mean diurnal variation of a little over 5° C. There is a further noteworthy feature, that the time of maximum is about 2 hours later at the top of the tower. It is probable that

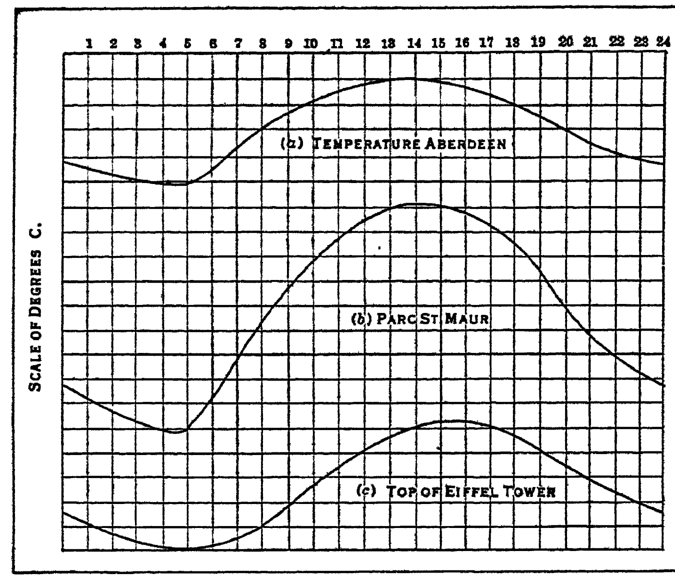

FIG. 1.—DIURNAL VARIATIONS OF TEMPERATURE

at still greater heights the diurnal variation of temperature rapidly diminishes. (Hergesell, *Lindenberg Publications*, vol. xiv.)

The temperature of air over the sea is subject to no considerable diurnal variation except possibly over shallow water. Observations made on board the *Challenger* indicated a diurnal range of about 1° C, and this value has been confirmed (*Q.J.R. Met. Soc.*, 1927) by observations made in the Mediterranean sea by N. K. Johnson. The changes of temperature are so slight that it is not possible to say with certainty how far they are vitiated by the changes of wind direction.

The diurnal variation of the temperature of the surface of the sea is probably very slight, but the difficulty of obtaining a fair sample of the surface water of the sea makes any accurate estimate of the true surface temperature impossible.

Lapse-rate of Temperature.—In overcast weather there is little or no variation of the lapse rate between day and night. In clear weather, however, for the lowest layers, there is a pronounced maximum in the middle of the afternoon, its value exceeding many times the dry adiabatic lapse rate. The lapse rate diminishes rapidly in the evening, giving place to a pronounced inversion. Over the sea there is no appreciable diurnal variation of the lapse rate.

Pressure.—In fig. 2, (a), (b) and (c) give for July the diurnal variations of pressure (from data in *Manual of Meteorology*, vol. ii.) at Aberdeen, Batavia and in the Arctic, the times being Greenwich mean time in (a) and local times in (b) and (c). It will be noted that within the tropics there is a very strongly marked pressure wave of 12 hours' duration, with maxima at 9 A.M. and 9 P.M., superposed on a 24 hourly wave. Some further details of these diurnal variations are given later in the section *Dynamical Aspects*. Curve (d) in the same figure shows the diurnal variation for July on Ben Nevis, 1343 metres above mean sea level, a single ill-defined maximum at 2 P.M.

Wind.—The surface wind velocity shows a maximum about 2 P.M. and a minimum in the early morning. The direction shows a corresponding change, the wind backing as it diminishes. At the top of the Eiffel tower the diurnal variation of wind velocity is the reverse of that observed at the ground, the maximum velocity occurring during the early morning and the minimum during the afternoon. At intermediate heights the nature of the diurnal variation is to some extent dependent on the strength of the wind. Hellmann (*Met. Zeit.*, Jan. 1915) set up three anemometers at

heights of 2, 16 and 32 metres above the ground, in a flat meadow at Nauen. He found that when strong winds were blowing, all three anemometers yielded maxima during the day, and minimum during the night. With light winds the anemometer at 2 metres showed a day maximum and a night minimum, but those at 16 metres and 32 metres showed two maxima, one about mid-day, and the other about midnight. At 16 metres the maxima were

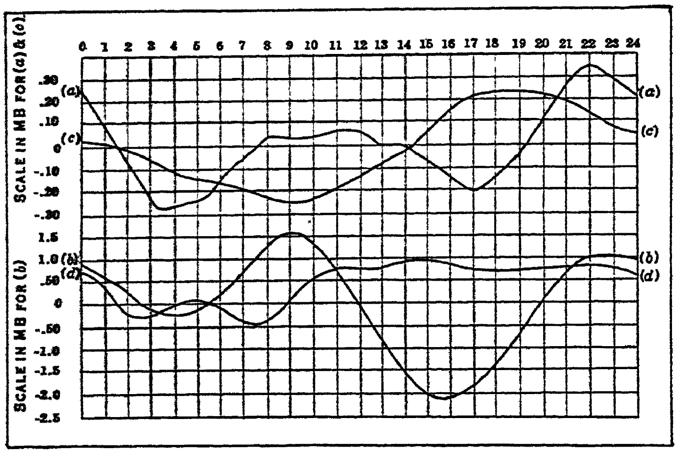

FIG. 2.—DIURNAL VARIATIONS OF PRESSURE; (A) ABERDEEN, (B) BATAVIA, (C) ARCTIC REGIONS, (D) BEN NEVIS

approximately equal in winter, but in summer the day maximum was slightly the greater. At 32 metres the night maximum was the greater in winter and summer. With light winds the height at which the night maximum becomes equal to the day maximum is thus about 16 metres in winter, and between 16 and 32 metres, in summer. With strong winds this height exceeds 32 metres.

Durward (*M.O. Professional Notes*, No. 15) investigated the diurnal variation of winds at 1,000 to 6,000 ft. by an examination of 1,736 pilot balloon ascents, made by the meteorological service with the British Armies in France during March 1917–Sept. 1918. The winds at 1,000 ft. showed a maximum about midnight, and a well marked minimum between 9 A.M. and 10 A.M. in reasonably good agreement with the Eiffel tower observations. The variation at 2,000 ft. and 3,000 ft. was of the same general character, but when all wind directions were taken together no appreciable diurnal variation was found at 4,000 and 6,000 feet.

At sea, the diurnal variation of wind is much less marked. Galle[1] (*K. Ned. Met. Inst.*, No. 102) states that from May to October the maximum velocity of the south-east trade-winds of the Indian ocean occurs during the night-hours. No detailed observations at one place are available, and it is not at present possible to give any definite statement of the variation of winds over the sea.

Land and Sea Breezes.—At places on a coast there is usually a pronounced tendency for a wind to blow from the sea to the land in the morning, and from the land to the sea in the evening. In some places, this wind follows the sun in the course of the day. For example, at Aberdeen, the sea breeze sets in suddenly in the morning as a wind from sea to land at right-angles to the coastline, but during the day it veers until it blows parallel to the coast.

Vapour Pressure and Humidity.—The vapour pressure remains substantially constant during the 24 hours, at land stations. At Kew observatory, England, there is no appreciable diurnal variation of vapour pressure during any month of the year, and the same holds at nearly all stations for which data are available. Since temperature normally varies considerably between day and night, it follows that relative humidity varies in the opposite sense to temperature.

Cloudiness.—No simple rule can be stated for the diurnal variation of cloudiness. The wind-direction is of considerable importance in this respect, and different types of cloud vary in different ways. The diurnal variation of cloudiness at Kew observatory has been investigated by Brunt (*M.O. Professional Notes*, Nos. 1 and 14), who showed that with all wind directions there is

[1] Vide also *Arbeiten Preuss. Aeronaut. Obs., Lindenberg*, Bd. XIV.

a well-marked tendency for the amount of cloud to diminish in the evening. Similar results were derived for a number of stations in the Rhine valley. At Batavia, 6° S. of the equator, cloudiness attains its maximum in the evening or early night, and its minimum about 4 A.M. local time (*Observations*, Batavia, xxxviii.). At Helwan cloudiness attains its maximum during the afternoon, and its minimum during the evening.

Thunderstorms.—The observations made by the "Challenger" showed that the frequency of thunderstorms at sea had a pronounced maximum between 2 A.M. and 4 A.M., while the occurrence of "lightning only" showed a maximum between 8 P.M. and 10 P.M. Over the land, heat thunderstorms occur most frequently during the afternoons, but certain types of thunderstorms, associated with the line of separation between warm and cold air currents, show no special preference for any hour of day or night.

Electric Potential Gradient.—The typical variation of potential gradient has a minimum in the early morning, and a maximum in late afternoon, the maximum being about twice the minimum; but at many stations there is a subsidiary maximum about 8 A.M. and a minimum in early afternoon.

Seasonal Variation of Meteorological Elements.—While it is possible to consider the diurnal variation of the meteorological elements separately, it is not possible to treat the seasonal variations in the same way. As is shown later, the whole of the circulation of the atmosphere and the distribution of pressure over the surface of the earth, with which this circulation is closely associated, are both subject to changes on a large scale during the course of the year. A noteworthy point which emerges from the discussion of the diurnal variations is the difference in the phenomena over land and sea, the former showing the greater variability. The same is true of seasonal variations. The land heats up more rapidly than the sea in the summer, and cools more rapidly than the sea in winter. Hence the marked distinction between continental and oceanic climates, the former being subject to extremes of heat and cold, and the latter being relatively equable. The centres of large land masses are associated with excessive heat in summer and excessive cold in winter, the lowest temperatures in the northern hemisphere occurring in northeast Siberia. In this region the seasonal change of temperature exceeds 60° C, while over the major part of the Eurasian continent and North America the seasonal variation exceeds 30° C. In the tropics the seasonal variation of temperature becomes relatively small, with the result that the change of temperature with latitude is greater in winter than in summer. All phenomena which are in any way related to or dependent on the horizontal gradient of temperature are therefore accentuated in winter.

Along the seaboard of a continent, the nature of the seasonal variations will depend upon the direction of the prevailing wind, since winds from the interior of the continent and winds from the ocean will carry with them the characteristics of their region of origin. Rainfall again depends largely upon the interaction of different currents of air and on the form of the land, and it is not possible to give any general rules as to the nature of the seasonal variations of rainfall over the whole globe, except such as will arise in the course of the following brief discussion of the general circulation of the atmosphere. The general question of seasonal variation of meteorological factors is closely bound up with climatology, and a large amount of information on this topic will be found in any standard text book on the latter; *e.g.*, Kendrew's *Climates of the Continents*, contains numerous tables giving seasonal variations of temperature, pressure and rainfall.

THE GENERAL CIRCULATION OF THE ATMOSPHERE

The Distribution of Temperature over the Earth.—The distribution of temperature over the earth is usually represented by two charts, one of the mean temperature for January and one of the mean temperature for July. These two months represent the extremes of winter and summer, the other months being intermediate between them. (*See* any physical atlas.)

We shall consider first the chart for January. It will be seen that in the southern hemisphere the isotherms, or lines of equal temperature, run across the chart in a regular manner, indicating

approximate symmetry of distribution of temperature about the poles, except that over South America, South Africa and Australia, the isotherms sweep downward over the land, indicating that the land is warmer than the sea in the same latitude. In the northern hemisphere there are two centres of extreme cold, one in northeast Siberia and one over Greenland. If in middle latitudes we restrict our attention to any one parallel of latitude, we note that the temperature is higher over the western coast of a continent than over the eastern coast of the same continent. This difference is associated with the fact that prevailing westerly winds bring with them the conditions of their region of origin.

The chart for July shows again in the southern hemisphere an approximately symmetrical distribution of temperature about the South Pole. In the northern hemisphere there are centres of high temperature over North Africa, over the southern portion of North America, and to the north of India, but the run of the isotherms is irregular. The land is, however, distinctly warmer than the sea, the difference being especially well marked over the north Pacific ocean and the contiguous continents.

The Distribution of Surface Pressure over the Earth.—Charts giving the distribution of pressure show in the southern hemisphere a belt of high pressure encircling the earth about latitude 30°, with somewhat higher pressures over the oceans than over the continents. These belts are known as the "sub-tropical anticyclones" or the "sub-tropical high pressure belts." Over the northern hemisphere the extensive land masses complicate the phenomena. The January chart shows the sub-tropical anticyclonic belts over the north Atlantic and north Pacific oceans, but in addition to these there is an intense anticyclone centred over Asia, and another over North America. Over the northern portion of the North Pacific, and also just south of Greenland, there are centres of low pressure.

In July, the anticyclonic centres over the north Atlantic and north Pacific persist, and extend somewhat further north. A shallow centre of low pressure is situated over north-east Canada, and a much deeper centre of low pressure is centred to the north-west of India, extending over the whole of Asia, and even over a part of north-east Africa. The subtropical anticyclonic belt is no longer traceable over southern Asia.

The Distribution of Winds over the Globe.—There is a simple relation between the direction of the wind and the distribution of pressure, which is known as Buys Ballot's law, after the Dutch meteorologist who first enunciated it. It may be stated as follows: "In the northern hemisphere an observer who stands with his back to the wind will have lower pressure to his left than to his right. In the southern hemisphere the reverse holds." In terms of isobars on a chart, this amounts to saying that the wind tends to blow round the isobars keeping low pressure to the left in the northern hemisphere, and to the right in the southern hemisphere. In practice the wind at the surface is found to blow slightly across the isobars into low pressure, at an angle of 20° to 30°.

Keeping this law in mind, we can interpret the pressure charts for January and July in terms of the prevailing winds. We shall first consider the chart for January. The equator is marked by a shallow belt of low pressure, to each side of which the pressure increases with distance towards the pole. The region on the equatorial side of the subtropical anticyclonic belts is therefore marked by easterly winds having a component towards the equator. These winds known as the *trade winds* are north-easterly in the northern hemisphere and south-easterly in the southern hemisphere. Between them is the equatorial belt of low pressure, known as the *doldrums*, with calms or light variable winds. It is situated slightly north of the equator in the northern winter, and moves slightly further north in the northern summer. The centres of the sub-tropical anticyclonic belts are regions of light winds. On the poleward sides of the anticyclonic belts the winds are westerly, especially in the southern hemisphere, where there is only slight disturbance by land masses. Over the north Atlantic the prevailing winds are westerly. The circulation over Asia is clockwise round the centre of high pressure, and over the China seas the winds are north-easterly. The regions of prevailing westerly winds on the poleward sides of the sub-tropical anticyclones are not regions of steady winds. Here the depressions of middle latitudes produce intermittent variations of conditions, yielding considerable local variations of wind, temperature and rainfall.

The July chart of mean pressure shows no fundamental difference from the conditions which prevail in January, so far as the southern hemisphere is concerned. In the northern hemisphere, however, the distribution of pressure has changed fundamentally. The Asiatic anticyclone has disappeared, and its function as the chief controller of conditions over Asia has been taken by a depression centred to the north of India. There is a continuous increase of pressure southward from the centre of the depression as far as the sub-tropical anticyclonic belt of the southern hemisphere. As a result, there is over the whole Indian ocean a broad current of air which blows into the southern edge of the depression as a south-west wind, known as the south-west *monsoon* of India (Simpson, "The South West Monsoon," *Q.J.R. Met. Soc.*). This current, having passed over warm ocean during a journey some thousands of miles in length, reaches India as a warm and very damp current. On reaching India it is forced by the configuration of the land to rise over the coastal ranges of mountains, and so gives rise to copious rainfall, which is known as the monsoon rainfall. It may be noted in passing that the word *monsoon* denotes seasonal, so that it might be applied to any seasonal changes of wind. The winds which blow around the south-eastern edge of the Asiatic anticyclone in winter are known as the north-east monsoon. An examination of charts of mean pressure month by month shows that the Asiatic anticyclone begins to diminish rapidly in intensity in April, and by early June the depression is formed. The monsoon winds, with the associated rainfall, develop during June, and usually persist until late September.

No verbal description of the distribution of temperature, pressure and wind over the earth's surface can take the place of an examination of the charts. The reader who desires fuller information is referred to Sir Napier Shaw, *Manual of Meteorology*, vol. ii., where maps are given showing the distribution of these elements, and some others, for each month of the year.

Rainfall.—In many respects rainfall (which for our present purposes will be taken to include all forms of precipitation, snow, hail, etc.) is the most important of all the meteorological elements. It is at the same time the most difficult of these elements to treat in a satisfactory manner, on account of its extreme variability with place, and the fact that an hour of torrential rain associated with a thunderstorm may affect in a marked manner the representation of both the mean diurnal and mean seasonal variations. What is known as the "normal" seasonal variation of any element is the average form of the annual cycle of that element taken over a number of years, but it is only over very restricted areas of the globe that the variation of rainfall in any one year will resemble at all closely the "normal" variation. The outstanding case where this is possible is that of the Indian peninsula, whose heavy rainfall in June to September is associated with the monsoon winds. The maximum rainfall in any year will occur within the period of the monsoons, and never outside it. Even in the British Isles averages taken over many years point to a definite maximum of rainfall in a particular month of the year. This month is October at Greenwich, December at Aberdeen and July at Edinburgh, but it would be extremely hazardous to apply this result to forecast the rainfall of any particular year.

Within the tropics rainfall usually has a well marked maximum and occasionally two maxima.

World Weather.—Under this title may be grouped a number of very extensive statistical investigations of the correlation between meteorological factors over different parts of the world. Among the most notable of these are two papers by G. T. Walker in the *Indian Meteorological Memoirs* (1923 and 1924) one by Walker and Bliss in the *Memoirs of the Royal Met. Soc.* vol. ii. No. 17, several papers by Exner in the *Sitzungsber. Akad. Wiss. Wien* (1913, 1924 and 1926); and a valuable general discussion of the work of other writers by Defant in the *Meteorologische Zeitschrift* (1926). Results of considerable value have been derived

by these writers, and an idea of the type of result obtained may be gathered from the following extract from a paper by Walker in the *Indian Meteorological Memoirs*, vol. xxiv. part 4: "We can best sum up the situation by saying that there is a swaying of pressure on a big scale backwards and forwards between the Pacific ocean and the Indian ocean, and that there are swayings, on a much smaller scale, between the Azores and Iceland, and between the areas of high and low pressure in the north Pacific: further, there is a marked tendency for the highs of the last two swayings to be accentuated when pressure in the Pacific is raised and that in the Indian ocean lowered."

VERTICAL DISTRIBUTION OF THE METEOROLOGICAL ELEMENTS

Temperature.—The rate of change of temperature with height is of fundamental importance in determining the processes of weather. The observations of Teisserenc de Bort showed that up to considerable heights the temperature decreases steadily with height, at an average rate of about 6° C per km., or 3° F per 1,000 ft., but that a limit is eventually reached beyond which the temperature remains constant, or even increases slightly at first. The lower region in which the temperature decreases with height is known as the *troposphere*, the upper region of vertically uniform temperature is known as the *stratosphere*, and the surface separating the two is known as the *tropopause*. Observations have now been obtained from a sufficient number of stations distributed over the earth to show that the tropopause is higher at the equator than at the poles, being on the average about 18 km. high at the equator, 6 km. high at the pole in summer, and coming down nearly to the earth's surface in winter. In intermediate latitudes, the height has intermediate values, the average height over southern Europe being given as 10·5 to 11 km. by W. H. Dines "The Characteristics of the Free Atmosphere," *M.O. Geophysical Memoirs*, No. 13.

A considerable amount of statistical work has been carried out by Dines (*M.O. Geophysical Memoirs*, No. 13), Schedler (*Beiträge Phys. fr. Atmos.* Bd. vii.) and others, into the relations which exist between the temperature at different heights, the pressures at different heights, the height of the tropopause, the temperature of the stratosphere, the total water-vapour-content of the atmosphere, and various other factors.

Diurnal Variation of Temperature in the Upper Air.—Reference has already been made to the diurnal changes of temperature on the Eiffel tower. Numerous observations have been made at greater heights, particularly a long series of kite soundings by Assmann in Berlin from Oct. 1, 1902, to Dec. 31, 1903, and of kite balloon ascents at Lindenberg. (*See Lindenberg Publications*, vol. xiv., 1922.) Temperature is far more variable at a height of 6 or 7 km. than it is at the ground, but we can draw no conclusion as to diurnal variations at different heights from this result. (*See* also W. H. Dines, *Q.J.R. Met. Soc.*, 1919; and *K. Mag. en Met. Obs. Batavia, Verhand* No. 4, 1916.)

Water Vapour.—Since temperature decreases with height, the saturation pressure of water vapour also decreases with height, and there is a finite limit to the amount of water vapour which the atmosphere can contain. The saturation pressure is independent of pressure, but on account of the rapid decrease of the density of dry air with decreasing pressure, we find that in saturated air the proportion of water to air is greater in the free air than it would be at the ground when at the same temperature.

The Variation of Wind with Height.—The variation of wind with height depends upon the horizontal distribution of temperature. It is therefore easy to realize that this variation cannot be summarized in a few words for the whole of the atmosphere. It is found that to a reasonable degree of approximation the motion of air is such as to produce a balance of the forces called into play, and this involves the motion of the air along the isobars, at all heights removed from the effects of surface friction. Near the ground the effect of friction is to diminish the velocity of the wind, causing the air to drift across the isobars from high to low pressure. It follows that in the lower layers the wind speed increases with height above the ground, while its direction veers (in the northern hemisphere). In the lowest layers, next to the ground, the wind speed increases rapidly, while the direction changes slowly, but at greater heights the increase of wind becomes slower, while the direction changes rapidly. The variations of wind in the lowest 2,000 ft. are nearly always in the sense indicated above. At greater heights the nature of the changes of wind depends upon the horizontal distribution of temperature, and upon the wind direction.

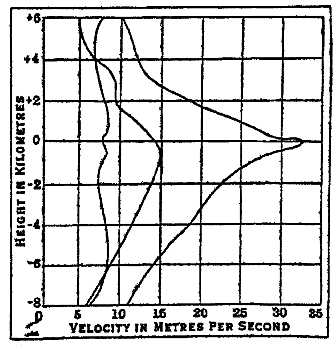

FIG. 3.—DIAGRAM SHOWING VARIATION OF WIND WITH HEIGHT

The variation of wind with height in the lowest layers can be represented with considerable accuracy by a formula $V=a+b \log (h+c)$, where h is height and a, b and c are constants (E. H. Chapman, *M.O. Professional Notes* No. 6). *Fig.* 3 (Dobson *Q.J.R. Met. Soc.*, 1920), shows the variation of wind with height in the upper part of the troposphere and the lower stratosphere. The heights are relative to the base of the stratosphere, and the data are classified according to the wind velocity in the highest two kilometres of the troposphere, the groupings being (a) less than 13 metres per sec., (b) 13 to 19 metres per sec., (c) greater than 19 metres per second.

The direction of the winds considered above showed no marked changes within the troposphere apart from the usual changes at the ground, and no appreciable change of direction was usually noted on passing into the stratosphere. The most noteworthy feature of fig. 3 is the steady increase of winds within the troposphere and the equally steady and rapid decrease within the lower stratosphere. The rapid falling off of wind in the stratosphere denotes that the stratosphere is warmer over low than over high pressure.

The general distribution of wind at different heights can be most readily summarized by reference to the distribution of pressure at different heights. Shaw (*Manual of Meteorology*, vol. ii., figs. 164–172) gives diagrams of isobars at the surface, and at heights of 4 km. and 8 km.

Further details of the variation of wind with height in different regions will be found in *Manual of Meteorology* vol. ii., 6. *See* also: van Bemmelen *Proc. K. Akad. Wet. Amst.*, (1918), Harwood, "The Free Atmosphere in India," *Memoirs Indian. Met. Dept.* (1924); *Arbeiten Preuss. Obs. Lindenberg*, especially vol. xiii.; Cave, *Structure of the Atmosphere in Clear Weather* (1912); Alfred de Quervain, *Schweizerische Gronlande Expedition 1912–13* (Zurich, 1920); E. Gold, "Barometric Gradient and Wind Force," M.O. 190, and "The International Kite and Balloon Ascents," *Geophysical Memoirs*, No. 5, M.O. 210.

STATICAL RELATIONS

The Fundamental Gas Equation.—The pressure p, the temperature T, the density ρ or the specific volume v, are connected by the relations:

$$p=R\rho T, \text{ or } pv=RT,$$

where R is a constant. If the pressure is in millibars, the temperature on the absolute centigrade scale, and the density in grams per cubic centimetre, or the specific volume in cubic centimetres per gram, the constant R is equal to $2{\cdot}8703\times10^{-3}$. When the air contains water vapour, but not sufficient to saturate it, an equation of the same form may be used with a slightly different value of R; but this equation must then be used only at temperatures which are sufficiently high to ensure that the air is not saturated.

The Variation of Pressure with Height.—The variation of pressure in the vertical is given by $\frac{\partial p}{\partial z}=-g\rho$. This equation is readily derived by the consideration of the vertical forces acting on a cube, two of whose faces are horizontal. It may be written in the form

$$\frac{\partial p}{\partial z}=-\frac{gp}{RT}, \text{ or } \frac{1}{p}\frac{\partial p}{\partial z}=-\frac{g}{RT}.$$

This equation cannot be integrated unless we know the manner in which temperature is related to height. If the temperature is constant the equation can be seen to yield on integration

$$\log\frac{p}{p_0}=-\frac{gz}{RT}, \text{ or } p=p_0\epsilon^{-\frac{gz}{RT}},$$

or

$$z=\frac{RT}{g}(\log p_0-\log p),$$

giving the height at which the pressure p is attained. If the relation of pressure to height is given by $T=T_0-\beta z$, so that

$$\frac{1}{p}\frac{\partial p}{\partial z}=-\frac{g}{R(T_0-\beta z)}, \text{ then } \log\frac{p_0}{p}=\frac{g}{\beta R}\log\frac{T_0}{T_0-\beta z},$$

These equations form the basis of barometric altimetry.

The Reduction of Pressure to Mean Sea Level.—When the pressure is measured at a station z metres above mean sea level, it is reduced to mean sea level by the addition of an amount equivalent to the weight of a column of air extending from the level of observation down to mean sea level; it being assumed that the mean vapour pressure through this column is equal to the vapour pressure at the point of observation, and that the mean temperature can be computed from the temperature at the level of observation, together with a lapse rate of 0·5° C per 100 metres. Moreover it is found that if the height of the station does not exceed 500 metres results well within the assigned limit of accuracy are obtained when we ignore the humidity of the air, and the variations of gravity with latitude and height, and adopt the dry bulb reading at the time of observation as the mean temperature of the column. For fuller details of these methods see *Computer's Handbook*, Section I.

Adiabatic Changes in Ascending or Descending Dry Air.—Let the state of the atmosphere be specified by the variables p, ρ, T, at height z, and let p', ρ', T' denote the state of any displaced mass when it is at height z. The accented letters will therefore refer to air which has been displaced from its normal environment. We denote specific heat of air at constant volume by c_v and at constant pressure by c_p. Let $v'=\frac{1}{\rho'}=$ specific volume of the moving air. In moving from height z to height $z+dz$, the loss of heat is equal to the work done by the moving mass in expanding against the action of the pressure due to the environment:

$$c_v dT'=-apdv',$$

where a is the reciprocal of the mechanical equivalent of heat

$$\frac{dT'}{dz}=-\frac{ag}{c_p}\frac{T'}{T}.$$

Thus the rate of decrease of temperature of air ascending adiabatically is proportional to the ratio of the temperatures of the moving air and of the environment at the same level. In all practical problems, this ratio may be taken as unity. Then $\frac{dT'}{dz}=-\frac{ag}{c_p}=0{\cdot}986°$ C/100 metres, or almost exactly 1° C per 100 metres.

Stability of Dry Air.—If a small mass of air originally at level z be displaced vertically to height $z+dz$, its temperature will change to $T+dT'$, where $dT'=-\frac{ag}{c_p}dz$. In its displaced position it will be lighter or heavier than its environment according as $\frac{dT'}{dz}$ is less or greater than $\frac{dT}{dz}$, *i.e.*, according as $\frac{dT}{dz}$ is $>$ or $<\frac{ag}{c_p}$. Hence the air is stable or unstable according as the lapse rate is less or greater than the adiabatic lapse rate of 1° C per 100 metres. It can be readily verified that the condition for stability is that the potential temperature shall increase with height.

Adiabatic Changes in Moist but Unsaturated Air.—The argument used above is applicable to moist unsaturated air, provided we give to R and c_p the appropriate values. The adiabatic lapse rate is given by $\frac{ag}{c'_p}$ where c'_p is now interpreted as the specific heat of the mixture of air and water vapour; but since the water vapour only accounts for a small fraction of the constitution of normal air, c'_p cannot differ by an appreciable amount from c_p, and the lapse rate for unsaturated air is only slightly less than that of dry air.

Adiabatic Changes in Saturated Air.—When saturated air rises through its environment the cooling produced by expansion causes condensation, and the latent heat so liberated becomes available for maintaining the temperature of the air. Let the air be composed of x kg. of water vapour to 1 kg. of dry air. When $(1+x)$ kg. of the mixture rises from a height z to height $z+dz$, a quantity dx of water vapour condenses, and an amount rdx of latent heat is liberated, and used in heating the mixture and the resulting water-drops. It will be assumed that the heating of the water-drops may be neglected. In practice most of the condensed water is eliminated, and the neglect of the heating of water-drops is in any case justified.

Near the ground $\frac{dT}{dz}$ has the value of 0·56° C per 100 metres. The saturated adiabatic lapse rate increases slowly with height, and at very low temperatures at which x has become very small, it approaches asymptotically the value of the dry adiabatic lapse rate.

The values of the adiabatic lapse rate for saturated and unsaturated air are of fundamental importance in meteorology. The mean lapse rate observed in the atmosphere is slightly greater than the saturated lapse rate, indicating stability for dry air, but instability for saturated air. In these conditions any mass of saturated air which rises becomes increasingly warmer than its environment at the successive levels which it attains.

Further, saturated air which is caused to descend immediately ceases to be saturated, and its temperature rises at the unsaturated or dry adiabatic lapse rate. Thus damp winds which rise over mountain ranges descend on the other side as very warm dry winds (*föhn winds*). The physical process involved in the consideration of the saturated adiabatic lapse rate is not in reality an adiabatic process, since, as we have seen, it is not reversible. For this reason it is frequently referred to as a *pseudo-adiabatic* process.

DYNAMICAL ASPECTS

The Equations of Motion in Three Dimensions.—The motion of an element of mass situated in latitude ϕ, longitude λ, at a distance r from the centre of the earth, may be represented by the following equations:

$$-r\cos\phi\ddot{\lambda}-2(\dot{\lambda}-\omega)(\dot{r}\cos\phi-r\sin\phi\,\dot{\phi})=X \qquad (1)$$

$$r\ddot{\phi}+2\dot{r}\dot{\phi}+r\cos\phi\sin\phi\dot{\lambda}(\dot{\lambda}-2\omega)=Y \qquad (2)$$

$$\ddot{r}-r\dot{\phi}^2-r\cos^2\phi\dot{\lambda}(\dot{\lambda}-2\omega)=Z-g, \qquad (3)$$

where ω is the angular velocity of the earth, g is the acceleration due to gravity, and X, Y, Z, are the components of the external forces resolved along axes drawn to east, to north, and vertically, respectively, but not rotating with the earth. In practice it is frequently more convenient to use cartesian co-ordinates referred to axes drawn as above, but rotating with the earth. The appropriate equations are:

$$\frac{du}{dt}-2\omega v\sin\phi+2\omega w\cos\phi=X \qquad (4)$$

$$\frac{dv}{dt}+2\omega u\sin\phi \qquad =Y \qquad (5)$$

$$\frac{dw}{dt}-2\omega u\cos\phi \qquad =Z. \qquad (6)$$

The derivation of these equations will be found in any standard textbook on dynamics; *e.g.*, Routh's *Rigid Dynamics*, vol. i. p. 205.

Equation (1) can be immediately integrated for the case of "no forces." Putting $X=0$, it may be written

$$\frac{1}{r\cos\phi}\frac{d}{dt}(r^2\cos^2\phi[\dot\lambda-\omega])=0,$$

$$\text{whence } r^2\cos^2\phi(\dot\lambda-\omega) = \text{constant.} \tag{7}$$

This equation simply states that when there are no forces the angular momentum about the axis of the earth is constant. If therefore we know the east to west component of velocity of a moving mass when in one latitude, we can compute the east to west component of velocity of that mass when it has moved to any other latitude. Care is needed in the use of this equation, since it represents only one aspect of the motion of the mass in question. By its use some highly questionable results have been derived in meteorology.

When there is no vertical velocity, there are only two equations

$$\frac{du}{dt}-2\omega v\sin\phi=X \tag{8}$$

$$\frac{dv}{dt}+2\omega u\sin\phi=Y. \tag{9}$$

The effect of the rotation of the earth is therefore allowed for by including in the statement of accelerations a term $2\omega\sin\phi\times$velocity, and it is readily seen that this acceleration is at right-angles to the direction of motion. This is known as the "deviating force due to the earth's rotation." The complete set of equations (4), (5), and (6) includes in addition an acceleration along the east-west line, which is positive to east when the motion is downward, and a vertical component of acceleration proportional to the east-west component of velocity. Equations (8) and (9) hold for any rectangular axes in the horizontal plane. The forces X, Y, Z include all forces other than gravitation, such as viscous or frictional forces, or the components of the gradient of pressure. The part of these forces due to the pressure distribution may be written

$$-\frac{1}{\rho}\frac{\partial p}{\partial x},\ -\frac{1}{\rho}\frac{\partial p}{\partial y},\ -\frac{1}{\rho}\frac{\partial p}{\partial z}$$

Equations of Horizontal Motion. Steady Motion.—The terms $\frac{du}{dt}$, $\frac{dv}{dt}$, $\frac{dw}{dt}$, above, represent the total acceleration of a given element of mass, or $\frac{d}{dt}$ is differentiation "following the fluid." In terms of the velocity at a given point, the equations become

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}-2\omega v\sin\phi=X, \tag{10}$$

$$\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}+2\omega u\sin\phi=Y. \tag{11}$$

In the special case of steady motion, $\frac{\partial u}{\partial t}=\frac{\partial v}{\partial t}=0$; and the terms, $u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}$, $u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}$ represent the centrifugal acceleration, plus the tangential acceleration. The deviating acceleration due to the earth's rotation is always at right angles to the path, and therefore cannot produce any change of velocity, but can influence the direction of motion. Any particle projected on the earth's surface, free from friction, will execute a circle, if we neglect variations of latitude. This circle is known as the *circle of inertia*. Its radius is proportional to the velocity of projection.

Horizontal Motion Under Balanced Forces. The Gradient Wind.—Equations (10) and (11) above form an algebraic statement of the balance between the accelerations relative to the earth and the deviating force, together with any other impressed forces. If V be the total velocity in the path, at a point where the radius of curvature is r, the accelerations relative to the earth are $\frac{V^2}{r}$ normal to the path, and $\frac{V\,dV}{ds}$ along the tangent to the path. Observational evidence points to the second of these terms being small by comparison with the other (Durward, *Professional Note No. 24, M.O. London,* and Shaw and Lempfert, *Life History of Surface Air Currents*), and it is usually left out of further consideration. Equations (10) and (11) then state that the centrifugal acceleration balances the sum of (a) the pressure gradient, which acts at right angles to the isobar, and is directed towards low pressure; (b) the deviating acceleration $2\omega V\sin\phi$ at right angles to the path; and (c) the viscous or turbulent resistance.

In the first consideration of the problem, we neglect the effect of friction and turbulence which are considered later. The centrifugal acceleration which acts at right angles to the path must then balance (a) and (b) above. Since however the centrifugal acceleration is along the same line as (b), it follows that (a), which balances the two, must act along the same line, and the motion under balanced forces must be along the isobars. The equation of motion then becomes

$$\frac{\text{pressure gradient}}{\text{density}}=2\omega\sin\phi\times V\pm\frac{V^2}{r} \tag{12}$$

The upper sign is used if the concave side of the isobar has low pressure, and the lower sign in the opposite case. These two cases correspond to cyclonic and anticyclonic curvatures of isobars.

It is convenient to represent the pressure gradient symbolically by $2\omega\rho G\sin\phi$, where ρ is the density of the air. Equation (12) then becomes

$$2\omega G\sin\phi=2\omega V\sin\phi\pm\frac{V^2}{r}. \tag{13}$$

The solution of equation (13) is called the gradient wind, and equation (13) is generally referred to as the gradient wind equation. The gradient wind is the wind which, blowing around the isobars, calls into play a centrifugal force and a deviating force exactly sufficient to balance the pressure gradient. When the isobars are not much curved, the term $\frac{V^2}{r}$ is small by comparison with $2\omega V\sin\phi$, and may therefore be neglected, and $V=G$. This particular solution is known as the *geostrophic* wind. Equation (13) may also be written

$$2\omega\sin\phi(V-G)=\pm\frac{V^2}{r}, \tag{14}$$

in which the upper sign is taken when the curvature of the isobars is anticyclonic, the lower sign when the curvature is cyclonic. It is readily seen from this that the geostrophic wind is an underestimate of the gradient wind in an anticyclone, and an overestimate in a cyclone.

The Solution of the Gradient Wind Equation.—For anticyclonic motion the solution of the quadratic equation (13) becomes

$$V=r\omega\sin\phi\left\{1\mp\sqrt{\left(1-\frac{2G}{r\omega\sin\phi}\right)}\right\} \tag{15}$$

Expansion of the radical gives

$$V=r\omega\sin\phi\left\{1\mp\left(1-\frac{G}{r\omega\sin\phi}-\frac{1}{2}\frac{G^2}{r^2\omega^2\sin^2\phi}-\text{etc.}\right)\right\}. \tag{16}$$

The upper sign gives a solution which is continuous near straight isobars, where $V=G$, while the second solution would demand indefinitely high velocities near straight isobars. Thus the only physically appropriate solution of (16) is

$$V=r\omega\sin\phi\left\{1-\sqrt{\left(1-\frac{2G}{r\omega\sin\phi}\right)}\right\}. \tag{17}$$

The corresponding solution for cyclonic motion is obtained

changing the sign of the radius of curvature r, and is therefore

$$V=r\omega\sin\phi\left\{\sqrt{\left(1+\frac{2G}{r\omega\sin\phi}\right)}-1\right\}. \qquad (18)$$

Equation (17) gives a system of winds blowing clockwise round a centre of high pressure, but everywhere with a velocity less than $r\omega\sin\phi$. The anticyclone therefore has a slower rate of rotation than the earth beneath it, and is therefore a counterclockwise circulation in space. Equation (18) gives a system of winds blowing counterclockwise round a centre of low pressure, both when considered relative to the earth and as motion in space. Thus both cyclone and anticyclone have in space the same direction of rotation as the earth beneath them. It can be readily verified that the second solution shown in equation (15) is a clockwise rotation in space, for both cyclone and anticyclone. Large scale systems conforming to this solution do not occur in nature, and the solution is to be regarded as an algebraic accident rather than as having a physical meaning. Some evidence has been adduced by Brunt (*Proc. Roy. Soc.*, A., 1924) to show that such systems would be unstable if they could be produced momentarily.

The geostrophic wind is readily evaluated by the use of a scale of reciprocals to measure the distance apart of consecutive isobars. The scale is graduated for standard density, and the small correction required for deviations from standard density is readily made. A detailed comparison of observed winds with winds computed from synoptic charts was carried out by E. Gold (*Barometric Gradient and Wind Force,* M.O. 190), and it was found that the geostrophic wind gives a close approximation to the wind observed at a height of 2,000 to 3,000 feet.

The computation of the gradient wind requires the solution of equation (13), which demands the evaluation of the curvature of the isobars, denoted by r. The gradient wind is therefore an inconvenient quantity to use, and the geostrophic wind is adopted as the most useful first approximation to the actual wind. The nature of this approximation is here emphasised because the major part of modern dynamical meteorology assumes the geostrophic wind as equivalent to the actual wind.

In low latitudes, where $2\omega\sin\phi$ is small, the term V^2/r usually exceeds $2\omega V\sin\phi$. Equation (13) then becomes meaningless for anticyclonic curvature, *i.e.* with the negative sign on the right hand side, showing that closed anticyclonic isobars are not physically possible as a steady state in low latitudes.

Effect of Changing Pressure Distribution.—The use of the gradient wind equation is, strictly speaking, restricted to regions where the pressure distribution is not changing. Brunt and Douglas (*Memoirs R. Met. Soc.* No. 22, 1928) have shown that in a region where the pressure distribution is changing the wind is approximately made up of the geostrophic wind with an added component blowing across the isallobars into the isallobaric low, and of intensity proportional to the gradient of isallobars. The magnitude of this component is readily evaluated from the chart of isallobars by the use of the geostrophic wind scale.

The hydrodynamical equation of continuity may be written

$$\frac{\partial\rho}{\partial t}+\frac{\partial}{\partial x}(\rho u)+\frac{\partial}{\partial y}(\rho v)+\frac{\partial}{\partial z}(\rho\omega)=0. \qquad (19)$$

If the effect of changing density be neglected it can be shown that systems of steady geostrophic winds satisfy the equation of continuity with no vertical velocity w. There can therefore be no convergence, and consequently no rainfall, in a system of geostrophic winds. The isallobaric components of winds discussed by Brunt and Douglas give convergence into regions of low values and divergence from regions of high values on the isallobaric charts, and so explain the rainfall associated with the low values, and fine weather associated with the high values.

The Nature of Wind. Turbulence.—On account of friction at the surface of the earth the air is always in turbulent motion, eddies being formed in much the same way as in a stream of water moving over an uneven bed. The pattern of the eddies is made visible by smoke from a chimney or other fire, but the fact that the motion of air is not steady motion is clearly shown by any anemometer chart on which the instantaneous velocity or direction of the wind differs considerably from the mean value over an interval of time. Since eddies formed in an air current are of finite size they must cause mixing of adjacent layers of air, and they therefore act as agents in diffusing momentum, heat, water vapour, dust, carbon dioxide, and other properties or constituents of the atmosphere.

G. I. Taylor (*Phil. Trans.* A, 1915) showed that the power of eddies for diffusing momentum, heat, or other constituents, may be represented by a constant K, the eddy diffusivity, which is roughly proportional to $\frac{1}{2}wd$ where w is the mean vertical component of velocity in the eddies, and d the mean diameter of the eddies. The value of K on any particular occasion will depend upon a number of factors, notably the nature of the surface of the ground and the lapse rate of temperature. Values of K have been estimated varying from 3×10^3 c.g.s. units in inversions over the Great Banks of Newfoundland, to 10^5 over Paris.

The theory elaborated by Taylor gives the flow of heat, etc. across unit area of a horizontal plane, moving with the mean motion of the air. This mean motion will depend upon the size of the area over which the mean is taken, since in the atmosphere there are eddies of widely varying sizes. The value of K which we adopt in a particular problem should therefore be a function of the size of the parcel of air with which we are concerned.

Taylor has approached the problem from a different standpoint in a paper in Proceedings London Mathematical Society 1921. Richardson (*Phil. Mag.*, 1925) has discussed the relation which must subsist between the vertical gradients of temperature and wind if turbulence is to increase. Richardson has also given a more general treatment of the question of turbulence, allowing for the possibility of K varying with height (*Proc. Roy. Soc.* A, 1919). In this connection *see* also a paper by Jeffreys in *Proc. Camb. Phil. Soc.*, 1929. An extension of these ideas to the general circulation, treating the cyclones and anticyclones as eddies, has been given by Defant *Geografiska Annaler*, 1921. A useful summary of the work of Richardson, Taylor and others is given by C. G. Rossby (*Monthly Weather Review,* 1927). The effect of turbulence upon evaporation from large sheets of water has been discussed by Giblett (*Proc. Roy. Soc.*, 1921) and Ångström (*Archiv. för Mat. Astr. och Fysik,* 1921).

The Variation of Wind with Height in the Lowest Layers.—If in fig. 4, $O\ G$ represents the geostrophic wind G in magnitude and direction, and $O\ P$ the wind at height z in magnitude and direction, then P sweeps out an equiangular spiral, and the line OS, representing the surface wind, is a tangent to this spiral. The spiral summarizes the distribution of wind with height in a convenient form. It attains the geostrophic velocity at a lower height than the geostrophic wind direction, and as was shown by G. I. Taylor (*Q.J.R. Met. Soc.*, 1914), this fits the observed facts with reasonable accuracy. The geostrophic wind should give a good approximation to the actual conditions at a height of about 1 km. It follows that the effect of turbulence due to the ground only extends to heights of 500–1,000 metres.

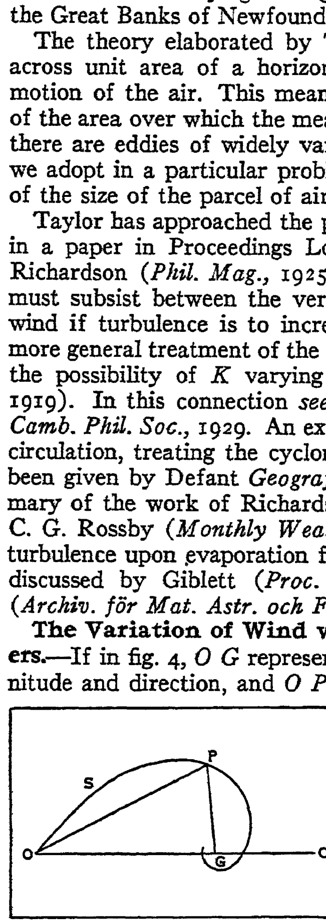

FIG. 4

Taylor's treatment of turbulence in terms of a coefficient K which is assumed to be independent of height thus enables us to account for the general nature of the variations of wind and temperature in the lower layers of the atmosphere, though the uncertainty as to the contribution of direct radiation and absorption to the temperature changes, renders uncertain any estimate of K from the temperature variations alone. The use of Taylor's coefficient K has led to a clearer physical understanding of the processes associated with turbulence in the atmosphere, yet it is certain that no theory at present available is capable of explaining all the facts. In this connection *see* also papers by L. F. Richardson in *Memoirs R. Met. Soc.* vol. i. No. 1, and *Proc. Roy Soc.* A, 1926.

A theoretical discussion of the form of clouds of smoke emitted from point and line sources, based on an extension of Taylor's method of treatment, has been given by O. F. T. Roberts in *Proc. Roy. Soc.* A, 1923. The subject of turbulent motion in the atmosphere has been discussed by Schmidt in a number of papers published in the *Sitzungberichte d. Wiener Akad. d. Wiss.* from 1917 onwards, by Sverdrup in papers in the publications of the Geophysical Institute, Leipzig, and elsewhere, and by Hesselberg in *Geofisiske Publ.* vol. iii. A discussion of this and many kindred subjects, together with full references to the work of English and Continental writers will be found in *Weather Prediction by Numerical Process* by L. F. Richardson, 1922.

Variation of Wind with Height in the Upper Layers.—The turbulence produced at the ground only affects the wind distribution in the lowest kilometre or so. Beyond these heights the variations of wind with height are to be ascribed to the horizontal distribution of temperature. For the wind at any level beyond the reach of turbulence will approximate to the geostrophic wind computed from the isobars at that level, and the distribution of pressure at any level depends not only on the distribution of pressure at mean sea level, but also on the distribution of the temperature in the intervening layers. Assuming the wind to be geostrophic mathematical analysis seems to indicate that when there is no horizontal gradient of temperature the wind is at all heights proportional to the absolute temperature. When there is a horizontal gradient of temperature the wind at a level z_2 can be derived from the wind at level z_1 by first reducing the wind at the lower level in proportion to the absolute temperature, and then adding to it a component blowing around the isobars of mean temperature in the intervening layer, keeping low temperature to its left, just as the geostrophic wind blows round the isobars, keeping low pressure to its left. The *Computer's Handbook* Section ii., Subsection 3, finds the magnitude of the horizontal temperature gradients corresponding to a given distribution of velocity.

The Transformation of Energy in the Atmosphere by Turbulence.—The effect of the vertical transfer of horizontal momentum by eddies can be represented as a virtual frictional force. Brunt has shown (*Phil. Mag.*, 1926) that the loss of energy of the winds due to turbulence is roughly equal to 5×10^{-3} kw. per square metre, amounting therefore to the equivalent of a little over 2% of the incoming solar radiation. In the same paper it is shown, with certain assumptions, that if there were no incoming solar energy, the effect of turbulence would reduce the winds to one-tenth their original value in six days. No such annihilation of the atmospheric circulation occurs, and the average conditions persist year after year. The loss of kinetic energy by turbulence is therefore continually compensated by the transformation of roughly 2% of the energy of the incoming solar radiation into kinetic energy. The compensation is not however to be regarded as a process which is always adjusted with precision. It probably proceeds by a kind of trial and error method, and this lack of smoothness must, in part at least, account for the variability of terrestrial weather.

The Classification of Winds.—If the motion of air be referred to three axes x, y, z, of which z is vertical, and x and y in the horizontal plane, drawn to east and north respectively, the equations of motion may be written in the forms

$$\frac{du}{dt}-2\omega v\sin\phi+2\omega w\cos\phi=-\frac{1}{\rho}\frac{\partial p}{\partial x}+K\frac{\partial^2 u}{\partial z^2} \qquad (1)$$

$$\frac{dv}{dt}+2\omega u\sin\phi=-\frac{1}{\rho}\frac{\partial p}{\partial y}+K\frac{\partial^2 v}{\partial z^2} \qquad (2)$$

$$\frac{dw}{dt}-2\omega u\cos\phi=-\frac{1}{\rho}\frac{\partial p}{\partial z}-g. \qquad (3)$$

Jeffreys (*Q.J.R. Met. Soc.*, 1924) has given a classification of winds based on the relative magnitude of the different terms in these equations. He points out that the pressure terms must always be important, since the contrary would mean that each portion of the fluid was free to pursue its own path independently of the remainder of the fluid, and unaffected by impacts with the surrounding portions. It could only be unaffected by the effect of impacts if the free path of a molecule were great when compared with the horizontal displacement of the fluid, a condition which is never satisfied in the portions of the atmosphere accessible to observation of any kind.

It can readily be shown that the left-hand side of equation (3) is usually negligible, and is always small by comparison with gravity. The acceleration $\frac{dw}{dt}$, even in thunderstorms, in which it probably attains its maximum value, never exceeds 5% of the gravitational acceleration. Equation (3) will therefore be replaced by

$$\frac{1}{\rho}\frac{\partial p}{\partial z}=-g \qquad (4)$$

and in equation (1) the term involving the vertical velocity w will be neglected. Since the pressure term is always important, at least one of the other terms must be comparable in magnitude with it. Jeffreys distinguishes three cases.

Eulerian Winds.—Case (1). The rotational and frictional terms are here small by comparison with the accelerational term. The winds satisfying these conditions are called "Eulerian," after Euler, who first found their equations.

Geostrophic Winds.—Case (2). The rotational terms far exceed both the accelerational and frictional terms.

The winds are everywhere along the isobars, with a velocity proportional to the gradient of pressure and to the secant of the latitude. Jeffreys calls such winds "Geostrophic," following Sir Napier Shaw.

Antitriptic Winds.—Case (3). The frictional terms exceed the rotational and accelerational terms, and the wind is driven by the pressure gradient, but its velocity is limited by friction, provided the journey is sufficiently long. Jeffreys calls these winds "antitriptic" (Gr. τρίψις = friction).

In applying this classification Jeffreys reaches the general conclusions that: (a) world-wide phenomena, including the general circulation and its seasonal variation, (b) phenomena on a continental scale, including the disturbance of the general circulation in the interior of continents, and (c) phenomena on a scale comparable with the British Isles, including the moving cyclone of temperate latitudes, all satisfy the condition that the rotational terms exceed the accelerational terms, so that they belong to classes (2) or (3) above. To distinguish between the two possible alternatives, Jeffreys appeals to observations of winds, which do not deviate more than four points from the isobar at the surface, and which at a height of a kilometre and above follow closely the direction of the isobars. These winds are thus at least approximately geostrophic. In tropical storms, whose average diameter may be taken to be comparable with 80 km., and in which the wind velocities may attain 70 metres per second, the accelerational terms are not negligible, so that the tropical storm is not geostrophic. Since the time of revolution of the tropical storm is only a few hours, while the storm might last for several days, the effect of friction must be relatively small, and the tropical storm, and *a fortiori* the tornado, must be Eulerian in character.

Jeffreys' detailed analysis of land and sea breezes, and of mountain breezes, show that they are mainly antitriptic.

The General Circulation.—The main features of the distribution of pressure and winds over the earth are best shown by maps. (*See* section on *Distribution of Winds over the Globe.*)

When we come to consider the theoretical explanation of the main features of the earth's circulation, we find that no satisfactory theory has been advanced to explain these phenomena. Two papers by Jeffreys in the *Q.J. of the R. Met. Soc.*, Jan. 1926 and Oct. 1927, indicate the most hopeful lines of future attack upon the problem. Jeffreys shows that no circulation which is completely symmetrical about the poles could maintain itself against friction, and concludes that the cyclones of middle latitudes are to be regarded as essential features of the general circulation rather than as disturbances superposed upon the general circulation.

Surfaces of Discontinuity.—The possibility of having two

currents of different densities flowing side by side with different velocities, separated by a definite surface of discontinuity, was first demonstrated by von Helmholtz. The slope of the surface of discontinuity to the surface of the earth can be derived from the equations (4), (5), (6) of the section *Dynamical Aspects*. The lines of the discussion would follow those laid down by Helmholtz and Margules. The two currents are assumed to be separated by a clearly defined surface of negligible thickness. In the atmosphere, however, this condition is never accurately reproduced, and the mathematical surface of separation is replaced by a layer of transition in which both the velocity and temperature change over gradually from one set of conditions to the other. Pilot balloon observations frequently display this layer of transition, whose thickness is usually of the order of 500 metres. It is not probable that the slope of the layer of transition differs much from the computed slope of the mathematical surface of discontinuity. The chief limitation met in the application of the formulae consists rather in the fact that the motions of the two currents are not always parallel to the surface line of separation, so that the warm current climbs up over the cold current.

THE ORIGIN OF CYCLONES OF MIDDLE LATITUDES

The Convection Theory.—The so-called convection theory of the origin of cyclones supposes that thermal causes produce a strongly localized ascending current in one place, and that the convergence of air from the surrounding regions to take the place of the air removed by the ascending current brings into existence a circulation of winds round the centre, in the counter-clockwise direction. The resulting cyclone is effectively to be regarded as a disc of revolving fluid. The nature of the circulations produced when fluid is removed from a disc of fluid revolving with a constant angular velocity ζ, was first given by Rayleigh (*Proc. Roy. Soc.* A., vol. xciii.) who showed that the resulting transverse velocity v at distance r from the centre is given by the equation

$$v=\zeta r+\frac{B\zeta}{r},$$

where B is proportional to the amount of fluid removed. It was shown by Brunt (*Proc. Roy. Soc.* A., vol. xcix.) that the original velocity of rotation ζ might be merely the rotation of the air with the earth, in which case the subsequent motion relative to the earth became

$$v=\frac{B\omega\sin\phi}{r}.$$

Thus intense localized convection in air originally still should give rise to a cyclonic circulation, provided it is possible for the air which rises to be carried away from the region in question, so as to provide for the diminution of pressure at the centre. The most obvious method of removal of the ascended air is by means of a strong current in the upper air. It is readily seen that unless there is somewhere in the upper air a current sufficiently strong to carry the ascended air quickly away from the region of ascent, there is no possibility of forming a cyclone. For if air is removed vertically from the lower layers, there is a converging flow of air from the surrounding region to take the place of the air removed, and the net result will be to increase the pressure over the region. This in turn will set up a pressure gradient opposing the inward motion, and must rapidly check the motion of convergence.

On this theory the cyclone consists of a column, or rather of a disc of revolving fluid, rotating about the centre of lowest pressure, and having a system of circular isobars. If the convection is set up in a moving current, the cyclone has the general motion of the current (Shaw, *Geophysical Memoir* No. 12 and *Proc. Roy. Soc.* A., 1917). This theory and some of its consequences have been discussed in some detail by Sir Napier Shaw in *The Air and its Ways*.

Shaw describes the cyclone as originating in the ascent of a mass of air which is lighter than its surroundings. The ascending mass of air has no inviolable boundary, and as it rises through its environment the turbulent motion set up at its boundaries causes a partial mixing with the environment, with the result that an increasing mass of air has its temperature raised above that of its immediate environment. This process is called the "eviction" of air.

The Polar Front Theory.—Dove developed in some detail the idea that a cyclone could be regarded as a region of opposition of warm and cold currents, and a number of later writers supported this same view. The work of Shaw and Lempfert (Shaw, *Forecasting Weather*, chap. 7) in the *Life History of Surface Air Currents* led them to the view that the air currents in a cyclone could be represented diagrammatically by fig. 5, and that the rain which fell in the cyclone could be explained by the forced ascent due to convergence, or by the ascent of warm air over cold air.

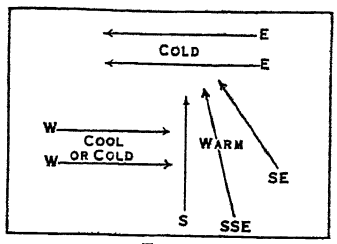

FIG. 5

Later V. Bjerknes combined this picture of the cyclone with the ideas of Helmholtz. The latter had shown that it was possible for two currents of different temperatures and different velocities to flow side by side, separated by a surface of discontinuity, the arrangement being entirely stable. Bjerknes ("The Dynamics of the circular vortex," etc., *Geofysiske Publikationer*, Oslo, vol. ii. No. 4 and "The Structure of the Atmosphere When Rain Is Falling," *Q.J.R. Met. Soc.*, 1920) suggested that the cyclone should be visualized as a wave on the surface of separation between cold easterly currents of polar origin, and warm westerly currents of equatorial origin. The cold air of polar origin is called "polar air," and the warm air of equatorial origin "equatorial air," while the surface of separation is known as the "polar front." The theory put forward by Bjerknes, the "polar front" theory, has not yet been fully developed. To begin with, the development of waves in an inclined surface of separation has not been treated with mathematical precision. The whole question of the exact processes involved in the production of cyclones at a polar front bristles with theoretical difficulties. The polar front is only inclined at a very small angle ($\frac{1}{2}°$ to $1°$) to the horizontal plane. Bjerknes regards the waves which form at the polar front as gravitational waves, and he suggests that the effect of the earth's rotation will be to increase the extent of the horizontal deviations, so that they become enormously greater (instead of much less) than the vertical displacements. The waves increase in amplitude, and a cyclone sometimes forms at the northern crest of a wave. This theory is strongly reminiscent of Emden's theory of sun spots (*Gaskugeln*, 1907). As put forward by Bjerknes it presents numerous gaps, and the argument is of a general character.

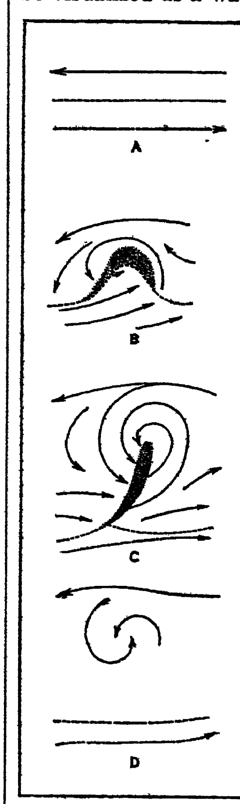

FIG. 6.—LIFE CYCLE OF CYCLONES

The process of formation of a cyclone according to this theory can be most readily explained by reference to the diagrams of figure 6, where in *a* the broken line represents a portion of the undisturbed polar front. The actual surface separating the warm and cold air is inclined to the horizontal at an angle of the order of $\frac{1}{2}°$, with the warm air above the cold. The first step is a bulge of the warm air into the cold air, as shown at *b*. This stage is marked by a fall of pressure at the tip of the tongue of warm air, and the bulge and the newly formed cyclone both travel with the warm current. This stage of the development is represented

in greater detail in figure 7, central portion, where the arrows represent the air currents, and the main rain areas are shaded. The association of rain with the ascent of air is clearly indicated in this diagram, there being an extensive area of precipitation in advance of the warm front. Heavy continuous rain does not occur in the warm sector. The lower diagram in figure 7 represents a vertical section from west to east across the warm sector.

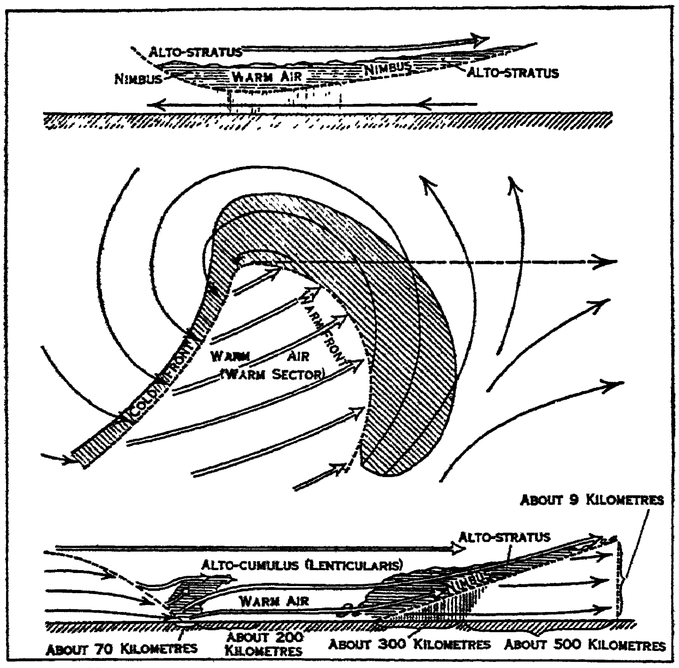

FIG. 7.—DIAGRAM OF IDEALIZED CYCLONE (YOUNG)

At the cold front the cold air pushes under the warm air, and this process is continued until the whole of the warm sector is lifted above the ground, as shown in figure 6c, and in the upper diagram in figure 7. The depression is then said to be occluded, and it subsequently diminishes steadily in intensity, and its motion dies away. Details of the association of weather with the polar front will be found in papers by J. Bjerknes and other Norwegian meteorologists in the *Geofysiske Publikationer,* Vols. i, ii, and iii, in papers by various English writers in the *Q.J.R. Met. Soc.* from 1923 onwards, and in a paper by J. Bjerknes, *Geophysical Memoirs,* No. 50.

A number of features of cyclones of middle latitudes can be more clearly realised by the study of fronts than has hitherto been possible. The Bjerknes cyclone starts its existence with a warm core, and ends with a cold core. Its cycle of growth is from asymmetry to symmetry, and only in the dying stage is the cyclone to be regarded as approximating to rotating fluid. The scheme of distribution of cloud and rain given by Bjerknes is in close agreement with the scheme of Abercromby which was previously accepted as the standard description of a cyclone, if we restrict our attention to the occluded cyclone, figure 6c. It is moreover undeniable that many of the cyclones which reach the British Isles from the Atlantic are occluded.

A very complete summary of the views of the Bergen (Norwegian) school, together with a detailed application of the Norwegian methods to a particular case of a polar front by Bergeron and Swoboda, in the *Proceedings of the Geophysical Institute* of Leipzig (vol. iii.) should be consulted.

A point of importance which is seldom mentioned in writings on these topics is that the cold front cannot be a true wedge with its point at the ground. The effect of friction at the ground, causing slowing down of the motion of air near the ground relative to the air at say 500 metres above the ground, is to cause the cold air to have a distinct nose raised above the ground. This has been confirmed by observations of temperature taken at different heights above the ground. Bjerknes has suggested that the polar front extends over very considerable distances, and may have a family of cyclones strung along its length. Each successive cyclone of a family passes further southward than its predecessor, and finally the family of 4 or 5 cyclones passes away, and a new family starts at a fresh polar front.

The practical application of the Norwegian ideas to the analysis of synoptic charts has led to very definite advances in forecasting weather, and though the theory which presents the cyclone as a wave in the polar front is very incomplete, the practical ideas developed by J. Bjerknes have helped to focus attention upon the physical consequences of the interaction of currents of air of different origin. It is beyond question that many cyclones do form at boundaries between cold and warm currents, and that they tend to follow the motion of the warm currents. Also the phenomena associated with the "occlusion" of cyclones are readily found on the weather map.

The Austrian View of the Origin of Cyclones.—Austrian writers, notably Exner (*Dynamische Meteorologie,* 2te Auflage, p. 337 *et seq.*), have regarded the development of cyclones at the surface of separation of warm and cold air as following a different course. In fig. 8 the cold air is shown shaded, the warm air unshaded. The first step is a deflection of the cold current southwards by one of the land masses of Greenland, Spitzbergen, Franz Josef Land, or Novaya Zembla, giving an outburst of cold air into the warm air, as shown in fig. 9 (a). The further development is shown in fig. 9 (b). The cold tongue C cuts off the direct supply of warm air into the region A, leading to the formation of a centre of low pressure there, with stream lines as shown in the diagram. The cold tongue is drawn along in the general direction of the warm air. Behind the cold tongue air is dammed up and forms an anticyclone.

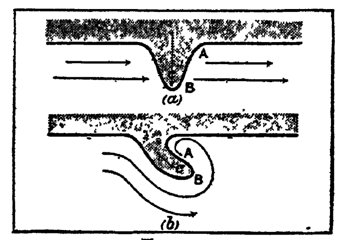

FIG. 8

Like the Norwegian scheme of construction of the cyclone, Exner's scheme attaches great importance to the phenomena of ascent and descent of cold air at fronts, but Exner does not regard the cyclone as of purely dynamical origin. Among recent important papers by Austrian writers on this and kindred subjects, reference should be made to papers by Exner in *Sitzungsber. Wiener Akad.* (from 1906 onwards), *Geografiska Annaler* (1920) and *Annalen Hydrog. u. Mat. Met.* (1919); by Ficker in the *Meteorologische Zeitschrift* (from 1910 onwards) and by A. Wegener in the same journal (1921). A paper by Ficker in *Met. Zeit.* (March, 1923) gives a bibliography of the more important papers up to that date.

The Amalgamation of Vortices.—In a series of papers (*Q.J.R. Met. Soc.,* vols. xlvii. and xlix.) Fujiwhara developed a theory of the origin of cyclones which he based upon observations of the behaviour of vortices in water. The usual hydrodynamical treatment of vortical motion in fluids leads to the conclusion that two vortices with the same sense of rotation should repel each other, while two vortices with opposite senses of rotation should approach each other. Fujiwhara's observations gave precisely the opposite result, that vortices rotating in the same sense attract each other and eventually amalgamate, and that vortices rotating in opposite senses should repel each other. Thus when a number of vortices having the same sense of rotation exist in proximity to one another, they tend to approach one another, and to amalgamate into one intense vortex. When a large vortex absorbs a smaller one, its intensity is increased. These results described in Fujiwhara's papers, are by no means new. Similar results are described by Mrs. Ayrton ("On a new method of driving off poisonous gases," *Proc. Roy. Soc. A.,* 1919), Ahlborn, (*Phys. Zeit.* xxiii.) and others.

The Travelling Anticyclone.—The anticyclone is to a certain extent the converse of the cyclone, in that it is a centre of high pressures and has a system of winds which blow round this centre in a clockwise sense relative to the earth. It is also commonly regarded as a region of descending air, but this is only true when the unit of time is the day or the week. The estimates which

have been made by Shaw of the rate of descent of air in anticyclones give velocities of the order of a few hundred metres per day.

No satisfactory theory of the origin of the travelling anticyclone has been evolved. Exner (*Dynamische Meteorologie* 2te. Aufl., p. 358) suggests that its origin may be due to the motion of currents of air from low latitudes which bring with them part of the stratosphere above them. Hanzlik (*Denkschriften Wiener Akad.*, 1908) investigated a number of anticyclones and classified them as "warm" and "cold." The cold anticyclone is shallow and does not extend to the stratosphere. Its motion is usually rapid. The warm anticyclone extends to higher levels, and its motion is slight. An anticyclone may frequently arrive over Europe as a cold anticyclone, but if it becomes stationary, then according to Hanzlik it may become warmer and more intense.

The line-squall, waterspout, and tornado are discussed in some detail by M. A. Giblett on "Line-Squalls," *Journal Roy. Aero. Soc.* 1927. Tropical cyclones (hurricanes) are described in any textbook (*e.g.*, Geddes' *Meteorology* or Hann's *Lehrbuch der Meteorologie*). Exhaustive studies of these phenomena are given by Mrs. E. V. Newnham in *Geophysical Memoir* No. 19, and by Cline in *Tropical Cyclones*. A fully illustrated article on "Tornadoes" by R. de C. Ward will be found in the *Quarterly Journal R. Met. Soc.*, 1917.

Elastic Oscillations of the Atmosphere.—Mathematical discussions of the elastic oscillations of the Atmosphere have been given by Rayleigh (*Collected Papers*, vol. iii. p. 335, and *Theory of Sound* § 333), and by Margules (*Sitzungsber. Wiener Akad.* ci part 2a, cii part 2a. An abstract of these papers was given by Trabert in *Met. Zeit.*, 1903).

At any station in the tropics a barograph trace shows two complete waves each day, maxima occurring approximately at 10 A.M. and 10 P.M., and the minima at 4 A.M. and 4 P.M. local time. The amplitudes of these waves are greatest at the equator, and diminish with increasing latitude. Beyond latitude 50°, this double wave becomes indistinct, and in latitudes above 70°, the nature of the phenomena changes. Near the poles the maxima of the pressure waves occur everywhere at approximately the same absolute time, between 10.30 and 13.30 Greenwich mean time (Simpson, "The Twelve-Hourly Barometer Oscillation," *Q.J.R. Met. Soc.*, 1918).

SOME PHYSICAL CONSIDERATIONS

Radiation in the Earth's Atmosphere.—The sun has an "effective" temperature of about 6,000° C and the position of maximum intensity in the band of wave lengths covered by the solar spectrum is at about 0·7 μ. Such radiation is only very slightly absorbed on its passage through the atmosphere, and so reaches the earth's surface with only a slight diminution of intensity by absorption, though with some loss by reflection from clouds. At the earth's surface, and particularly over the sea, some of the incoming beam of solar radiation is reflected upwards, while the remainder is absorbed. The radiation reflected back from clouds or the earth's surface passes outwards with very slight loss by absorption, and is therefore of no effect in heating the earth or its atmosphere. Aldrich (*Annals Astroph. Observatory* iv., App. 2, 1922) computes the fraction of radiation lost by reflection by clouds, the earth's surface, dust and other causes as ·43.

The earth in turn sends out radiation, whose wave-length is appropriate to its temperature. The maximum intensity of the terrestrial radiation is in the neighbourhood of 10 μ and such radiation is partly absorbed by the water vapour in the atmosphere, which also in turn sends out long wave radiation.

In any discussion of the effects of radiation upon an isolated element of air we must therefore take into account the radiation coming upward from the lower layers of the atmosphere, and the radiation coming downward from the upper layers of the atmosphere. Unfortunately these do not include all the possible sources of heat affecting the element of mass under consideration. As we have seen in the section *Dynamical Aspects*, one of the effects of turbulence is to produce a vertical flow of heat, which is upward or downward according as the lapse rate is greater or less than the adiabatic. In addition to this, there is a latitude transfer of heat. The equator being warmer than the poles, any motion of air across the circles of latitude carries warm air pole-ward or cold air equator-ward. Hence in considering the radiative effects over any particular zone, we must allow for the fact that it receives heat not only by direct radiation from the sun, but also by horizontal convection from other latitudes.

In computing the total amount of the incoming solar radiation, a deduction of 43% is made from the theoretical value, to allow for albedo or loss by reflection.

Variability of the Solar Constant.—The intensity of solar radiation falling in unit time on unit area of a surface placed perpendicular to the incoming beam, and at a height sufficiently great to be free from the scattering and absorption of the atmosphere, is called the *solar constant*. Its mean value is usually given as 1·93 gram calories per sq.cm. per minute, or 135 kw. per sq.dm. A long series of measurements at the Carnegie Institution's observatory on Mt. Wilson show it to vary between 1·90 and 1·98. Clayton in a discussion of solar activity and long period weather changes (*Smithsonian Misc. Coll.*, vol lxxviii., No. 4), shows that high values at Mt. Wilson are simultaneous with high values at Calama, Chile. This appears to establish definitely that the changes noted from time to time in the measurements of solar radiation are real changes in the amount of solar radiation. (See *Annals of the Astrophysical Observatory of the Smithsonian Institution.*)

Abbot has recently discovered a persistent period of 15¾ months in the variation of the solar constant, and there is evidence of a number of other shorter periods. It has been suggested by American writers that the variations of the solar constant are effective in varying terrestrial weather (H. H. Clayton, *World Weather*).

The Direct Effects of Incoming Solar Radiation.—The process of *convection* of heat does not become effective until the lapse rate has surpassed the adiabatic limit, but temperature at some distance above ground begins to rise before the lapse rate has reached the adiabatic limit. This phenomenon is probably due to the effect of direct radiation from the ground. The combined effects of radiation and turbulence have been discussed by Chapman (*Q.J.R. Met. Soc.*, 1925) and Brunt (*Proc. Roy. Soc.*, 1929, and 1930). Over land, the lapse rate near the ground may amount to several hundred times the dry adiabatic on sunny afternoons, while at night the cooling of the ground by radiation to clear skies builds up large inversions. The effect of night cooling on the formation of fog and mist has been discussed by G. I. Taylor (*Q.J.R. Met. Soc.*, 1917).

Over the oceans more incoming radiation is lost by direct reflection, some is used up in evaporation of water, and a considerable depth of water is necessary to absorb completely the remainder. Further the specific heat of water is about four times that of dry soil. Hence the temperature of the surface of the sea is far less variable than that of a land surface, and observations indicate that the diurnal range of temperature over the sea is of the order of 1°F. For the same reasons the seasonal variation of temperature is much less over the sea than over land, and so oceanic climates are more equable than land climates.

Efforts have been made to explain the existence of the stratosphere as a direct effect of balance of incoming and outgoing radiation. Reference should be made to the original memoirs of Gold (*Proc. Roy. Soc.*, 1909), Humphreys (*Astrophysical Journal*, 1909), Emden (*Sitzber. bayr. Akad. Wiss.*, 1913) and Milne (*Phil. Mag.*, 1922). Estimates of the amount of radiation leaving the earth in different latitudes have been given by Mugge (*Zeitschrift für Geophysik*, 1926) and Simpson (*Memoirs R. Met. Soc.*, 1928, 1929).

Mathematical discussion of the effects of radiation in the atmosphere is complicated by the presence of air and water vapour in varying proportions. The dry air is of little consequence in producing absorption or radiation, but as it shares with the water vapour the heat which the latter absorbs, its presence is equivalent to weighting the water vapour with an added specific heat.

The Ascent and Descent of Air.—While the lapse-rate remains on the average less than the dry adiabatic, but slightly greater than the saturated adiabatic, we can readily conceive

of any isolated mass of air which has become saturated and at a slightly higher temperature than its environment, being able to rise through its environment, since in the circumstances postulated its temperature would be at each successive level higher than that of its immediate environment. The converse process of the descent of air, however, is not readily understandable. This problem has not yet been satisfactorily solved, probably because the time scale of radiation effects has not been clearly laid down, and until this problem is solved it will not be possible to evolve a satisfactory explanation of the general circulation of the atmosphere. The direct effect of solar radiation is an ascent of air in the doldrums. The air which ascends flows away from the equator and it is of vital importance to determine at what stage in its flow poleward such air will be in a suitable condition to descend again to the surface of the earth.

The existence of ascending currents on a large scale is shown by the occurrence of rainfall, and it is thus possible to obtain some idea of the extent and intensity of such currents. Descending currents are usually less rapid, and in consequence their physical effects may be largely masked by the horizontal motions of the air. The outstanding feature of the distribution of temperature in the troposphere is its approximation to horizontal stratification, which is not a condition favourable to the descent of large masses of air from high levels to the ground. Moreover it appears probable that the conditions existing in the upper air do not show the same variability from place to place which characterises the surface layers.

The amount of energy which can be made available by vertical motion in particular cases can be evaluated by means of the tephigram (vide Shaw, *Manual of Meteorology*, Vols. i, iii). For an important discussion of the use of the wet bulb temperature in connection with the thermodynamics of vertical motion reference should be made to a paper by Normand (*Memoirs Indian Met. Dept.*, Vol. xxiii).

The Maintenance of the Atmospheric Engine.—It has been shown by Jeffreys (*Q.J.R. Met. Soc.*, 1926) and Brunt (*Phil. Mag.*, 1926) that if no external source of energy were effective the atmosphere would be brought to rest relative to the earth in about 10 days by friction. Brunt has shown that the energy destroyed by friction could be made good by the conversion of about 2 per cent of the energy of the incoming solar radiation into kinetic energy. This may in part be brought about by the ascent of heated air in the doldrums, followed by motion poleward and descent in latitude 35° North or South in consequence of cooling, but the physical processes involved in such a cycle are not clearly understood (see *Dictionary of Applied Physics*, vol. iii, article by N. Shaw). Further the general circulation of the atmosphere has been shown to be a very complex phenomenon, lacking symmetry about the earth's axis, so that no simple theory can be expected to explain it. It is now considered that the cyclones and anticyclones form an essential part of the general circulation, (*see* Jeffreys *Q.J.R. Met. Soc.*, 1926, 1927, and Exner *Dynamische Meteorologie*, 2nd edition, chap. ix). The distribution of temperature in the upper atmosphere, in particular the fact that the stratosphere is highest and coldest over the equator, is bound up with the general problem of the circulation of the atmosphere. For a discussion of some aspects of the stratospheric distribution see various papers by Simpson in the *Memoirs R. Met. Soc.*, 1928, 1929. For a discussion of the present position of theories of the general circulation of the atmosphere by E. W. Barlow see *Quarterly Journal R. Met. Soc.*, Jan. 1931; *see* also a paper by T. Bergeron in *Meteorologische Zeitschrift*, 1930. The work of Dobson and others on the distribution of Ozone (see *Proceedings of the Royal Society*, 1929, 1930) suggests a new line of attack upon some problems associated with the general circulation.

The Present Position of Meteorology as a Science.—The preceding pages give an outline of such parts of the Science of Meteorology as may be considered to be definitely accepted. In spite of the immense volume of literature on the subject, the amount of progress which has been made is still slight, and there remain many outstanding problems. Among these may be noted (1) various aspects of the distribution of temperature in the free atmosphere, (2) the nature of turbulence, (3) the physical causes underlying the formation of depressions and anticyclones and (4) the true nature and method of maintenance of the general circulation.

Under heading (1), at least four difficulties remain unsolved.—(a) The approximate constancy of the mean lapse-rate at all heights within the troposphere and in all latitudes. (b) The sudden nature of the change in lapse-rate at the tropopause. (c) The relative constancy of the lapse-rate within the stratosphere, and (d) The decrease of temperature within the stratosphere from equator to pole. With regard to (2) the defects of existing theories have been outlined on page 351. With regard to (3) and (4), which are perhaps only different aspects of the same problem, there is not available any satisfactory theory of the origin of the depression and anticyclone, and even the subtropical anticyclonic belts which form the most permanent feature of the earth's atmosphere have as yet not been adequately explained. Nor is it clear to what extent changes of pressure are to be ascribed to the effects of instability in the lower atmosphere, or to the effects of advection in the upper atmosphere. Until these problems have been solved at least in part, it is difficult to see how the practical application of the science of meteorology to the successful forecasting of weather can make any further progress.

METER, GAS: *see* GAS METER.

METER, WATER: *see* WATER METER.

METERS, ELECTRIC. These include induction-motor, mercury-motor and commutator meters, which register the revolutions of a disc or other armature caused to revolve, by the action of the current, at a speed proportional to the amperes or watts passing through the meter, and electrolytic meters in which the current or a shunted fraction of it passes through an electrolyte and decomposes it, the rate of decomposition being proportional to the current employed.

Induction-motor Type.—In the Ferranti alternating current watt-hour meter, a series coil of a few turns of thick wire carrying the main current is arranged below, and a shunt coil of many turns of fine wire is arranged above a horizontal rotary disc of aluminium. This disc is situated in the gap between the poles of a permanent magnet and the lower bearing of its vertical spindle is a sapphire carefully selected to reduce friction to a minimum. The magnetic fields due to the shunt and series windings produce a resultant rotating or shifting field which interacts with eddy

currents, induced in the disc so as to exert a driving torque proportional to the watts. A retarding torque is produced by the action of the permanent magnet also causing the speed of the disc to be proportional to the watts. A worm on the spindle drives the registering train; the registering dials are of the clock pattern, or of the cyclometer pattern.

To read the meter is a simple operation. In the clock pattern, starting from left to right, the figure last passed by the thousands pointer in its revolution is written down and the same procedure is followed for the hundreds, tens and units pointers in succession, the tenths registered on the small lower dial being read only when testing the meter. In the cyclometer pattern, the figures are written down just as they appear on the register. The cyclometer figure wheels are actuated by a falling weight; thus, the changing of the figure wheels does not throw any extra load on the meter.

Mercury-motor Meters.—In the Chamberlain and Hookham direct current ampere-hour meter, a copper disc is caused, by the action of the current, to rotate in a mercury chamber subject to the influence of a magnetic field due to a large permanent magnet. The vertical spindle of the disc, arranged to rotate with the minimum friction, is connected to the registering train with its series of clock dials. The peripheral wall of the mercury chamber is formed by a leather-lined metal band which is readily removable to permit inspection and refilling with mercury.

Commutator Meters.—Commutator meters have a wound armature connected in parallel with a shunt and arranged to rotate in the field of a permanent magnet.

Electrolytic Meters.—In the Reason syphon-tube meter, a solution of a mercury salt is hermetically sealed in a container, at the top of which are arranged a mercury anode and a cathode. During the operation of the meter, mercury is liberated at the cathode and collects in a syphon tube in the container; this tube, when full of mercury, discharges into the lower part of the container. Close to the right limb of the syphon tube is a vertical scale which registers the mercury level; in one form of the meter, this scale reads from 0 to 200 units. Below the scale is another which registers the level of the lower mercury column; this scale may read from 0 to 4,000 units. When reading the meter, both scales are read and the sum of the readings is taken. The Reason single-tube meter has one vertical mercury tube, which is read like a thermometer. In both forms, the mercury can be used repeatedly, the meters being re-set by tilting; the container is flexibly mounted to facilitate this operation.

In the Bastian electrolytic meter, acidulated water is decomposed by the action of the current, and the amount of water decomposed is read off on a vertical scale. (T. E. L.)

METHODISM, a term denoting the religious organizations which trace their origin to the evangelistic teaching of John Wesley. The name "Methodist" was given in derision to those Oxford students who in company with the Wesleys used to meet together for spiritual fellowship; and later on when John Wesley had organized his followers into "societies" the name was applied to them in the same spirit. It was however accepted by him, and in official documents he usually styles them "the people called Methodists." The fact that standards of Methodist doctrine are laid down as consisting of "Mr. Wesley's Notes on the New Testament and the 1st Series of his Sermons" (fifty-three in number), might seem to indicate a departure from existing systems, but it was not so. He fully accepted the recognized teaching of the Church of England, and publicly appealed to the Prayer Book and the Thirty-nine Articles in justification of the doctrines he preached. Methodism began in a revival of personal religion, and it professed to have but one aim, viz. "to spread Scriptural holiness over the land." Its doctrines were in no sense new. It was the zeal with which they were taught, the clear distinction which they drew between the profession of godliness and the enjoyment of its power—added to the emphasis they laid upon the immediate influence of the Holy Spirit on the consciousness of the Christian—which attracted attention, gave them distinction, and even aroused ridicule and opposition. Wesley and his helpers, finding the Anglican churches closed against them, took to preaching in the open air; and this method is still followed, more or less, in the aggressive evangelistic work of all the Methodist Churches. As followers rapidly increased they were compelled to hold their own Sunday services, and this naturally led them to appoint as preachers godly laymen possessing the gift of exhortation. These followed their ordinary avocations on week-days, but on Sundays preached to congregations in their own immediate neighbourhood, and hence were called *local preachers* as distinguished from *travelling preachers*. Some 13,000 congregations, chiefly in the villages, are dependent on local preachers. In the organization adopted to foster spiritual life the very characteristic "Class-meetings for Christian fellowship" take a prominent place. Membership in the church depends solely upon being enrolled in such a meeting for Christian fellowship, and accepting pastoral oversight.

The *Wesleyan Methodists* now represent the original body as founded by John Wesley in Great Britain and Ireland; but in America those who looked upon him as their founder adopted the episcopal mode of Church government after the War of Independence, and have since that time been known as *Episcopal Methodists* (*see* below). It should be noted that the *Welsh Calvinistic Methodists* are only slightly connected with the original body. They were indirectly the outcome of the evangelistic efforts of Howell Harris and Rowlands. Their work received the sympathy of Wesley and liberal financial help from the Countess of Huntingdon. For a time Whitefield was leader, and we find a reference to the "Whitefieldian and Wesleyan Methodists" in the Supplement to the *Gentleman's Magazine* for 1747, p. 619. The theological views of these teachers proved quite incompatible with the Arminianism of Wesley, and a definite breach between them and him took place in 1770. Other divisions have been formed at various times by secessions from the Wesleyan Methodists not on points of doctrine but on matters of church government. They are: Methodist New Connexion (founded 1797–1798); Bible Christians (1815); United Methodist Free Churches (about 1836); Primitive Methodists (founded 1807–1810); Independent Methodist Churches (about 1806); Wesleyan Reform Union (1850, reorganized 1859). The first three of these were joined in 1907 under the name of the United Methodist Church. *See* WESLEYAN METHODISTS, CALVINISTIC METHODISTS, PRIMITIVE METHODISTS, together with separate articles on the other bodies named above; and on the American branches, *see* below.

Missions.—The British Foreign Missionary Societies working under the direction of the three Methodist Conferences have a record of expansion and success. The Wesleyan Missionary Society has erected and equipped 12 colleges with 5,031 students, and also 36 high schools with 6,068 scholars, in addition to 16 theological and normal training institutions for native preachers. Important medical, agricultural and industrial hospitals and schools have also been established in West Africa, South India and China. These societies work in close co-operation with other branches of Christendom by adopting the apportionment of regions of missionary enterprise. They develop a missionary spirit among the native Christians and the creation of a native ministry.

Educational and Social.—The decline in the number of Sunday school teachers and scholars has given serious concern to the conferences. Efforts have therefore been made to increase the efficiency and the attractiveness of the Sunday schools, the work of which is not limited to Sunday, nor to school methods. The boy scouts, girl guides and life brigade movements, summer schools and Bible study circles supplement the work of the Sunday schools. The Wesley Guild and Christian Endeavour societies in British Methodism and the Epworth League in America are doing much to consolidate the work among young people.

In addition to a number of important educational institutions, the three British Methodist Churches have six theological colleges for training candidates for the ministry, which are being more and more brought into line with the curriculum of the various universities. In 1926 Oxford celebrated the bi-centenary of the election of John Wesley to a fellowship of Lincoln College, and, to honour the occasion, conferred the degree of Doctor of Divinity upon the Rev. John H. Ritson, the president of the mother conference, a scholar and graduate of Balliol College, and the first Oxford man elected to the chair of John Wesley.

*Seating accommodation, 2,418,356.

†These figures include the Solomon Islands Mission with 64 lay preachers, 4,791 members, 41 Sunday schools, 1,384 scholars and 122 churches and preaching places.

**Methodism is also represented in several European countries by Conferences and Missions affiliated to the Methodist Episcopal Church of America, and their membership is included in the figures given above. The latest returns available are: Austria, 1,042 members; Bulgaria, 757; Denmark, 4,201; Finland, 2,254; France, 1,094; Germany (North), 23,200; Germany (South), 18,054; Hungary, 692; Italy, 3,860; Jugo-Slavia, 1,440; Norway, 7,567; Russia (and Baltic Mission), 3,545; Sweden, 16,475; Switzerland, 11,938.

Another department of British Methodism is its home missionary work in the villages and city centres. Wesleyan Methodism has its connectional and lay evangelists. Open air evangelistic services are regularly held, and in many places the theatres and public halls are utilised for extra services. New central halls take the place of down-town churches.

The British Methodist churches have been impressed with the economic and social results which have followed prohibition (*q.v.*) in the United States. Each of the sections has an active temperance and social welfare department. The three Churches have adopted a progressive temperance policy—first of local option, secondly, the complete extension of magisterial licensing authority to all political and social clubs, rich and poor alike; and, thirdly, the entire Sunday closing of all drinking bars.

The Methodist Brotherhood works in unison with the Dominion agents in London, who assist emigrants to the United States, Canada, Australia and South Africa, arrange their passages, and secure them employment. The Brotherhood embraces all Methodist churches, and it has met with success in bringing the emigrant into touch with Methodism overseas.

Methodist Union.—Methodist union transcends in importance all other movements in Methodism at the present time, and it is probably fraught with more momentous issues to the churches concerned than anything since the death of Wesley. A great impetus was given to this movement by the decennial gatherings of the Methodist Oecumenical Conference, which, instituted in 1881, meets alternately in London and America. It consists of delegates from all parts of the world, half of whom are ministers and half laymen. Each assembly has been followed by some decisive step forward along the path of union, and in all cases the ministry has loyally accepted the decisions of the majority. The results of union have far exceeded the anticipations of the churches, and there has been a great increase in membership and revenues.

In 1913, the Wesleyan Methodist Conference appointed a committee to collect information on the subject of union and to report to the next Conference. A final scheme of union was submitted to the yearly conferences of the three Churches in 1925 and was adopted by a very large majority.

General Statistics.—The general statistics of Methodism throughout the world are given in the table on p. 358, based on the latest returns obtainable.

METHODISM IN THE UNITED STATES

There are in the United States sixteen distinct Methodist denominations, all agreeing essentially in doctrine. John Wesley had been conducting his United Societies for more than twenty years before the movement took root in North America.

A.—Episcopal Methodist Churches.—Philip Embury (1729–1775), a Wesleyan local preacher, emigrated in 1760 from Limerick to New York. Robert Strawbridge (?–1781), a local preacher and native of Ireland, settled in Maryland. In 1766 Embury was stimulated by his relative, Mrs. Barbara Heck, to begin Methodist preaching, and a society was soon formed which grew rapidly. Five years later Francis Asbury was sent over, and was made assistant superintendent. Meanwhile Strawbridge had been preaching with success in Maryland and in Virginia. These "advance agents" of his spiritual propaganda brought with them Wesley's Arminian Theology. They brought also "the means of grace" on which Wesley placed the greatest stress; such as personal testimony in private and public, class and prayer meetings, watch-nights, love-feasts, the direct and fervent preaching of the Gospel and the singing of Wesleyan hymns, carried on by means of circuits and stations and exhorters. Wesley appointed Thomas Rankin (*c.* 1738–1810) superintendent of the entire work in America.

The first American Conference was held in 1773, and consisted of ten preachers, all of whom were born in England or Ireland. Asbury came to America to remain permanently; but Rankin, unable to identify himself with its people, to take the test oaths required in the Revolution, or to sympathize with the colonies, returned to England, as did all the English preachers except Asbury. By May 1776 there were 24 preachers and 4,921 members; but in the first year of the Revolution there was a loss of 7 preachers and nearly 1,000 members.

The preachers in the South determined upon administration of the sacraments, and a committee was chosen whose members ordained themselves and others. The Northern preachers opposed this step and for several years the Connexion was on the verge of disruption. An agreement was finally made to suspend the administration until Wesley's desires and judgment should be ascertained. He perceived that the society would disintegrate unless effective measures were speedily taken, and early in 1784 he ordained Thomas Coke (1747–1814), already in orders of the Church of England, as superintendent. Wesley sent Coke to America as his commissioner to establish, for the Methodist Society, a system of Church government, which should include the administration of Baptism and of the Lord's Supper. Wesley also appointed Thomas Coke and Francis Asbury "to be joint superintendents over our brethren in North America." Soon after Coke and his companions arrived they met Asbury and fifteen preachers, and a special conference was called, which opened on the 24th of December, 1784, in the suburbs of Baltimore, Maryland. This convention organized itself into a Methodist Episcopal Church, in which the liturgy sent by Wesley should be read, and the sacraments should be administered and deacons to be ordained by a presbytery using the episcopal form. Coke and Asbury were unanimously elected superintendents, Coke, aided by his clerical companions from England, ordaining Asbury as deacon and elder and formally consecrating him a general superintendent. This convention adopted the first Discipline of the Methodist Episcopal Church. It adopted the existing doctrinal standards, consisting chiefly of Wesley's Sermons and his Notes on the New Testament; also twenty-five of the Articles of Religion of the Church of England, modified so as to eradicate all trace of High Church ritualism, Anglican or Roman, and the distinctive doctrines of Calvinism. The Church thus established began its ecclesiastical career with 18,000 members, 104 travelling preachers, about the same number of local preachers, and more than 200 licensed exhorters. There were 60 chapels and 800 regular preaching places. Within five years the number of preachers swelled to 227, and the members to 45,949 (white) and 11,682 (coloured).

To bind the whole body the existing method required the concurrence of each Annual Conference with every proposition. This was inconvenient and occasioned much loss of time; therefore a General Conference was established to meet once in four years. The first was held in 1792, and therein arose a sharp conflict. James O'Kelly (1735–1826), a Presiding Elder in control of a large district, proposed that, when the list of appointments was read in the Conference, if any preacher was not pleased with his assignment he might appeal to the Conference. The motion being lost, O'Kelly and several other preachers seceded. As all "travelling preachers" were eligible, without election, to seats in General Conferences, widespread dissatisfaction prevailed among the distant Conferences. The era of the steamboat and the railway not having arrived, it was possible for two Annual Conferences, adjacent to the seat of the General Conference, to out-vote all others combined. This led to a demand for the substitution of a delegated General Conference, which was conceded by the Conference of 1808 to take effect four years later.

The slavery storm burst on the Conference in 1844. Bishop James Osgood Andrew (1794–1871), a native of the South, had, by inheritance and marriage, become a slaveholder. After debates of many days, he was requested "to desist from the exercise of the office of Bishop while this impediment remained." The Southern members declared that the infliction of such a stigma upon Bishop Andrew would make it impossible for them to maintain the influence of Methodism in the South, and a tentative plan of separation was adopted by the Conference by an almost unanimous vote. The result was that the Methodist Episcopal Church was bisected, and the members of the General Conference of 1848 represented 780 travelling preachers and 532,290 members fewer than it had numbered four years before. After the Civil War the increase in membership was noteworthy. The quadrennial Conference of 1868 represented 222,687 members more than its predecessor; of this gain 117,326 were in the Southern States. In 1872 lay representatives were admitted, the Constitution having been amended so as to make it legal. It was not, however, an equal representation. Not until 1900 were lay and clerical representation equalized. In 1864 the time limit of pastorates was lengthened to three years, and in 1888 to five years. This limit was taken off in 1900, and pastors can be reappointed at the will of the Bishop.

In 1900–1904 a general revision of the Constitution took place, and the words "lay members" were substituted for "laymen" in that part of the Constitution which deals with the eligibility of delegates to the General Conference, making possible the election of women. The General Conference has power to make rules and regulations for the Church, subject only to restrictions which protect the Standards of Doctrine, the General Rules, the disposition of the property of the Book Concern and its income, the income of the Chartered Fund, and the right of ministers to trial before a jury of their peers, an appeal, and similar rights of the laity. By a two-thirds vote of a General Conference, and two-thirds vote of the members of the Annual Conference, all of the members of the Lay Electoral Conferences, present and voting, what is said in these "Restrictive Rules" can be altered or repealed, except that which deals with the Articles of Religion and "the present existing and established Standards of Doctrine." In the Annual Conference the Bishop is the sole interpreter of law, subject to appeal to the General Conference. The district superintendent visits each charge several times annually. The Methodist

Episcopal Church in 1912 adopted the Episcopal area system with a flexible limit on the residence of a bishop in any one area.

The Methodist Episcopal Church South.—After the adjournment of the General Conference of 1844, the representatives of thirteen constituents resolved to determine what should be done to prevent Methodism in the South from being deprived of its influence over the whites and of the privilege, till then fully accorded, of preaching the Gospel and teaching its precepts to slaves. In 1845 a representative Convention was called; this body, with the approval and participation of Bishop Andrew, organized the Methodist Episcopal Church South. At its first General Conference, in 1846, the senior Bishop of the Methodist Episcopal Church, Joshua Soule (1781–1867), offered himself to the Church, which accepted him in his episcopal capacity. The Church thus founded began with 460,000 members, of which 2,972 were Indians, 124,961 coloured, and 1,519 travelling ministers. At the close of the war the Missionary Society of the Church was $60,000 in debt, the Publishing House practically in ruins, and of the more than 200,000 coloured members in 1860 there remained fewer than 50,000. The Conference of 1866 was held in New Orleans. Radical changes in polity were effected. The time limit on the continuation of pastorates was extended from two to four years. The most radical change was the introduction into the General Conference of a number of lay representatives equal to the number of clerical, and the admission into each Annual Conference of four lay delegates for each Presiding Elder's district.

The coloured people, with the consent of the Church, withdrew in 1870, and formed a new Church called the Coloured Methodist Episcopal Church. This church leads all branches of Episcopal Methodism with increases of over 60% in membership and over 100% church-school enrolment from 1910–25.

The titles to 175 educational institutions are held by the Church. The chief foreign missions are in China, Mexico, Brazil, Japan, Korea and China. Its mission in Japan and the mission of the Methodist Episcopal Church and the Methodist Church of Canada were united in 1907 as the Methodist Church of Japan.

The African Methodist Episcopal Church.—This body originated in 1816 in strained relations between the white and coloured Methodists of Philadelphia, Pennsylvania. It sustains Wilberforce University (of Wilberforce, Ohio) and other educational institutions, and has missions in Africa, South America, the West Indies and Hawaii. It is the largest Christian denomination consisting wholly of the Negro race.

The African Methodist Episcopal Zion Church.—Some of the coloured people in the city of New York, "feeling themselves oppressed by caste prejudice, and suffering the deprivation of Church privileges permitted to others," organized among themselves, in 1796, and in the year 1800 built a church and named it Zion. In this church the sexes are equally eligible to all positions. Its educational operations at first were failures, but gradually became successful. Its foreign missions were made a separate department in 1884.

The Coloured Methodist Episcopal Church.—In 1866 the General Conference of the Methodist Episcopal Church South authorized the bishops to organize its coloured members into an independent ecclesiastical body, if it should appear that they desired it. The bishops formed a number of Annual Conferences, consisting wholly of coloured preachers, and in 1870 these Conferences requested the appointment of five commissioners of the Caucasian part of the Church to meet five of their own number to create an independent Church. Two Bishops of the Methodist Episcopal Church South presided, and ordained to the Episcopacy two coloured elders, selected by the right coloured conferences. The coloured people by vote named the organization the Coloured Methodist Episcopal Church. The Union American Methodist Episcopal Church (coloured) agrees in doctrines and usages with other Methodist bodies, but maintains a separate corporate existence.

B.—Non-Episcopal Methodist Churches. The Methodist Protestant Church.—During the Methodist Episcopal General Conference of 1824, held in Baltimore, a Convention of "Reformers" met, and established a periodical entitled *The Mutual Rights of the Ministers and Members of the Methodist Episcopal Church* and made arrangements to organize Union Societies. Travelling and local ministers and laymen were expelled for schism and spreading incendiary publications. Prior to the Conference those expelled, and their sympathizers, formed themselves into a society named "Associate Methodist Reformers." These sent memorials to the General Conference of 1828, and issued addresses to the public. After a powerful and painful discussion, the appeals were rejected. The controversy centered upon lay representation, the episcopacy and the presiding eldership.

A General Convention was held on the 2nd of November 1830, a Constitution was adopted, and a new organization was established, styled the Methodist Protestant Church. Within eight years it had 50,000 members, the majority of whom were in the South and bordering states. The Methodist Protestant Church has a presbyterial form of government, the powers being in the Conference. There is no episcopal office or General Superintendent; each Annual Conference elects its own chairman. Its General Conference meets once in four years. Ministers and laymen equal in number are elected by the Annual Conferences, in a ratio of one delegate for 1,000 members. The General Conference of the Methodist Episcopal Church of 1908 sent delegates to the Conference of the Methodist Protestant Church, suggesting union, but formal negotiations have not been instituted.

The Wesleyan Methodist Connection or Church of America.—In the Methodist Episcopal Church slavery was always a cause of contention. In 1842 certain Methodist abolitionists conferred as to the wisdom of seceding. Among the leaders were Orange Scott (1800–1847), Jotham Horton and LeRoy Sunderland (1802–1885) and in a paper, which they had established, known as *The True Wesleyan,* they announced their withdrawal from the Church, and issued a call for a convention of all like-minded, which met on the 31st day of May 1843, at Utica, New York, and founded the Wesleyan Methodist Connection or Church of America numbering about 20,000 members within 18 months of its organization. As the Methodist Episcopal Church purged itself from slavery in 1844, and slavery itself was abolished in 1862, a large number of ministers and thousands of communicants, connected with the body, returned to the Methodist Episcopal Church. It had in 1926, 666 ministers, 675 churches, and 21,000 communicants. *The Congregational Methodists* originated in Georgia in 1852; but in polity they are not strictly Congregational. This Church has its membership chiefly in Southern states. *The Free Methodist Church* was organized in August 1860, and was the result of ten years of agitation. It was the purpose of the founders to conserve the usage and the spirit of primitive Methodism. The government of the Church is simple, in all but the Episcopacy and its adjuncts resembling that of the Church whence it sprang. The Free Methodist Church had in 1926 1,259 churches, and 34,751 communicants. The *Primitive Methodist Church,* as it exists in the United States, came from England.

The noteworthy changes in American Methodism since 1909 include (1) the steady growth of all its major branches; (2) movements toward the organic union of various units within the Methodist group and with other evangelical churches; and (3) educational advances resulting in liberalizing tendencies in theology, a higher appreciation of non-Christian religious groups with a consequent new approach to the problem of world evangelisation, the democratisation of Episcopal Methodist Churches and an increasing zeal for social justice, inter-racial understanding and the application of the teachings of Jesus to all human relationships and affairs, in politics and sociology as well as to purely personal conduct and belief.

The year 1925 saw the consummation of the Union of the Methodist, Presbyterian and Congregational Churches of Canada in the United Church of Canada. The Methodist Church, as the largest of the three denominational units, went into the United Church with 100% of its constituency, which at the time of the merger included 2,475 ministers, 1,946 lay preachers, 414,047 members, 451,636 church-school pupils, with 43,333 officers and teachers. In the United States a plan for the organic reunion of the Methodist Episcopal Church and the Methodist Episcopal

Church South failed (1925) by a narrow margin of the combined votes of lay and ministerial members of the southern church. The vote in the Methodist Episcopal Church at the same time was overwhelmingly in favour of the union. The vote of the Methodist Episcopal Church South referred the issue for reconsideration at the next session of the respective General Conferences of the two bodies.

The educational advances to which must be attributed certain tendencies already summarized include the following (1) an increase, commensurate with the growth in church membership, in the number, enrolment and financial support of secondary schools and colleges; (2) a rapid rise, especially in the United States, from the previous low average educational preparation and professional training of ministers, together with a corresponding advance in the curriculum standards for collegiate and theological institutions; (3) increasing attention to religious education through the church-school with the extension of the programme of religious education to include week-day instruction; (4) the widespread distribution and use of religious-educational literature in text-book and periodical form, the total regular circulation of which exceeds the membership of all Methodist Churches.

METHODIST NEW CONNEXION, a British Nonconformist Church, formed in 1797 by secession from the Wesleyan Methodists, and merged in 1907 into the United Methodist Church (*q.v.*). The secession resulted from a dispute regarding the position and rights of the laity. In its conferences ministers and laymen were of equal number, the laymen being chosen by the circuits and in some cases by representatives elected for life by conference. Otherwise the doctrines and order of the Connection were the same as those of the Wesleyans. At the time of the union with the Bible Christians and the United Methodist Free Church in 1907 the Methodist New Connexion had some 250 ministers and 45,000 members.

METHODIUS (*c.* 825–885), the apostle of the Slavs, was a native of Thessalonica, probably by nationality a Graecized Slav. His father's name was Leo, and his family was socially distinguished; Methodius himself had already attained high official rank in the government of Macedonia before he determined to become a monk. His younger brother Constantine (better known as Cyril, the name he adopted at Rome shortly before his death) was a friend of Photius, and had earned the surname "the Philosopher" in Constantinople before he withdrew to monastic life. Constantine about 860 had been sent by the emperor Michael III. to the Khazars, a Tatar people living north-east of the Black Sea, in response to their request for a Christian teacher, but had not remained long among them; after his return to within the limits of the empire, his brother and he worked among the Bulgarians of Thrace and Moesia, baptizing their king Bogoris in 861. About 863, at the invitation of Rastislav, king of "Great Moravia," who desired the Christianization of his subjects, but at the same time that they should be independent of the Germans, the two brothers went to his capital (its site is unknown), and, besides establishing a seminary for the education of priests, successfully occupied themselves in preaching in the vernacular and in diffusing their translations of Scripture lessons and liturgical offices. Some conflict with the German priests, who used the Latin liturgy, led to their visiting Pope Nicholas I., who had just been engaged in his still extant correspondence with the newly converted Bulgarian king; his death (in 867) occurred before their arrival, but they were kindly received by his successor Hadrian II. Constantine died in Rome (in 869), but Methodius, after satisfying the pope of his orthodoxy and obedience, went back to his labours in "Moravia" as archbishop of Syrmia (Sirmium) in Pannonia. His province appears to have been, roughly speaking, co-extensive with the basins of the Raab, Drave and Save, and thus to have included parts of what had previously belonged to the provinces of Salzburg and Passau. In 871 complaints on this account were made at Rome, nominally on behalf of the archbishop of Salzburg, but really in the interests of the German king and his Germanizing ally Swatopluk, Rastislav's successor; they were not, however, immediately successful. In 879, however, Methodius was again summoned to Rome by Pope John VIII., after having declined to give up the practice of celebrating mass in the Slavonic tongue; but the pope, contrary to all expectation, ultimately decided in favour of a Slavonic liturgy, and sent Methodius (880) back to his diocese with a suffragan bishop of Neitra, and with a letter of recommendation to Swatopluk. The closing years of the life of Methodius were embittered by continual ecclesiastical disputes, in the course of which he is said to have laid Swatopluk and his supporters under the ban, and the realm under interdict. Methodius is said to have died at Hardisch on the March, on April 6, 885. He was buried at Welehrad (probably Stuhlweissenburg).

The Greek Church commemorates St. Cyril on February 14 and St. Methodius on May 11; in the Roman Church both are commemorated on March 9. Their canonization (by Leo XIII. in 1881) is noteworthy, in view of the fact that Gregory VII. and several other popes condemned them as Arians. After the death of Methodius much of his work was undone; his successor Gosrad, a Slav, was expelled, with all the Slav priests, and the Latin language and liturgy supplanted the vernacular.

See Schafarik's *Slawische Alterthümer;* L. K. Götz, *Geschichte der Slavenapostel Konstantinus und Methodius* (Gotha, 1897); N. Bonwetsch, *Cyrill und Methodius, die Lehrer der Slaven* (Erlangen, 1885), and art. in Hauck-Herzog's *Realencyk. für prot. Theol.* iv. 384, where the literature is cited; G. F. Maclear, *Conversion of the Slavs* (London, 1879).

METHODOLOGY: *see* SCIENTIFIC METHOD.

METHUEN, a town of Essex county, Massachusetts, U.S.A., 10 m. N.E. of Lowell, on the Boston and Maine Railroad. The population was 15,189 in 1920 (34% foreign-born white, almost half of them from England) and was 21,069 in 1930 by the Federal census. It is a manufacturing centre, making cotton and woollen goods, hats and shoes. The factory product was valued at $11,973,260 in 1925. Methuen was set off from Haverhill and incorporated as a town in 1725. In 1917 it was chartered as a city, but the town form of government was resumed in 1921.

METHUSELAH, eighth in the list of ante-diluvians, Genesis v., is credited with the longest life, 969 years: he appears in the parallel list, Genesis iv., as Methushael. In each case he is the father of Lamech. Attempts—for which see the commentaries—

have been made to find etymologies for the name, and to equate it with a name in similar Babylonian lists, but all are precarious.

METHVEN, village, Perthshire, Scotland, $7\frac{3}{4}$ m. W. by N. of Perth by the L.M.S. railway. Pop. civ. parish (1931) 1,670. Only an aisle remains of the collegiate church founded in 1433 by Walter Stewart, earl of Atholl. One mile east of the village, Methven Castle, dating partly from 1680, occupies a fine situation in a park in which stands the Pepperwell oak, 18 ft. in circumference. At Dronach Haugh near the banks of the Almond, which bounds the parish on the N., the earl of Pembroke defeated Robert Bruce in 1306. At Lynedoch, his estate on the Almond, Thomas Graham, the Peninsular general, afterwards Lord Lynedoch, carried on many experiments in farming and stock-breeding. Trinity College occupies a beautiful position $4\frac{1}{2}$ m. north-west of Methven in Glenalmond, and is usually called by the latter name. It was the first public school on the English model in Scotland and was opened in 1847. At Tibbermore, or Tippermuir, about 3 m. south-east of Methven, Montrose won his first battle over the Covenanters in 1644.

METHYL ALCOHOL, in a more or less impure form known in commerce as wood spirit, being produced by the destructive distillation of wood. The name methyl from the Greek *μέθυ*, wine, *ὕλη*, wood, explains its origin. Discovered in 1661 by R. Boyle, it was studied in greater detail by Dumas and Peligot in 1831, and its synthesis by M. Berthelot from methane through methyl chloride followed in 1858. It is the simplest alcohol (*q.v.*) of the aliphatic series (*see* CHEMISTRY: *Organic*) with the formula CH_3OH; it is also known as methanol.

The older process of manufacture consists in distilling wood in iron retorts at about 500° C, when the aqueous distillate, containing methyl alcohol, acetic acid, acetone and methyl acetate, is neutralised with lime to fix the acetic acid and again distilled. Crude methyl alcohol thus obtained in the distillate can be purified by conversion into the calcium chloride methyl-alcoholate, $CaCl_2$, $4CH_3{\cdot}OH$, which is separated and again decomposed by redistilling with water. Purified methyl alcohol is dehydrated over caustic potash or lime. Further purification may be effected by converting methyl alcohol into one of its esters (acetate, oxalate or benzoate). Methyl alcohol is also obtained in the dry distillation of molasses.

Industrial Synthesis of Methanol.—A formidable rival to the wood distillation has arisen from the modern development of pressure chemistry (*q.v.*). The thermochemical equation $CO+2H_2 \rightleftarrows CH_3{\cdot}OH+27{,}200$ cal. shows that the synthesis of methyl alcohol from carbon monoxide and hydrogen will be favoured by increased pressure and also by diminishing temperature, providing that the reaction is facilitated by a suitable catalyst. These conditions have been realised by using a zinc oxide–chromic acid catalyst prepared by interaction between zinc oxide (3 mols.) and chromic acid (1 mol.) with subsequent reduction in hydrogen at 350° C. A mixture of one volume of carbon monoxide and two volumes of hydrogen when passed over the heated catalyst at 350–400° C under a pressure of 200 atmospheres gave a liquid product consisting mainly of methyl alcohol (up to 90%); the other ingredients are higher alcohols and water, the latter being formed during further condensation and also from the gradual reduction of the catalytic oxides. The catalytic chamber consists of a strong steel cylinder lined with copper, and the inlet and exit tubes consist chiefly of the latter metal. The organic product contains smaller amounts of the higher primary alcohols among which *n*-propyl alcohol and *iso*butyl alcohol, $(CH_3)_2CH{\cdot}CH_2{\cdot}OH$, have been identified (Morgan, Taylor and Hedley, *J. Soc. Chem. Ind.*, 1928). From these higher alcohols and water, methyl alcohol is readily separated by fractional distillation. When purified from traces of aldehydes by successive digestion with 2:4-dinitrophenyl-hydrazine and sodium and again rectified by distillation, it is obtained as a colourless, almost inodorous liquid, boiling at 66–67° C and having a specific gravity of 0·8142 at 0° C. It mixes in all proportions with water, ethyl alcohol or ether. Its chief industrial uses are as follows:—(1) starting material for formaldehyde, (2) denaturant for ethyl alcohol (wine spirit), (3) in varnish manufacture, (4) as a fuel, (5) as a chemical reagent in the fine chemical and synthetic colour industries.

The following derivatives have some industrial importance: *Methyl chloride,* CH_3Cl, a colourless gas boiling at −23° C, obtained by chlorinating methane, or preferably by passing hydrogen chloride into methyl alcohol in presence of zinc chloride. It is soluble in water and more so in alcohol. *Methyl bromide,* similarly prepared by the use of hydrogen bromide, is a volatile liquid boiling at 13° C (sp. gravity, 1·73). *Methyl iodide* boils at 43° C (sp. gravity 2·19). *Dimethyl sulphate,* prepared by adding chlorosulphonic acid or sulphur trioxide to methyl alcohol diluted with carbon tetrachloride, is a colourless oily liquid boiling at 187–188° C (sp. gravity 1·327). It is greatly used as a methylating agent in spite of its poisonous character. The inhalation of its vapours should be avoided. (G. T. M.)

METHYLATED SPIRIT: *see* ALCOHOL IN INDUSTRY.

METHYLENE BLUE, a "basic" dye of the thiazine class. (*See* DYES, SYNTHETIC.)

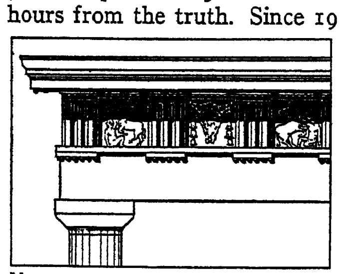
METHYL ORANGE: *see* AZO-COMPOUNDS.

METHYL VIOLET and the closely related crystal violet are "basic" dyestuffs belonging to the triphenylmethane or carbonium series. (*See* DYES, SYNTHETIC.)

METOCHITA, THEODORE [THEODOROS METOCHITES], a Byzantine author, man of learning and statesman, who flourished during the reign of Andronicus II. Palaeologus (1282–1328). After the deposition of his patron by Andronicus III., Metochita was deprived of his office of great logothete (chancellor) and sent into exile. He was soon recalled, but retired from political life to a convent, where he died in 1332. He was a man of very great learning, only surpassed by Photius and Michael Psellus.

Only a few of his numerous works have been preserved. The best known is *Ὑπομνηματισμοὶ καὶ σημειώσεις γνωμικαί*, *Miscellanea philosophica et historica* (ed. C. G. Müller and T. Kiessling, 1821), containing some 120 essays; for a list of them see Fabricius, *Bibliotheca graeca* (ed. Harles), x. 417; in these he chiefly made use of Synesius. Of his rhetorical pieces two have been published by C. N. Sathas in *Μεσαιωνικὴ βιβλιοθήκη* (1872), and two poems on religious subjects by M. Treu (1895). Metochita was also the author of works on philosophical and astronomical subjects.

METONIC CYCLE, in chronology, a period of 19 years during which there are 235 lunations, so called because discovered by Meton. Computation from modern data shows that 235 lunations are 6,939 days, 16·5 hours; and 19 solar years, 6,939 days, 14·5 hours. The relation between integral numbers of months and years expressed by Meton's rule therefore deviates only two hours from the truth. Since 19 Julian years make 6,939 days, 18 hours, the relation errs by only 1·5 hour when the Julian year is taken. Meton was an Athenian astronomer (fl. 432 B.C.).



METOPE. SCULPTURED SQUARE PANELS BETWEEN TRIGLYPHS, GREEK DORIC

METOPE, in architecture, the square portion of the Doric frieze, situated between the triglyphs (*q.v.*) or grooved blocks. In Greece the slab was often sculptured. (*See* ORDER.)

METRE: *see* VERSE and MEASURES AND WEIGHTS.

METRIC SYSTEM, that system of weights and measures of which the metre is the fundamental unit (adapted from Gr. *μέτρον*, measure). The theory of the system is that the metre is a $\frac{1}{10,000,000}$ part of a quadrant of the earth through Paris; the litre or unit of volume is a cube of $\frac{1}{10}$ metre side; the gramme or unit of weight is (nominally) $\frac{1}{1,000}$ of the weight of a litre of water at 4° C.

The idea of adopting scientific measurements had been suggested as early as the 17th century, particularly by the astronomer Jean Picard (1620–1682), who proposed to take as a unit the length of a pendulum beating one second at sea-level, at a latitude of 45°. These suggestions took practical shape by a decree of the National Assembly in 1790 appointing a committee to consider the suitability of adopting either the length of the seconds pendulum, a fraction of the length of the equator or a fraction of the quadrant of the terrestrial meridian. The com-

mittee decided in favour of the latter and a commission was appointed to measure the arc of the meridian between Dunkirk and Montjuich near Barcelona. Another commission was also appointed to draw up a system of weights and measures based on the length of the metre and to fix the nomenclature, which on the report of the commission was established in 1795. It was not until 1799 that the report on the length of the metre was made. This was followed by the law of the 10th of December 1799 fixing definitely the value of the metre and of the kilogramme, or weight of a litre of water, and the new system became compulsory in 1801. It was found necessary however to pass an act in 1837, forbidding as and from the 1st of January 1840, under severe penalties, the use of any other weights and measures than those established by the laws of 1795 and 1799. The metric system is now obligatory in Argentina, Austria, Hungary, Belgium, Brazil, Chile, France, Germany, Greece, Italy, Mexico, Netherlands, Norway, Peru, Portugal, Rumania, Yugoslavia, Spain, Sweden, Switzerland. Its use is legalized in Egypt, Britain, Japan, Russia, Turkey and the United States. In 1875 there was constituted at Paris the International Bureau of Weights and Measures, which is managed by an international committee. The object of the Bureau is to make and provide prototypes of the metre and kilogramme, for the various subscribing countries.

In England action has frequently been taken both by individuals and by associations of commercial men for the purpose of endeavouring to make the metric system compulsory. A Decimal Association was formed in 1854, but did not make very much headway. A bill was introduced into parliament in 1864 to make the metric system compulsory for certain purposes, but owing to government objections a permissive bill was substituted and subsequently became law as the Metric Act 1864. It was, however, repealed by the Weights and Measures Act 1878. In 1871 another bill was rejected in the Commons by five votes. In 1893 a representative delegation of business men pressed its adoption on the chancellor of the exchequer (Sir W. V. Harcourt), but he declined. But in 1897 a statute was passed, the Weights and Measures (Metric System) Act, which legalized the use in trade of the metric system, and abolished the penalty for having in one's possession a weight or measure of that system. (*See* also DECIMAL COINAGE and MEASURES AND WEIGHTS.)

METROCLES, a Greek philosopher of the Cynic school, was a contemporary of Crates, under whose persuasion he deserted the views of Theophrastus. His philosophical views, which were identical with those of Crates (*q.v.*), he expounded by precept and example with great success, and had among his pupils Menippus of Sinope. Having weighed the probable pains and pleasures of approaching old age, he decided that life offered nothing, and drowned himself. He is said to have written several works, which he afterwards burnt.

METRODORUS [of CHIOS], a member of the Atomistic school. A pupil probably of Democritus himself, he accepted the Democritean theory of atoms and void and the plurality of worlds, but held that the stars are formed from day to day by the moisture in the air under the heat of the sun. His radical scepticism is seen in the first sentence of his Περὶ φύσεως, quoted by Cicero in the *Academics* ii. 23 § 73. He says, "We know nothing, no, not even whether we know or not," and maintains that everything is to each person what it appears to him to be.

METROLOGY, a name for the science of pure measurement, is in practice restricted to mean measurement of the three fundamental quantities, mass, length and time, from which all other quantities, such as volume, density, velocity, acceleration, force and power, are derived. If "science is measurement" then without metrology there is no science. Even in its most direct application it covers a very wide field (*see* MENSURATION; SURVEYING; GEODESY; EARTH, FIGURE OF THE; MICROMETER; MEASURING INSTRUMENTS; TIME; CLOCKS; WEIGHTS AND MEASURES; WEIGHING MACHINES; METRIC SYSTEM). The question of the time standard, moreover, is particularly an astronomical one. There is no "absolute" standard; all measurement is relative.

Problems Involved.—The problem of metrology is twofold. First to provide and maintain unaltered the standards of reference by which other quantities are compared and measured; and secondly to provide means by which the comparisons may be made with accuracy sufficient for the particular purpose in view. The demands of science and industry at the present day require, for certain purposes, an extremely high degree of accuracy in these fundamental comparisons, so that what, at first sight, would appear to be a fairly simple problem becomes in fact one of great difficulty, involving the most expensive and elaborate apparatus. No measurement is ever absolutely correct. Some degree of experimental error is always necessarily present, and the approximate degrees of accuracy at present attainable in certain of the more fundamental operations in metrology, are as follows:—

Comparison of two platinum-iridium copies of the International Prototype Kilogramme: 1 part in 100,000,000.
Comparison of ordinary chemical weights: 1 part in 1,000,000.
Comparison of smaller masses by micro-balance: 1 part in 100,000,000.
Comparison of two yard or metre (line or end) standards: 1 part in 10,000,000.
Comparison of end standard with line standard: 1 part in 1,000,000.
Determination of volume and density for very special work: 1 part in 1,000,000.
Determination of volume and density, ordinary: 1 part in 10,000.
Calibration of set of end standards (not less than 1 in. in length): 1 part in 1,000,000.
Calibration of subdivisions of graduated yard or metal scale in terms of whole length: 0·000005 in. or 0·0001 millimetre.

STANDARDS OF LENGTH

The history of standards of length is one of varying ascendency of three principal competing types. A length may be defined by the distance, under certain specified conditions, either between the two end surfaces of a material standard bar, or between two suitable marks engraved upon it. Alternatively reference may be made to some "natural" standard. The standard yards of Henry VII. and Elizabeth preserved in the Standards Department of the Board of Trade, are end standards, incisions marking subdivisions of the yard being secondary only. The Elizabethan yard was superseded by one defined by the distance between two small dots on gold plugs inserted in it. When this bar was legalized in 1824, it was provided that in the event of loss it should be replaced by reference to a "natural" standard, the length of the pendulum beating seconds in the latitude of London.

It so happened that within a very short period this bar was in fact destroyed by the fire in the Houses of Parliament in 1834. The commission charged with its replacement found, however, that it was impossible to reproduce the seconds pendulum with so high an accuracy as the length of the bar itself could be reproduced by means of direct comparison with other bars which had previously been compared with the lost standard. The new standard yard, which is legal at the present day, was thus restored.

The metre was originally intended to be the 10,000,000th part of the earth's meridional quadrant. But it was soon found that not only was the determination of this natural standard an extremely laborious undertaking, but the accuracy attainable was less than that possible in the comparison of material standards, and the material Mètre des Archives, a platinum end standard, became the accepted standard of reference for the metric system until superseded in 1889 by the present International Prototype Metre, a platinum iridium line standard (*see* WEIGHTS AND MEASURES).

Wave Lengths as Natural Standard.—Some later developments, however, have appreciably changed the situation. In the first place the experiments of Michelson, followed by those of Fabry and Perot (*see* LIGHT) have finally established a natural standard (the wave length of the red line in the spectrum of cadmium) which is reproducible with accuracy at least as great as that attainable in the comparisons of material standards, which is definitely free from the suspicion of possible secular variation inevitably attaching to all material standards, and by means of which the material standards necessarily employed in everyday practice can be verified in any part of the world without the risk of accident or damage involved in the periodical transport of material national reference standards to and from the international central laboratory for comparison with the prototype. Secondly, such improvement has been effected during the last few years in the production of flat-ended standards that bars with accurately

parallel ends of the quality of optical mirrors are now available, whose lengths can be more directly determined by the method of optical interference than is the case with line standards, and which are also more accurately comparable with each other.

The International Committee on Weights and Measures, at its meeting in 1923, decided in principle on a wave-length standard subject to experiment in the various national laboratories. Such experiments are proceeding and within the next decade a very important result may be achieved.

Use of Material Standards.—There is evidence that the imperial standard yard has probably shortened by about 0·0002 inch since it was originally constructed in 1844, but has remained unchanged for the last 40 years. So far as is known, the international prototype metre has remained unchanged since its verification (1875–79). The evidence for this rests partly on subsequent recomparison with various national copies constructed in the same manner at the same time, and partly on two determinations, by different methods, at an interval of about 15 years, the first by Michelson and Benoit, and the second by Fabry and Perot, against the wave length of the red line of cadmium. These metre standards are all made of an alloy of 90% platinum and 10% iridium, regarded as the most satisfactory for ultimate standards. Its cost would be prohibitive for any other purpose.

Temperature Conditions.—All materials change in size to a greater or less degree with variation of temperature. It is therefore essential to specify exactly the temperature at which the material standard defines the unit of length, and further either to control the standard exactly to this temperature when making comparisons with it, or at least to ascertain its temperature exactly, and make allowance for its known expansion between that temperature and the standard temperature. The Imperial Standard Yard is correct at 62° F, the International Prototype Metre at 0° Centigrade. The numerical relationship between the two units has been twice accurately determined: in 1895 by Chaney and Benoit, with the result 1 metre = 39·370113 in.; and more recently (1922–25) at the National Physical Laboratory, with the result 1 metre = 39·370147 inches. The two results may be said to be in agreement within the experimental error of the various observations involved, and for all practical purposes the simple ratio 1 in. = 25·4 mm. (equivalent to 1 metre = 39·370079 in.) is exact.

The use of this ratio implies that the two objects being compared are both simultaneously at their common temperature of employment. For all everyday purposes of measurement, as for example in measuring a piece of work in an engineering workshop, it is unnecessary to bring the object to be measured to the standard temperature. If the work and the gauge with which it is being measured are made of materials having the same coefficient of expansion, and the former has been compared with the reference standard at the standard temperature, it is only necessary, when comparing the work with the gauge, to ensure that both are at the same temperature (not necessarily the standard temperature) to ensure that the work will be correctly measured.

Use of Invar.—For many purposes where very precise measurement is involved, it is of great advantage to have a material with a very small thermal expansion. Two such materials have been discovered. The first, known as "Invar," is a nickel-steel alloy, containing 36% of nickel, invented by Dr. Ch. Ed. Guillaume of the Bureau International (Sèvres). Different samples have coefficients ranging from about $1·5 \times 10^{-6}$ per 1° C, for large bars, down to zero, or even slightly negative values, for smaller bars, pendulum rods, drawn wire or rolled tape. These figures are to be compared with 11×10^{-6} per 1° C for steel, and 18×10^{-6} per 1° C for brass. Invar, unfortunately, has one very serious defect as a standard of length. It grows longer, rapidly at first and subsequently more slowly but continuously, so that after 20 years the length of a bar of invar will still be increasing at a rate of about 1 part in 2,000,000 per annum. More recently Dr. Guillaume has introduced a slightly different alloy, containing a percentage of chromium in addition to the nickel, which is described as "stable" invar. This alloy grows at an appreciably slower rate than ordinary invar, but still cannot be regarded as constant. Invar therefore is principally useful in a laboratory, in work where temporary constancy of length is the primary consideration, or in circumstances, as for example in the case of tapes and wires used for geodetic surveying, where the accurate ascertainment of temperature presents considerable difficulty. In these cases it is necessary to return the tapes or wires to the laboratory periodically for reverification. For the reasons indicated above, in everyday workshop measurements, gauges or scales should be made of material having a similar coefficient of expansion to the work to be measured, and invar therefore should not ordinarily be used for the construction of workshop standards.

Fused Silica and Natural Crystal Quartz.—The other material which has a very low coefficient of expansion is fused silica, which expands only $0·4 \times 10^{-6}$ per 1° Centigrade. A metre standard constructed of fused silica, in the form of a tube, with parallel plates fused in at the ends on the platinised surfaces of which the defining lines are ruled, has been made and kept under observation at the National Physical Laboratory since 1913. So far as can be detected, no change has occurred in its length. Such a standard is extremely fragile, and for this reason would hardly be adopted either as a fundamental reference standard or for everyday use, except in a metrological laboratory.

Reference should be made to the recent work of Perard, at the Bureau International, on end standards of natural crystal quartz. Such standards cannot, of course, be of the full length of the yard or metre. But they present several great advantages. Firstly, since the material is of great age and the molecules of which it is composed are arranged structurally in definite crystalline array, there seems little possibility of any secular change. Secondly, it lends itself to perfect optical finish of the defining end planes, which enables direct determination of length to be made in terms of light waves, with extremely high precision resulting in a proportional accuracy no less than is at present obtained in the comparison of yard or metre line standards, although the largest available specimens of crystal quartz, as well as the method of use, only enable such standards to be verified up to about 4 inches.

Line Standards; Mode of Comparison.—The comparison of two line standards is effected as follows: The bars are placed side by side, each on one of two parallel girders contained in a water bath, which is mounted on a carriage capable of being moved in a direction perpendicular to the length of the bars. The bars are constructed with their graduations on polished surfaces in the neutral plane of their cross section, and each is supported on two rollers spaced at such a distance apart that the distance between its graduation marks has a maximum value. Under these conditions any changes in the flexure of the bars due to slight errors in the positions of the supports can have no effect on the measured distances between the graduations. Two micrometer microscopes (*see* MICROMETER) are rigidly held in brackets supported in such a manner as to be unaffected by the motion of the carriage. Each girder has independent adjustments by means of which the lines on the bars can be brought into focus in the field of the microscopes. The water in the bath is stirred and the temperature read by means of accurately calibrated thermometers. Readings are taken by means of the microscopes alternately on the defining lines of each bar, and the mean of several independent readings is taken. The comparison is repeated with each of the bars turned end for end in turn in order to overcome any effect of asymmetry in the illumination of the graduation marks, and the bars are then interchanged on the two girders and the whole repeated once more, making eight complete sets of readings in all, from which the difference in length between the two bars is finally computed. In an important determination several bars (say six or eight) may be included, and each will be completely compared in the manner described above, against all the others, the best values for the differences between all the various bars being then computed from the individual observed differences by the method of least squares (*see* PROBABILITY), the residual errors serving to indicate the degree of accuracy which has been attained in the work.

Calibration.—The calibration of the subdivisions of a divided scale is done in a similar way, except that in this case the carriage of the comparator moves in the direction of the length of the bar. The microscopes are fixed successively at a series of suitable inter-

vals apart, for example, 1 dm., 2 dm., 3 dm., etc., and each principal interval of 1 dm., 2 dm., etc., is compared with every other interval of the same magnitude throughout the metre. By computation from the results so obtained the value of each decimetre is determined in relation to the whole length of the scale. In a similar manner each centimetre of one decimetre is compared with every centimetre of another decimetre, and as a result the value of each centimetre is found in relation to the whole of the other decimetre, and so in turn, in relation to the whole length of the metre. Millimetres are derived from centimetres in the same way, and so on. The complete calibration of a divided scale will be seen to be a very laborious process involving an enormous number of observations. The process is, however, simplified by the fact that the whole of the measurements are made on the one bar, so that, provided reasonable precautions are taken to ensure constancy of temperature, exact temperature measurements are not important.

The apparatus used to determine coefficients of expansion is similar to the transverse comparator, but has two independent water baths mounted on the carriage. One of these, containing a bar preferably of invar, is kept at a constant temperature, while the other, containing the bar under examination, is brought successively to a series of suitable temperatures. The two bars are compared at each temperature of the second, and so the variations of its length with temperature are determined.

A number of machines of different types, and varying sensitivity, are available for comparing end standards by contact measurement, or, if the end faces are of sufficiently perfect finish, they may be directly compared by the method of optical interference. In the latter case the two bars are brought in turn between two semi-silvered optically flat glass surfaces, and the number of wave lengths in the small spaces at either end between the measuring surface of the bar, and the semi-silvered surfaces of the optical flats are determined by direct measurement of the angular diameters of the interference rings formed by monochromatic light. This enables the fraction of a wave length to be determined with exactness, and if several different wave lengths are used in turn, whose mutual ratios are known, the whole number of waves is easily determined by deduction, as only a particular set of corresponding whole numbers will give fractions agreeing in every case with the series actually observed.

In the mechanical contact type of measuring machine the bar is measured between two opposed anvils, one of which may either be fixed, or may be movable by means of a micrometer screw, while the other is capable of a small movement operating some form of sensitive indicator. The two bars to be compared are inserted in turn between the anvils, and if the whole difference between them is sufficiently small the movement of the indicator over a calibrated scale may suffice to determine it. If the difference is greater, the indicator must be brought to a fixed mark by an adjustment of the moving anvil, the difference in length being then ascertained by the difference in reading of the micrometer wheel.

Mode of Calibration of End Standards.—The calibration of a set of subdivisional end standards is effected by taking them together in pairs of nominally equal added lengths, and comparing their sums, in the manner just described. In the last 20 years there have been developed, first by the firm of C. E. Johansson, Sweden, and later at the National Physical Laboratory, England, and by Hoke in America, methods of producing short flat-ended gauges of such perfection that any two of them if put together will adhere firmly to each other by "wringing." The process of wringing appears to depend essentially on the presence of a very minute trace of liquid (grease or moisture) between the surfaces of the gauges. This wringing film is extremely thin, and the bond between the two surfaces appears to be formed by short chains of liquid molecules, only two or three molecules long, attached at either end to the molecules of the solid surfaces.

These gauges are usually made in series, *e.g.*, 1 in., 0·9 in., 0·8 in. . . . 0·1 inch. Suppose we wish to calibrate such a series, of which the 1 in. is supposed to be already known as the result of some previous calibration. For convenience we will assume that we have available a duplicate set of pieces, which we denote by 0·1′ in., 0·2′ in. . . . 0·9′ inch. To determine, for example, the value of the 0·7 in. gauge, we wring up in turn all the various nominally equal combinations indicated below, and compare them in a suitable measuring machine, the small observed differences being indicated by

$$\begin{aligned}
0{\cdot}7 &= 0{\cdot}7'+\alpha_0\\
0{\cdot}7+0{\cdot}1 &= 0{\cdot}8+\alpha_1\\
0{\cdot}7+0{\cdot}2 &= 0{\cdot}9+\alpha_2\\
0{\cdot}7+0{\cdot}3 &= 1{\cdot}0+\alpha_3\\
0{\cdot}7+0{\cdot}4 &= 1{\cdot}0+0{\cdot}1+\alpha_4\\
0{\cdot}7+0{\cdot}5 &= 1{\cdot}0+0{\cdot}2+\alpha_5\\
0{\cdot}7+0{\cdot}6 &= 1{\cdot}0+0{\cdot}3+\alpha_6\\
0{\cdot}7+0{\cdot}7' &= 1{\cdot}0+0{\cdot}4+\alpha_7\\
0{\cdot}7+0{\cdot}8 &= 1{\cdot}0+0{\cdot}5+\alpha_8\\
0{\cdot}7+0{\cdot}9 &= 1{\cdot}0+0{\cdot}6+\alpha_9
\end{aligned}$$

Adding up all these equations we see that the sums of the second columns on either side cancel out, and we get

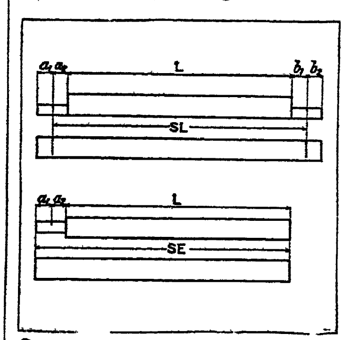
$$10\times 0{\cdot}7 = 7\times 1{\cdot}0+\sum_0^9 \alpha$$

$$\text{or}\qquad 0{\cdot}7=\tfrac{7}{10}\times 1{\cdot}0+\tfrac{1}{10}\sum_0^9 \alpha$$

The size of each of the other pieces may be determined in a precisely similar manner.

It may be noted that in the determination of sizes in this manner, the length of each gauge is automatically associated with the thickness of one wringing film, which, for clearness in conception, may be regarded as representing half a film thickness on either end surface, so that when two gauges are wrung together a whole film is established between them. As the gauges are normally used in this manner, this result is logically what is required. The wringing films, moreover, are in any case exceedingly thin. When initially formed, their thickness depends to some extent on the viscosity of the liquid of which they are composed, but if a sufficient length of time is allowed to elapse they tend to thin down to a limiting thickness, less than 0·000001 in. for all liquids.

There is one more fundamental operation which, whatever may be the nature of the ultimate standard adopted, will always be required in its practical application to everyday requirements, and that is the determination of the length of an end standard in terms of the corresponding line standard, or vice versa. This is a matter of considerable difficulty, and several methods have been employed for the purpose. Probably the best method is that introduced by Mr. H. L. P. Jolly, formerly of the National Physical Laboratory, and now of the Ordnance Survey Department, Southampton. It involves the use of an intermediate end standard, and of two special parallel-faced end blocks, which can be wrung on to the ends of this standard.



COMPARISON OF LINE AND END STANDARDS

Each of the end blocks carries graduation marks as shown on its polished upper surface. The composite bar is compared in the ordinary way in a comparator, with the standard line bar. Each of the end blocks is turned round in turn, and re-wrung on the end of the bar, and the comparison repeated. We thus obtain the four results:—

$$\begin{aligned}
L+a_2+b_1&=S_L+\beta_1\\
L+a_1+b_1&=S_L+\beta_2\\
L+a_1+b_2&=S_L+\beta_3\\
L+a_2+b_2&=S_L+\beta_4
\end{aligned}$$

or, adding and dividing by 2

$$2L+a_1+a_2+b_1+b_2 = 2S_L+\tfrac{1}{2}\{\beta_1+\beta_2+\beta_3+\beta_4\}$$

Each of the end blocks is then removed in turn and the other wrung centrally on the end of the bar, the new combinations being compared in a measuring machine with the standard end bar, with the results

$$L+a_1+a_2=S_E+\gamma_1$$
$$L+b_1+b_2=S_E+\gamma_2$$

or adding

$$2L+a_1+a_2+b_1+b_2=2S_E+\gamma_1+\gamma_2$$

From this equation, and the one previously found, we obtain the result

$$2S_L+\tfrac{1}{2}(\beta_1+\beta_2+\beta_3+\beta_4)=2S_E+\gamma_1+\gamma_2$$

which gives us the desired value of the line standard S_L in terms of the end standard S_E or vice versa.

To complete our survey of the fundamental operations involved in length measurement, reference must be made finally and very briefly to the process of verifying longer measures, such as are used in surveying. In the first place a long bar, graduated in multiples of the standard length unit, is required. This is compared, yard by yard, or metre by metre, with the standard line bar, in a large comparator. This bar in turn is compared either with suitable reference marks engraved on metal studs let into a mural base at intervals corresponding to the length of the bar, or else directly with the divisions of a graduated tape. The tapes or wires after verification, either directly, or by comparison with the mural base, are used to determine base lines in the field, by comparison with temporary bench marks set up at intervals apart roughly equal to the length of the tape.

STANDARDS OF MASS

No attempt has so far been made to define a unit of mass by means of any natural standard, though a standard of this kind, *e.g.*, a definite multiple, say, of the atomic mass of helium, would not be inconceivable. Prior to the discovery of the radioactive elements mass was regarded as the essentially constant attribute of matter, and there was no reason to anticipate any change in a material standard of mass except by actual damage due to abrasion, oxidation, hygroscopic absorption or other similar causes. And there still remains a reasonable choice of materials, which, given due care in preservation and handling, may be expected with considerable confidence to exhibit constancy of mass.

Platinum and Platinum-iridium.—Our predecessors, ignorant of radioactive processes, were fortunate in the choice of platinum and platinum-iridium (10% iridium) as the materials of construction for the ultimate reference standards of mass, the Imperial Standard Pound, and the International Prototype Kilogramme, respectively. The degree of consistency (within 1 part in 10^8) with which recomparisons of various national copies of the kilogramme, made after the lapse of many years, have in general repeated the original determinations, speaks convincingly, not only as to the suitability of the standards themselves, but as to the perfection of the balances used in the comparisons. The relation between the two units, according to the best ascertained determination, is 1 kg. = 2·2046223 pounds. This value has received legal sanction in Great Britain.

Crystal Quartz.—Another material presenting a high degree of constancy of mass is crystal quartz. This, however, has the disadvantage of having a comparatively low density. It also suffers from hygroscopicity, and requires careful handling to ensure the elimination of any effects due to surface electrical charges caused by cleaning.

Buoyancy Corrections.—In the comparison of two standard masses in air, allowance must be made for the upward buoyant effect due to the volumes of air which they respectively displace. The less the density of the mass, the greater will be the buoyancy correction. The accuracy attained in the intercomparison of a series of platinum-iridium standards is no doubt attributable to a considerable degree to the fact that they all have comparatively high, and very closely equal, densities, so that the net buoyancy corrections are very small, and a comparatively rough determination of the air density consequently suffices to give the correction with negligible error. In comparing a number of masses differing appreciably in density, *e.g.*, platinum, quartz and brass, the accurate determination of the buoyancy correction presents much greater difficulty, and several attempts have been made to overcome it by actually conducting the weighing *in vacuo*. This involves enclosing the whole balance in an air-tight case, and manipulating the weights entirely by mechanical means from outside, without opening the case. Leakage at the glands where the operating spindles enter the case has, however, so far proved an almost insuperable obstacle to successful weighing *in vacuo*. Everyday weighings for commercial purposes are of course necessarily conducted in air, but the differences in buoyancy between the weights used, and the goods weighed, are negligible for this purpose. It is necessary, however, to provide a basis for the periodical reverification by inspectors of weights and measures of traders' weights, which may be of iron, brass or other materials. For this purpose a "commercial" standard is employed. This standard is of brass (of density 8·143) adjusted to agree *in vacuo* with the Imperial Standard Pound of platinum. Inspectors' standards are also of brass, and all verifications of these standards, and thus indirectly of traders' weights, are made by comparison, *in air*, with the commercial brass pound.

Use of the Balance.—Even when weighings are not conducted *in vacuo* the construction and manipulation of a balance for the accurate comparison of primary standards of mass are distinctly elaborate. It is necessary for the greatest care to be taken to preserve constancy of temperature, in order to maintain a steady zero reading of the balance. For this reason the room containing the balance must be thermostatically controlled, and the observer either works entirely from outside the room, or, if he enters it, must remain at a distance from the balance, all the manipulation of the weights being effected from outside the balance case by mechanical control operated by means of long rods, and the movement of the balance beam being observed either through a telescope, or by the movement across a scale of a spot of light reflected by a small mirror attached to the beam.

Consecutive Weighings.—To eliminate any effect due to slight inequality in the lengths of the two arms of the balance, at the same time to minimise the effect of any small residual drift of zero due to a gradual change in temperature conditions and to obtain a determination of the sensitivity of the balance at the time of weighing, consecutive weighings should be made to the following order:—

Left-hand pan	*Right-hand pan*	*Mean Reading*
$A+x$	B	p_1
A	$B+x$	p_2
B	$A+x$	p_3
$B+x$	A	p_4
$B+x$	A	p_5
B	$A+x$	p_6
A	$B+x$	p_7
$A+x$	B	p_8

Here A and B are the two masses being compared, and x a small known weight which serves to determine the sensitivity. Each mass is weighed an equal number of times on each pan of the balance, and the mean time of all the weighings of each mass on each pan is the same, so that the effect of any steady temperature drift is eliminated. In weighing, the balance is not brought to rest, but the pointer, or spot of light, is observed while swinging, and the extreme positions of several successive swings to right and left are noted. From these the mean readings or rest points corresponding to each arrangement of weights on the scale pans are calculated. If, for example, four successive readings are q_1, q_2, q_3, q_4, then, allowing for the effect of the gradual reduction in the amplitude of the swing, due to damping, the corresponding rest point, p, is $\frac{1}{8}(q_1+3q_2+3q_3+q_4)$.

If p be the rest point when two *equal* masses of value nominally equal to A and B are on the pans, then we have

$$A-B+x=k(p_1-p) \qquad B-A+x=k(p_5-p)$$
$$A-B-x=k(p_2-p) \qquad B-A-x=k(p_6-p)$$
$$B-A-x=k(p_3-p) \qquad A-B-x=k(p_7-p)$$
$$B-A+x=k(p_4-p) \qquad A-B+x=k(p_8-p)$$

whence

$$8(A-B)=k(p_1+p_2-p_3-p_4-p_5-p_6+p_7+p_8)$$
and
$$8\ x\ =k(p_1-p_2-p_3+p_4+p_5-p_6-p_7+p_8),$$
so that
$$A-B=x\frac{p_1+p_2-p_3-p_4-p_5-p_6+p_7+p_8}{p_1-p_2-p_3+p_4+p_5-p_6-p_7+p_8}$$

Usually of course several masses will be compared each with each in turn, and the best values for the differences between them finally computed by the method of least squares from all the observed differences obtained in the above manner.

The construction of the balance must be such as to ensure that after each successive arrestment of the beam and pans, the knife edges are brought into exactly the same relationship with the planes, and to secure this it is necessary to support the pans by means of a series of crossed knife edges below each terminal knife edge on the beam. If the weighings are not conducted *in vacuo*, the air density must be calculated for each weighing from observations of temperature, pressure and hygroscopic state of the air, and each observed reading corrected for air buoyancy, allowing for the effect of temperature on the volumes of the weights.

The volumes, and hence the densities, of the weights are determined by weighing them, first in air, and then immersed in distilled water, against other weights always in air. The density of the air must be calculated as usual from its temperature, barometric pressure and humidity, and that of the distilled water is known from its temperature. The difference between the two weighings, due allowance being made for the air buoyancy corrections on all the weights involved, is equal to the difference in weight between the quantities of water and air at the observed densities of each, which would fill a volume equal to that of the weight being examined. If for any reason it is considered objectionable to immerse a standard weight in water, it is possible to determine its volume, though somewhat less accurately, by means of a volumenometer, which is an apparatus for observing the change of pressure of the air enclosed within a given space, when a definite change is made in its volume, firstly when it is filled with air alone, and secondly when the weight is enclosed within it.

The calibration of a set of fractional or multiple weights in terms of the original unit can be effected by weighing together in groups of nominally equal sum by a process precisely analogous to that described above for a set of fractional end standards.

Ordinary brass weights usually exhibit a certain variability of mass, which is probably attributable to variations of surface condition depending on the degree of humidity of the surrounding atmosphere. Care should, of course, be taken to see that the metal of which weights are made is free from porosity, and weights intended for precision work should be made solid, without screwed-in tops covering holes containing adjusting material. The surfaces of high class weights are frequently electroplated with gold or platinum, with the object of minimising the effects of oxidation and hygroscopic action on the surface. Of the two, platinising is the preferable process, but weights coated with either gold or platinum have been found to exhibit instability to a certain degree, though usually less than in the case of unplated weights. The success of gilding or platinising depends upon the care exercised to obtain a firm and hard deposit.

To minimise the effects of temperature upon the action of a balance, a beam of invar may be used. But it must be remembered that invar is to a certain extent magnetic, and if results of high precision are required, care must be taken with such a beam as to ensure that it is completely screened from any possible magnetic influence. The balance should preferably be entirely enclosed within a sheet iron case.

For weighing very small quantities, and in particular for comparing the densities of small quantities of gases, micro-balances constructed entirely of fused quartz have been used. Such balances have been made both with knife edges, and preferably, with the beam torsionally supported on a thin horizontal quartz fibre at right angles to its length, and the pans supported from its ends by means of other fibres fused directly to it. The weighings are usually made by arranging a small bulb or similar contrivance at one end of the beam, counter-balanced by solid quartz at the other end. The two ends of the beam are therefore differently affected by the buoyancy of the air, and weighings are made by adjusting the pressure of the air in the balance case until the buoyancy just restores the beam to balance. The air pressure is read by means of a suitable manometer, and serves to measure the weight of the object under examination. With such balances loads as small as $\frac{1}{10}$ gramme have been weighed to an accuracy of 1 part in 10^8.

STANDARDS OF CAPACITY

Theoretically, the unit of capacity should be the same as the unit of volume—that is, the volume of a cube each of whose sides is equal to the unit of length. In practice, however, it is extremely difficult to construct such a cube with accuracy, and still more difficult to measure the internal volumes of vessels of different shapes in terms of the unit of length. Practical necessity has therefore ordained the use of a unit of capacity based on the unit of mass, rather than on the unit of length.

In the metric system the kilogramme was originally intended to be the mass of one cubic decimetre of pure distilled water when at its temperature of maximum density (4° Centigrade). Although great care was taken in the construction of the original kilogramme from this definition, and the result attained was closer than might have been anticipated in view of the difficulty of the problem, it has been found by very careful experiment that the litre, which is now defined as the volume occupied by 1 kilogramme of water at 4° C, actually equals 1·000028 cubic decimetres. The gallon is somewhat similarly defined as the volume occupied by 10 lb. of pure distilled water at 62° F when weighed in air at a barometric pressure of 30 in. of mercury, against brass weights. As the weighing has to be made in air, and the density of the brass weights is not prescribed by the Act (Weights and Measures Act 1878) there is a certain ambiguity about this definition. On reasonable assumptions it has been calculated that 1 gallon = 4·5459631 litres.

It will be noted that in the case of the litre the definition refers to the kilogramme *mass*—that is to say, the weighings are to be reduced to vacuum, by applying a suitable correction for the difference of the air buoyancy on the distilled water and on the weights used for weighing it. This entirely eliminates the difficulty mentioned as regards the exact definition of the gallon. Much confusion of thought has, however, arisen from the preference of some chemists for the use of the so-called "Mohr's litre," which is defined, on the same lines as the gallon, as the volume occupied by 1 kg. of distilled water, when weighed in air, against brass weights, at a temperature which has never been explicitly laid down. Roughly, a Mohr's litre equals 1·002 true litres. It is very unfortunate that the term litre should have been appropriated to a unit so vaguely defined and which differs from the true litre by an amount that, although small, is too great to be negligible. For most purposes the difference between the millilitre and the cubic centimetre can safely be neglected.

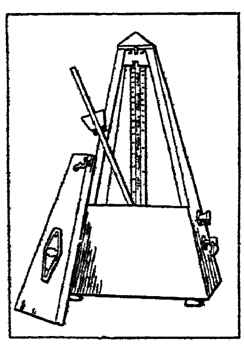
Commercial and Scientific Purposes.—For *commercial purposes* the gallon and the litre are both represented by material standards of capacity, constructed as nearly as possible in accordance with their respective definitions. These standards are in the form of cylindrical metal vessels with flat brims, and are filled exactly to their brims by the aid of flat glass "strikes." Comparisons with other vessels are made by transfer, the vessel under comparison being first filled and emptied to compensate for the amount of water left behind in the standard when the latter is emptied into the vessel being tested.

For *scientific apparatus*, such as flasks, burettes, pipettes, etc., where higher accuracy is needed, it is found necessary as a rule to base the verification directly on the original definition by actually weighing the quantity of pure distilled water contained in, or delivered from, the vessel, making due allowance for the temperature of the water at the time of weighing and for the buoyancy of the surrounding air. In the case of vessels, such as burettes and pipettes, which are intended to deliver, and not to contain, definite quantities of liquid, it must be remembered that after delivery the walls are left wet to an extent which depends not only on the rate at which delivery is effected and the time

allowed for subsequent drainage but also on the viscosity and surface tension of the liquid being measured. The rate of delivery is of more importance than the drainage time, and provided it is sufficiently slow the quantity of liquid delivered will be reasonably constant. Suitable delivery times and error allowances are scheduled in a pamphlet on testing volumetric glassware issued by the National Physical Laboratory.

Bibliography.—The literature of metrology is somewhat scattered. The best collected account will be found in a series of articles contained in the *Dictionary of Applied Physics* (1922–23) (and in particular vol. 3 thereof), edited by Sir R. T. Glazebrook, K.C.B., F.R.S., and published by Macmillan, London. Many detailed references are given in these articles. For full descriptions of the more fundamental operations the various volumes of the *Travaux et Mémoires du Bureau International des Poids et Mesures* (Paris, Gautier-Villars) should be consulted. In addition, consult the annual reports of the Standards Department, Board of Trade (H.M. Stationery Office, London); Miller, *Phil. Trans.*, 146 (1856), on the construction of the new standard pound; Airy, *Phil. Trans.*, pt. 3, p. 17 (1857), on the construction of the new standard yard; Kaye, "A Silica Standard of Length," *Proc. Roy. Soc.*, A85 (1911); Michelson, *Light Waves and Their Uses* (Chicago University Press); C. E. Soc.*, 32, 374; Sears, *Precise Length Measurements*, Cantor Lectures, Royal Society of Arts (1923). (J. E. S.)

METRONOME, an instrument for denoting the speed at which a musical composition is to be performed. Its invention is generally ascribed to Johann Nepomuk Maelzel, a native of Ratisbon (1772–1838), but erroneously, since its actual inventor was a Dutch musician named Winkler. It consists of a pendulum swung on a pivot; below the pivot is a fixed weight, and above it is a sliding weight that regulates the velocity of the oscillations by the greater or less distance from the pivot to which it is adjusted. In its simplest form the metronome is put in motion by hand and allowed to go on swinging to and fro of its own momentum till it comes to rest. It has a scale of numbers marked on the pendulum, and the upper part of the sliding weight is placed under that number which is to indicate the quickness of a stated note, as M.M. (Maelzel's Metronome) 𝅗𝅥 = 60, or ♩ = 72, or ♪ = 108, or the like. The number 60 implies a second of time for each single oscillation of the pendulum—numbers lower than this denoting slower, and higher numbers quicker beats. A more complicated metronome is actuated by clock-work, makes a ticking sound at each beat, and continues its action till the works run down; while a still more intricate machine has also a bell which is struck at the first of any number of beats.



BY COURTESY OF CARL FISCHER
METRONOME WITH FRONT OFF TO SHOW PENDULUM

METROPOLIS, a city of southern Illinois, U.S.A., on the Ohio river and Federal highway 45; the county seat of Massac county. It is served by the Burlington Route, the Illinois Central, the Nashville, Chattanooga and St. Louis and the Paducah and Illinois railways, and (for freight) by river steamers. Pop. (1920) 5,055 (84% native white, 15% negro); local estimate at 7,000 in 1928. It has numerous and diversified manufacturing industries, with an annual output valued at $3,500,000. The city was founded about 1837 and incorporated in 1871.

METROPOLIS, a mother-city (Gr. μήτηρ, mother, πόλις, city), and so the name of the parent state from which colonies were founded in ancient Greece (*see* Greece: *History, Ancient*). The word was used in post-classical Latin for the chief city of a province, the seat of government, and ecclesiastically for the see of a metropolitan bishop (*see* Metropolitan). It is thus used now for the capital of a country, which contains the various official buildings of the administrative departments, the houses of parliament, etc. In the case of London, the term "metropolitan" is sometimes applied to the whole area including the "City of London," *e.g.*, "Metropolitan Asylums Board"; and sometimes, as in "Metropolitan Police," excludes the City, which has its own police force (*see* London).

METROPOLITAN, in the Christian Church, the title of a bishop who has the oversight over bishops of subordinate sees. In the Western Church the metropolitan is practically the same as the archbishop (*q.v.*); in the Eastern Church he ranks above the archbishop, but below the patriarch (*q.v.*).

METSU, GABRIEL (1630–1667), Dutch painter, was the son of Jacob Metsu, a painter of Leyden, by his third wife Jacomina Garnyers. According to Houbraken, Metsu was taught by Gerard Dow. He was registered among the first members of the painters' corporation at Leyden; and he was still a member in 1649. In 1650 or soon after he settled at Amsterdam. One of his earliest pictures is the "Lazarus" at the Strasbourg museum, painted under the influence of Jan Steen. Under the influence of Rembrandt he produced the "Woman taken in Adultery" (1635), now in the Louvre. To the same period belong the "Departure of Hagar," formerly in the Thoré collection, and the "Widow's Mite" at the Schwerin gallery. But sacred art was ill suited to his temper, and he turned to other subjects for which he was better fitted. That at one time he was deeply impressed by the vivacity and bold technique of Frans Hals can be gathered from Lord Lonsdale's picture of "Women at a Fishmonger's Shop." Metsu depicted with surprising success the low life of the market and tavern, contrasted, with wonderful versatility, by incidents of high life and the drawing-room. In no instance do the artistic lessons of Rembrandt appear to have been lost upon him. The same principles of light and shade which had marked his schoolwork in the "Woman taken in Adultery" were applied to subjects of quite a different kind. A group in a drawing-room, a series of groups in the market-place, or a single figure in the gloom of a tavern or parlour, was treated with the utmost felicity.

Metsu married in 1658, and became a citizen of Amsterdam in 1659. One of the best pictures of his manhood is the admirable "Market-place of Amsterdam," at the Louvre. Equally fine are the "Sportsman" (1661) and the "Music Lovers" at The Hague, and the "Game-Dealer's Shop" at Dresden, with the painter's signature and 1662. Among the five examples of the painter at the Wallace collection, including "The Tabby Cat," "The Sleeping Sportsman" is an admirable example. Among his finest representations of home life are the "Repast" at the Hermitage in St. Petersburg (Leningrad); the "Mother nursing her Sick Child" of the Steengracht gallery at The Hague. Metsu died at Amsterdam in 1667, and was buried on Oct. 24 of that year.

See Hofstede de Groot, *Catalogue of Dutch Painters* (1907).

METTERNICH-WINNEBURG, CLEMENS WENZEL LOTHAR, Prince (1773–1859), Austrian statesman and diplomatist, was born at Coblenz, May 15, 1773. His father, Count Franz Georg Karl von Metternich-Winneburg zu Beilstein (d. 1818), was a diplomatist who had passed from the service of the archbishop-elector of Trier to that of the court of Vienna; his mother was Countess Maria Beatrix Aloisia von Kagenegg. At the time of Clemens Metternich's birth, and for some time subsequently, his father was Austrian ambassador to the courts of the three Rhenish electors, and the boy was thus from the first brought up under the influence of the tone and ideas which flourished in the small German courts that lay within the sphere of influence of the France of the *ancien régime*. In 1788 he went to the university of Strasbourg, but the outbreak of the French Revolution caused him to leave after two years.

Metternich was a witness of the excesses of the mob in Strasbourg, and he ascribed his life-long hatred of political innovation to these early experiences. In 1790, by way of striking contrast, he was deputed by the Catholic bench of the Westphalian college of counts to act as their master of the ceremonies at the coronation of the Emperor Leopold II. at Frankfurt, a function which he again performed at the coronation of Francis II. in 1792. The intervening time he spent at Mainz, attending the university and frequenting the court of the archbishop-elector, where his impressions of the Revolution were strengthened by his intercourse with the French *émigrés* who had made it their centre. The outbreak of the revolutionary war drove him from Mainz, and he went to Brussels, where he found employment in the chancery of his father, at that time Austrian minister to the Government of

the Netherlands. Here, in Aug. 1794, he issued his first publication, a pamphlet in which he denounced the "shallow pates" of the old diplomacy and argued that the only way to combat the French revolutionary armies was by a *levée en masse* of the population on the frontier of France—singular views for the statesman who was destined to be the last great representative of the old diplomacy.

After a long stay in England, where he made the acquaintance of the prince of Wales (afterwards George IV.), Metternich went to Vienna; and on Sept. 27, 1795 he married at Austerlitz the Countess Eleonore von Kaunitz, a grand-daughter of the Austrian chancellor of that name. This alliance not only brought him great estates in Austria, but introduced him into the most exalted circles of Viennese society. Here he was well qualified to hold his own by reason of his handsome presence, the exquisite courtesy of his address and a certain reputation for gallantry. In Dec. 1797 he was chosen by the Westphalian counts as their representative at the Congress of Rastadt, where he remained till 1799. In Jan. 1801 he was appointed Austrian envoy to the elector of Saxony, and he then came into touch with many Russian and Polish families of importance. In Nov. 1803 his serious diplomatic career began with his appointment as ambassador at Berlin. His diplomacy here was not very successful although Prussia ultimately (1805) signed a treaty with Austria and Russia; but he had made himself personally so agreeable to the French envoy that after his appointment as ambassador to Petersburg, Napoleon requested that he might be sent to Paris, where he took up his residence as ambassador in Aug. 1806. His influence in European politics grew rapidly henceforward. At first he ingratiated himself everywhere at the French court and in society, notably with Talleyrand and Caroline Murat, Napoleon's sister. In 1809, however, war broke out between France and Austria, as Metternich had personally urged in his court. He was arrested as a reprisal for the action of the Austrian Government in interning two members of the French embassy in Hungary, and in June, on Napoleon's capture of Vienna, he was conducted there under military guard.

In July he was exchanged at Komárom for the French diplomatists, and was present with Emperor Francis at the battle of Wagram. On July 8, he succeeded to Stadion's place, and became minister of State on Aug. 4. He was absent at the peace conference at Altenburg when the emperor signed the Treaty of Schönbrunn on Oct. 14, 1809, and thus had nothing to do with this document, although on Oct. 8 he had been appointed minister of foreign affairs, a post he held for 40 years.

The position of Austria, reduced as she was by the Treaty of Schönbrunn to the level of a second-rate power, was one of great difficulty and danger, and of this Metternich was fully conscious. Up to this time, his policy had not been wholly free from emotional impulse; but henceforward it was nothing but calculation, caution and a mechanical balancing of chances. His first ambition was to gain time, and to separate Napoleon from the tsar. The power which seemed to him best worth courting was Austria's late enemy, although he was determined not to lose his freedom of action by any too great concessions. Napoleon's request for the hand of the Archduchess Marie Louise, whether due to Metternich's initiative or not, fitted his plans admirably. He accompanied the archduchess to Paris on March 13, 1810. The definite concessions which he established for Austria were, indeed, small; Napoleon declared that anything further must depend on Austria's attitude in the Franco-Russian War which he now stated to be inevitable. Yet Metternich had restored Austria's freedom to move. He hurried back to Vienna on Oct. 10, just in time to stop the strong pro-Russian party at the Austrian court from compromising this liberty by concluding an alliance with Russia, and to win over the emperor for his policy of armed abstention. With the approach of the Franco-Russian War, this policy became increasingly difficult to maintain in its entirety; but although Metternich concluded an alliance with Napoleon on March 14, 1813, promising him military assistance in return for considerable concessions which France was now obliged to offer, he at once informed Russia that Austria's troops would only act on the defensive, and held out a prospect of a renewal of the old alliance of the conservative powers. When Napoleon suffered by catastrophe in Russia, Metternich extricated Austria from her alliance, alleging that it had been abrogated by Napoleon's own act; reverted to neutrality; and had soon manoeuvred his country into the position of arbiter of Europe. Napoleon's signature of the armistice of Pleiswitz gave Austria time to complete her armaments. When Metternich visited Napoleon at Dresden on June 26, he still posed as the impartial "mediator," assuring the emperor "on his honour as a German count" that Austria was still free of "engagements." Yet he already had in his pocket the draft of the second treaty of Reichenbach (which was not, indeed, signed till the following day), whereby Austria contracted with Russia and Prussia to put 150,000 men in the field, and not to make peace without the consent of her allies, should Napoleon reject the ultimatum which was to be put to him. Metternich's object was, in fact, only to gain an extension of the armistice, till Austria was ready to take the offensive. As for the terms offered to Napoleon, his acceptance of them need not hamper the plans of the allies, while his rejection of them would be a blow to his waning popularity in France.

In the war that followed, although Metternich signed a fresh treaty with Russia at Töplitz (Sept. 9), committing Austria more closely to the policy of the allies, he was chiefly anxious to ensure that the balance did not swing too far, nor strengthen overmuch either Russia or Prussia. The course of events forced him, against his wishes, to agree to the restoration of the Bourbons, but in other respects the Treaty of Chaumont (March 1, 1814) was a real triumph for him, since it laid down that at the final settlement Germany was to be reconstituted as a confederation of sovereign States, and also did much to temper the fear of a Russian dictatorship by consecrating the principle of that concerted action of the Great Powers, in affairs of international interest, which after Napoleon's fall governed the European system.

On April 10, Metternich arrived at Paris, ten days after its occupation by the allies. He was now at the height of his reputation; on Oct. 20, 1813, two days after Leipzig, he had been created an hereditary prince of the Austrian Empire; he now received from the Emperor Francis a unique honour: the right to quarter the arms of the house of Austria-Lorraine with those of Metternich. At the same time (April 21) the countship of Daruvar was bestowed upon him. On May 30, Metternich set his signature to the Treaty of Paris, and immediately afterwards accompanied the Emperor Alexander and King Frederick William on a visit to England. On July 18, he was back in Vienna, where the great congress was to meet in the autumn. The dignity of a Hungarian magnate was bestowed upon him.

At the congress Metternich's charm of manner and great social gifts gave him much personal influence; the ease and versatility with which he handled intricate diplomatic questions, too, excited admiration; at the same time he was blamed for his leaning to intrigue and *finesse* and for a certain calculated disingenuousness which led to an open breach with the Emperor Alexander.

Whatever the real wisdom of the decisions, he reached a settlement in Germany and Italy precisely in accordance with his wishes and emerged from the congress, of which he had been unquestionably the greatest figure, wholly content with his work. He was destined to spend most of the remainder of his life in an attempt to stabilize and make permanent the situation which he had so largely helped to create. The key-note of his policy henceforward was his attempt to use the European concert as an instrument for ensuring the "stability" of Europe by suppressing any "revolutionary" movements. Both Austria's multinational character, and her central position in Europe caused him to follow a policy that was essentially European. *"C'est que depuis longtemps l'Europe a pris pour moi la valeur d'une patrie,"* he said to the Duke of Wellington in 1824; and to his wife he wrote: "I have become a species of moral power in Germany, and perhaps even in Europe." In part this was due, no doubt, to personal vanity, but he had also arranged his system so that it must feel the shock of any disturbance even in the remote parts

of Europe, much more in Germany, Italy or Austria itself. So in his system of diplomacy by congress, Metternich, everywhere the central figure, busied himself in repressing liberty, whether in Germany, Spain or Italy. At first his dominance was unquestioned, especially after he had finally won the Tsar Alexander over to his side; it was weakened first by the ascension to office of Canning in England, and still further by the revival of the Eastern Question (*q.v.*) in the shape of the Greek revolution, which left Austria isolated in the Near East. The revolutions of 1830 seemed to threaten Metternich's system, yet gave it, at least, a temporary new lease of life. The Berlin convention of Oct. 15, 1833, which reaffirmed the divine right of intervention was a fresh triumph for Metternich's diplomacy, yet it was his last conspicuous intervention in the general affairs of Europe. Although he himself hardly realized it, his system had already passed away.

In domestic affairs Metternich was not, indeed, the whole-hearted reactionary for which he was often taken. He was too intelligent not to see the abuses inherent in the Austrian governmental system, and would gladly have remedied some of them. The real author of the incredibly reactionary and aggressive *régime* in Austria in the opening half of the 19th century was the Emperor Francis I. Metternich declared himself more than once, and possibly believed himself to be a liberal. But in any case, he lacked the moral courage to urge the reforms which he felt to be necessary, and he certainly misjudged the forces of his time. His mind was essentially 18th century, and he thought in terms of the State not the nation. He saw that nationalism was fatal to Austria's position in Germany, Italy and at home, and for this reason struggled against it; but he totally miscalculated its real strength, and so the work of his later years, and even at the Congress of Vienna, failed completely to secure the stability which he preached. Although for many years chancellor of Austria, he was not, indeed, primarily interested in internal policy, not mainly responsible for it, and probably could not have reformed it greatly. After the death of Francis I. he was, in any case, too old to change. He was too experienced not to realize the sickness of the State, but he was content to veil it from himself and to attempt to veil it from others. The world was not deceived; but it was not until the Vienna mob, in 1848, was thundering at the door of his cabinet that Metternich himself realized the truth to which he had tried to blind himself. With his fall his system also fell; and his flight from Vienna was the signal for the revolutions of 1848.

The resignation of Prince Metternich, handed in on March 13, 1848, was accepted by the emperor on the 18th, and the prince and his family at once left for England. Here he lived in great retirement, at Brighton and London, until Oct. 1849, when he went to Brussels. In May 1851 he went to his estate of Johannesberg; in September he returned to Vienna. The events of 1848 had not shaken his self-complacency; they seemed to him rather to confirm the soundness of his own political principles. He died on June 11, 1859.

Probably no statesman has, in his own day, been more beslavered with praise and bespattered with abuse than Metternich. By one side he was reverenced as the infallible oracle of diplomatic inspiration, by the other he was loathed and despised as the very incarnation of the spirit of obscurantism and oppression. The victories of democracy brought the latter view into fashion, and to the liberal historians of the latter part of the 19th century the name of Metternich was synonymous with that of a system in which they could recognize nothing but a senseless opposition.

The later reaction against this view found its fullest expression in the work of Srbik (*see* below); but Srbik's own estimate has been questioned. Of the "technique" of diplomacy Metternich was a master. His despatches are models of diplomatic style. They, are, indeed, sententious, over-elaborate and excessively lengthy, yet their phrase-making was often the result of astute calculation.

In private life Metternich was a kind, if not always faithful, husband and a good father, devoted to his children, of whom he had the misfortune to lose several before his death. He was three times married. His second wife, Baroness Antonie von Leykam, Countess von Beilstein, died in 1829; his third wife, Melanie, Countess Zichy-Ferraris, died on March 3, 1854. Of his sons three survived him: Richard Clemens Lothar (1829–95), his son by his second marriage, who was Austrian ambassador in Paris from 1859 to 1871; Prince Paul (1834–1906) and Prince Lothar (1837–1904), his sons by his third marriage. His grandson Prince Clemens (b. 1869), son of Prince Paul, married in 1905 Isabella de Silva Carvajal, daughter of the marquis de Santa Cruz.

Bibliography.—A vast mass of unpublished material for the life of Prince Metternich exists in public and private archives; to some of those in the F.O. Records references are given in the bibliography to chap. 1. of vol. x. of the *Cambridge Mod. Hist.* Of published documents the most important are in the collection *Aus Metternichs nachgelassenen Papieren* (1880–84), edited by his son, Prince Richard Metternich. There is a complete French translation issued contemporaneously, and an English version, of which only five volumes (down to 1835) have been published, under the title *Memoirs, etc.* (London, 1880–82). These *Memoirs,* especially the autobiographical parts, must be read with considerable reserve; even the official letters and documents, which are their most valuable contents, have been to a certain extent "edited." Fedor von Demelitsch's *Fürst Metternich und seine auswärtige Politik,* vol. i., to 1812 (Munich, 1898), is an elaborate and useful analysis of Metternich's foreign policy, based on a large mass of unpublished archives. A very full modern biography is that by H. von Srbik, *Metternich, der Staatsmann und der Mensch* (Vienna, 1925).

METZ, a town of France, capital of the department of Moselle, on the Moselle, 99 m. N.W. of Strasbourg by rail, and on the through route from Paris to Mainz and Frankfort. Pop. (1926), 63,125.

History.—Metz, the Roman *Divodurum,* was the chief town of the Mediomatrici, and was also called by the Romans Mediomatrica; Metz is a contracted form. Caesar describes it as one of the oldest and most important towns in Gaul. The Romans, recognizing its strategical importance, fortified it, and supplied it with water by an imposing aqueduct, the remains of which still exist. Under the Roman emperors Metz was connected by military roads with Toul, Langres, Lyons, Strasbourg, Verdun, Reims and Trier. Christianity was introduced in the 3rd century. In the middle of the 5th century the town was plundered by the Huns under Attila; later it came into possession of the Franks, and was made the capital of Austrasia. On the partition of the Carolingian realms in 843 Metz fell to the share of the emperor Lothair I. as the capital of Lorraine. Its bishops, whose creation reaches back to the 4th century, now began to be very powerful. Metz became a free imperial town in the 13th century, and soon became prosperous. Having adopted the reformed doctrines in 1552 and 1553, it fell into the hands of the French and was defended against Charles V. by Francis duke of Guise. It now sank to the level of a French provincial town, and its population dwindled from 60,000 to about 22,000. At the peace of Westphalia in 1648 Metz, with Toul and Verdun, was formally ceded to France. It was taken by the Germans in 1870 and ceded to them in 1871. It was retroceded to France after the World War.

Buildings, Industries, etc.—The general appearance of the town is quaint and irregular, but there are several handsome modern streets. The Moselle, which is here joined by the Seille, flows through it in several arms, and is crossed by 14 bridges. Of the ten city gates the most interesting are the Porte des Allemands on the east, a castellated structure built in 1445, and the Porte Serpenoise, flanked by turrets belonging to the old ramparts, on the south. The cathedral, 13th to 16th centuries, with huge pointed windows, slender columns and numerous flying buttresses, belongs to the period of the decadence of the Gothic style. St. Vincent, 13th and 14th century Gothic, has a Renaissance façade, and St. Eucaire, 12th–15th century restored, has a pilgrimage chapel. The public library contains an extensive collection of works relating to the history of Lorraine. Metz is the seat of a bishopric, of a prefect, of the VI. military region and the XXXV. army corps, of tribunals of first instance and of commerce, of a board of trade-arbitrators and of a chamber of commerce. The chief industries are the manufacture of shoes and metal-goods and the preserving of fruits and vegetables. There is a national tobacco factory. Trade is in wine, grain, cattle and garden produce.

As a fortress, Metz has always been of the highest importance,

and throughout history down to 1870 it had never succumbed to an enemy, thus earning for itself the name of La pucelle. The original town walls were replaced by ramparts in 1550, and the citadel was built a few years later. By 1674 the works had been reconstructed by Vauban. Under Napoleon III. the fortress was strengthened by a circle of detached forts, which, after 1870, were modified and completed by the Germans, who treated the fortress as the pivot of operations against France.

BATTLES AROUND METZ, IN THE FRANCO-GERMAN WAR, 1870

Colombey–Borny (August 14).—The French army under Marshal Bazaine was in and about Metz. The German I. and II. Armies, on the march from the Saar, were heading for the Moselle between Metz and Pont-à-Mousson, and on the morning of Aug. 14 the German I. Army (I., VII. and VIII. Corps, under General v. Steinmetz) lay on and east of the French, with outposts well to the front, watching the French camps east of Metz, which were little more than 1m. to the front. Steinmetz had received from headquarters overnight instructions that on Aug. 14 the I. Army would maintain the positions occupied during the 13th, and merely passed on these orders to his corps commanders. In Metz, meanwhile, Bazaine had decided to retreat. The II. Corps (Frossard) and VI. (Canrobert) began to retire about midday, the III. (Leboeuf), IV. (Ladmirault) and Imperial Guard (Bourbaki) were to follow. These preparations being observed, the German outposts got under arms. Goltz, in command of the VII. Corps determined at 3 P.M. to advance to the ridge between Colombey and Borny (which was still occupied by French outposts), in order to clear up the situation. The ridge was easily captured, but the sound of the firing at once set all the neighbouring troops in motion, and fortunately so, for the French had immediately retaliated on Goltz. Between 4 and 6 P.M. there was continuous heavy fighting on the front from Borny to Mey, held by Leboeuf's corps, as both sides brought fresh troops into the field, and the troops engaged rapidly slipped from all superior control. Shortly before 6:30 Ladmirault's corps came up, endangering the right flank of the Prussian I. Corps (General v. Manteuffel). Meanwhile Steinmetz had been sending peremptory orders to the battlefield to stop the battle, but neither of the corps commanders was able to enforce them. Fortunately for the Prussians, Bazaine had issued similar orders to his subordinates, who, having their men better in hand, were able to obey; and as night began to close in the French broke off the action and retired under the guns of the Metz forts, convinced that at last they had "broken the spell" of German success. In this action the Germans brought only 30,500 on to the battlefield out of more than 100,000 which could have been engaged before darkness. Bazaine actually deployed 50,700 to oppose them. He might, however, had he been so minded, have struck with his whole army—nearly three times this force, and, judging from the course events actually took, we can have little doubt as to the result of such a blow. The losses on either side were in killed and wounded—French 3,600, Germans 4,800.

The Battle of Vionville—Mars-la-Tour (August 16).—On the following day (15th) the German II. Army approached the Moselle above and below Pont-à-Mousson, with a view to overtaking and heading off Bazaine in his presumed retreat to the Meuse (*see* FRANCO-GERMAN WAR). So far, however, from being ahead of the Germans on the road to Verdun, the French were actually, late in the afternoon of Aug. 15, bivouacked on the plateau of Rezonville, and there their outposts were placed, not where they could see the surrounding country, but at the regulation distances of 600 to 1,000 paces from the bivouacs. At daybreak on the 16th, no Prussians being reported in sight by the outposts, the troops began nonchalantly to prepare for the resumption of the march. On the Prussian side, Alvensleben's Corps (III.) shortly after daybreak was moving north-westward from the Moselle in two columns, on Vionville and Mars-la-Tour, Alvensleben himself riding in advance. The 6th cavalry division was ordered to precede the right column and scout towards Rezonville. No one was aware of the dangerous proximity of the French army.

About 9 A.M. the 5th cavalry division, with two horse artillery batteries (flank guard of the X. Corps from Thiancourt), and accompanied by Caprivi (chief of staff, X. Corps, and afterwards chancellor of the German Empire), were trotting up the western slopes of the ridge which runs between Tronville and Vionville. Reaching its summit they suddenly found themselves in face of at least 40,000 encamped French troops. The temptation proved too great for the artillery, who promptly fired into the midst of the nearest camp. This gave the alarm and Frossard's II. Corps at once stood to arms and advanced, encountering the Prussian 6th cavalry division, which promptly bore away to cover. Meanwhile Alvensleben himself had seen the surprise of the French camps. The sound of the heavy firing coming from the eastward convinced him of what had been gradually dawning on him—that with barely 30,000 men he was in the presence of the whole French army.

In a few moments his decision was taken. Calling on the X. Corps, away to the south-westward, for support, he determined to screen his own weakness by a vigorous attack. By universal consent this is approved as the boldest resolution arrived at by an independent commander throughout the war. His 5th infantry division had already encountered the advancing French as it came out of the defile leading from Gorze up to Rezonville. Now the 6th infantry division, at this moment between Puxieux and Tronville, was ordered to wheel in to their right and attack. Under the onset of this division the French began to retire eastward. Bazaine had meanwhile arrived on the scene, and ordering forward fresh troops to relieve (not to reinforce) those already engaged, he rode forward to watch the operations—and narrowly escaped capture.

After an ill-advised French cavalry charge had been shattered by the Prussian infantry volleys, for about two hours there was a lull in the fighting, which the Prussians utilized on their right in bringing up reinforcements through the Bois des Ognons. On their left, however, no fresh troops were as yet available, and on being informed, about 2:30 P.M., that French cavalry seemed to be about to charge the exhausted 6th division, Alvensleben ordered Bredow's cavalry brigade to charge, and if necessary to sacrifice itself, to save the infantry. Bredow's command (six squadrons of the 16th Ulans and 7th Cuirassiers) moved off in line of squadron columns and ascended the gentle incline which still hid them from their enemy. Arrived at the summit, Bredow sounded "line to the front" but the men, no longer to be restrained, dashed forward, before the line could be completed, almost due east against long lines of infantry and artillery which they now saw for the first time about 1,200 yards in front of them.

This distance was covered at the fullest extended speed of the horses, and reaching the infantry they swept over them "like hounds over a fence"—in the words of an eyewitness. So sudden had been their onset that very few were hit until the infantry had been passed; then the latter, recovering from the shock, turned and fired into the cavalry from behind, whilst a whole fresh division of French horsemen charged them in flank. After a desperate melée of some minutes, the survivors, breaking their way a second time through the French infantry, eventually reached the shelter of their own lines, having lost rather more than half their numbers, but having saved the situation momentarily.

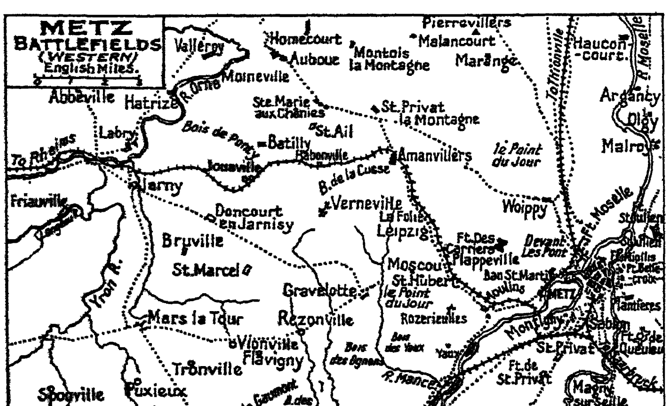
Meanwhile, unknown to Alvensleben, a fresh storm was brewing on his left, where Ladmirault's Corps had arrived from St. Privat—on his own initiative, not Bazaine's intention—and reached a position north of the Tronville copses whence his guns could fire into the left rear of the long line of Prussian guns on the heights above Vionville and Flavigny. Their fire threw the latter into serious confusion and he had decided to attack with his nearest division (de Cissey) in the direction of the steeple of Vionville, when the sudden apparition of a closed mass of Prussian troops detaching itself from the low dust-cloud of a slow-moving infantry column, and forming to the south of Mars-la-Tour, arrested his attention. Unanimously he and his staff agreed that this fresh enemy could only be the advanced guard of a large Prussian force, and delay occurred while the situation was investigated. Actually this body consisted only of the 38th brigade (Wedell), forming part of the X. Corps. In equal ignorance of the situation it moved diagonally across the front of Cissey's division, which, catching sight of them, opened a devastating fire

upon their left flank, and then charged, rolling up their line. The 1st Guard Dragoons, however, rode down the pursuers and by their self-sacrifice relieved the remnants of the infantry.

This was the scene which for the moment held the attention of Prince Frederick Charles when at length he reached the battlefield from Pont-à-Mousson. All along the rest of the line the Prussians were still holding their own, and on the extreme right fresh troops from the IX. Corps were streaming up through the woods against the French left wing. But on the left there was every sign of incipient disaster, and to avert this only the cavalry were at hand. Sending, therefore, hasty orders to the 5th and 6th cavalry divisions to concentrate to the west of Mars-la-Tour, the prince ordered them from there to sweep round on the right rear of the French army. The same idea had, however, occurred to Ladmirault, and he had called on the two nearest French cavalry divisions to put it into execution, and as the Prussians began to reach the plateau west of Mars-la-Tour and the Yron brook from the south, the French were deploying across it some two thousand yards to the north.

Then followed a duel—the one great cavalry duel of the war—between upwards of two thousand horsemen a side. But it was delivered by both sides in a series of regimental charges, and was singularly indecisive. For about half an hour great crowds of riders, hidden by dense clouds of dust, drifted aimlessly about the plain, till at length the charge of a single squadron delivered on the outer French flank, brought the whole mass into motion northeastward, and, both sides sounding the rally, the engagement gradually ceased. It was now about 7 P.M. and night was coming on. Seeing the dust-clouds drifting away northward, and noting the lethargy which seemed to have settled over the whole French line, Prince Frederick Charles decided to assert his own independent will to conquer by a final assault along his whole front. Guns, cavalry, infantry, everything that could still stand were to take part in it. But the troops soon lost direction in the smoke dusk and became involved in the direst confusion; and exhaustion put an end to the Prussian advance.

Thus closed the hardest fought battle of the Franco-German War. From 9 A.M. to 3 P.M. only 23,700 rifles, 8,100 sabres and 126 guns had been brought into action by the Germans against 59,100 rifles, 6,700 sabres, and 300 guns on the French side, and



even at the close of the day the former had only deployed 47,100 rifles, 8,300 sabres and 222 guns against 83,000 rifles, 8,000 sabres and 432 guns including 24 mitrailleuses. The chief characteristic of the day's fighting was the terrible effectiveness of the Prussian artillery, which was handled in masses and not, as on the French side, by batteries. The latter arriving singly on the field, were quickly reduced to silence. Deprived of their support, the gallant counter-attacks of the French infantry were repeatedly shattered, after rolling back the opposing infantry. As for the cavalry, on both sides, although they several times intervened to avert a menace, they proved altogether incapable of affecting the decision.

Gravelotte-St. Privat (August 18).—The position on to which the French army fell back from the field of Vionville is formed by a ridge some six miles long running from Rozerieulles almost due north to Roncourt, and connected with the general plateau between the Meuse and Moselle by a gentle saddle running from Amanvillers west towards Doncourt. North of this saddle the slopes are passable by troops of all arms in close order. To the south the rivulet of the Mance forms a formidable obstacle. Scrub and woods with dense undergrowth line both its banks, and, except by the great chaussée from Metz to Verdun, access to the French side becomes impossible to troops in ordered bodies. It does not appear that the position had been systematically examined or apportioned to the several corps. The army merely swung backwards, pivoting on its left wing. No lines of march were assigned to the several units, consequently the confusion became great; and, arriving late, many of them had so little idea of the general situation that they actually placed outposts to the north and east, whilst the whole enemy army lay south and west.

Fortunately for the French the Germans were too exhausted by the battle of the 16th to attempt to interfere with these movements. At daybreak on the 18th the royal headquarters (which now for the first time arrived at the front) still had no certain knowledge as to whether the French main army was in retreat, or in a position for a fight. Hence the orders issued overnight on the presumption that the main force of the French was retreating to the north and west were allowed to stand, and the whole II. Army (Prince Frederick Charles) moved off in échelon from left to right, the I. Army under Steinmetz, being left in observation of the troops visible on their front and of the garrison of Metz itself. And it had only the VII. Corps immediately available if the enemy counter-attacked. But Steinmetz had not ordered, nor had Zastrow, the corps commander, undertaken any preparations to meet an emergency. About 10 A.M. the corps of the II. Army had reached the following positions: VIII. Corps, Rezonville; IX. near St. Marcel; Guard approaching Doncourt; XII. towards Jarny; the III. and X. still in their bivouacs preparing to move. The cavalry of the Saxons had established the fact that the French had not retreated northward, but though scouts from the Guard had already seen the enemy on the heights of St. Privat, this information had not yet reached headquarters, nor had it been transmitted to the IX. Corps, which it most closely concerned.

Shortly after 10 A.M. Moltke, still under the impression that the French right extended no farther than La Folie (2m. north of the Metz road), determined to attack with the IX. and VIII. Corps whilst the Guard executed a turning movement via Habonville against the French right. The IX. Corps was to engage, but not to push its attack home until the Guard could co-operate. The XII. Corps was left to its own devices, but fortunately the crown prince of Saxony, who commanded it, had ridden forward and, seeing the French force towards Roncourt, had issued orders which in the event proved decisive. In pursuance of his instructions Manstein, commanding the IX. Corps, set his two divisions in motion towards La Folie and the Bois de la Cusse, and advanced to reconnoitre the French position. Suddenly coming in sight of the camp of a whole French corps (the 4th), he decided to execute an artillery surprise on a grand scale. At noon, just as the French infantry were falling in for midday roll-call, sufficient guns were in position, and suddenly opened fire. But the effect was disappointing. The French infantry ran to their arms, and moved forward to attack, while their artillery also took up the challenge, and from the heights near St. Privat the 6th Corps, whose presence was unsuspected by the Prussians, joined in. The batteries on the extreme Prussian left were saved by the timely arrival of companies of Hessian infantry. An obstinate fight ensued.

Prince Frederick Charles now brought forward the 2nd division of the Guard to the Hessians' assistance, while the 1st division attacked Ste. Marie. Meantime the crown prince of Saxony (XII. Corps), with a better view than his superior, was already aware that the French position extended to Roncourt at least, and had despatched a whole division down the valley of the Orne to outflank them. No news of this movement, however, appears to have reached Prince Frederick Charles. The Prussians rushed Ste. Marie, but became disordered, and more than an hour passed

before the troops could be re-organized. With the Hessians and the IX. Corps the action still dragged; the 3rd brigade of the Guard had become involved in the fight, and notwithstanding the arrival of the corps artillery of the III. Corps the situation was still critical.

About 4:30 P.M. the prince therefore had to consider how long it would take to obtain a decision. To postpone it till the morrow seemed undesirable; to achieve it before nightfall was only possible at the cost of immediate effort. He therefore decided to assault St. Privat with all the Guards available, and called up the III., X. and Saxons to assist them. The 4th brigade of the Guards now received their orders to attack Jérusalem (a hamlet a little south of St. Privat), and the 1st division was ordered to assault St. Privat itself. Pape, commanding the division, after pointing out his lack of artillery support transmitted the order. The deployment of his 2nd brigade was hindered first by the gardens of Ste. Marie and then by the overlapping of the 4th brigade, so that it had to wheel half-left in mass before it could gain room to deploy. Almost as the commands were given, the French suddenly opened an overwhelming long-range fire and their bullets swept like hail through the crowded mass of the German troops. Nevertheless the wheel was effected, the fresh direction taken, the troops extended for attack, and then the whole brigade dashed towards their objective. Meanwhile the 1st brigade had moved round the north of the village and carried out its extension without serious hindrance. The whole line then raced forward to reach the effective range of their very inferior weapons, which were about equal at 200yd. to the French rifle at 600. But the losses of the 2nd brigade, particularly in officers, had been too heavy, and the rush died out.

It was now about 6 P.M. and a long pause ensued, while the 220 guns, which by degrees had unlimbered behind them, brought these villages under fire. About 7P.M. the Saxon turning-movement took effect; their infantry from the Orne valley attacked Roncourt from the north, and about 7:15 the village was carried. With the III. and X. Corps now coming up, Prince Frederick Charles, although still unaware of the capture of Roncourt, decided to call on the whole of his force to attack. He was in the act of issuing his orders when a psychological wave swept through the fighting-line, and the men rose and rushed the village at the point of the bayonet. It was now about eight o'clock, and the light was failing.

The confusion in and around St. Privat, where troops from four corps were all intermingled, became so extreme that no further infantry-advance could be attempted; so under cover of a fierce artillery duel the remnants of the unfortunate French 6th Corps drifted away towards Metz down the many ravines leading into the river valley. The "annihilation" of the Guard at St. Privat has become historic. Yet, heavy as were the losses of the 1st Guard division they were not excessive compared to those previously endured—roughly one-third of their effectives had fallen. But the legend cannot be justified when the facts are compared with the slaughter of the Seven Years' War, of Napoleon's battles, the Crimea, and the American Civil War.

In the southern sector of the battlefield, where an entirely independent engagement had been raging all the afternoon; when Manstein's guns had opened fire opposite Amanvillers, Goeben's VIII. Corps and Zastrow's VII. Corps had promptly moved "to the sound of the guns," and his support. Both corps took as their primary objective the farms of St. Hubert and Point du Jour, standing just above the defile made by the Verdun-Metz road where it climbs out of the Mance ravine towards the French position. About 3:30 P.M. St. Hubert was carried and Steinmetz, believing the main French position to have been pierced, ordered the 4th cavalry division to cross the ravine by the *chaussée* and pursue. Simultaneously Zastrow had ordered his corps artillery to advance and Goeben, also, pushed up reserves.

All these columns converged upon the defile and a hopeless entanglement ensued. Here, exposed to all the random bullets and shells of the French, a panic ensued, thousands of men breaking away and flying in wildest confusion through Gravelotte towards the west. Hardly had they melted away when the French made a most brilliant counter-attack from their main position between the farms of Leipzig and Moscow. This was stopped almost entirely by the Prussian artillery fire; but the news of its coming sent another wave of panic through the mass, many thousands bolting right upon the front of their own batteries, thus masking their fire at the most critical moment, and something like a crisis in the battle arose. Fortunately the II. Corps was now rapidly approaching (about 6 P.M.) and the king, against Moltke's advice, now ordered Steinmetz to attack again with all his forces. Darkness and a third panic delayed the preliminary movements, but at length the II. Corps, together with all of the VII. that could be collected, moved down into the valley. Just as the leading German troops were approaching St. Hubert the French again began to fire, their bullets plunging down among the fresh arrivals, who knowing nothing of what had taken place about St. Hubert (where the remnant of their own infantry were still offering a desperate resistance) opened fire into the backs of their own men, and a fourth panic began which soon spread to the stragglers crowding the Mance ravine. Fortunately, by the superb gallantry of some of the company officers and men, the new arrivals were induced to recognise their mistake, and by degrees about 10 P.M. the whole of the II. Corps succeeded in reaching the plateau between St. Hubert and Point du Jour, where the débris of VII. and VIII. Corps had gathered. But in the darkness and confusion no forward movement against the French (only 400yd. to their front) could be initiated, therefore the whole mass passed the night where they stood until daylight disclosed the French retreat.

Meanwhile the king, Moltke and Bismarck, had ridden back behind Gravelotte where they passed two hours of intense anxiety. From the flash of the rifles it was clear that the French main position was still intact, and as every body of troops within thirty-six hours' call had been engaged there seemed little prospect of renewing the struggle next morning. No news too had come from Prince Frederick Charles. About midnight tidings of the capture of St. Privat arrived, and all anxiety ended.

The Investment of Metz (Aug. 19–Oct. 14).—During the night following the battle of Gravelotte the French army withdrew within the line of the forts round Metz. The 6th Corps only was severely shaken, the 4th (the best of the whole army), though it had fought hard twice within forty-eight hours, losing nearly 30% of its strength, was still well in hand, and the 3rd, 2nd and Imperial Guard were almost intact. After a fresh issue of ammunition and food they would have been capable of an attempt to thrust aside the I. German Corps, the only one in their direct path, and then fight their way across the communications of the II. and III. German Armies until they regained touch with the French railways to the south-west about Troyes. And although the latter army would have been a difficult obstacle, the chance of success was fair.

Bazaine, however, withdrew entirely under cover of the forts, and set about the reorganisation of his troops in the most leisurely manner. The Metz forts, though insufficiently armed and some incomplete, were nevertheless too formidable for any field army to attempt without the aid of a powerful siege train, which for the moment was not available. Hence the Germans decided from the first to reduce the place by hunger, calculating that with the extra 150,000 men thrown back upon the fortress, its food supplies could not last very long. On the morning of the 19th the German army was far too exhausted for further efforts. In the course of the afternoon the royal headquarters, creating a new army under the crown prince of Saxony for field operations towards the Meuse, assigned the remainder of the II. Army, and the whole of the I. Army to Prince Frederick Charles as commander-in-chief of the army of investment. Steinmetz was shortly afterwards relieved of his command and returned to Germany. This brought the strength of his command to eight corps, numbering some 220,000 men; an enormous mass to feed.

For the moment the chief care of the Prince was to guard against an attempt of the French army to break out to the westward. The encircling positions were fortified with a light outpost line, behind which was drawn a main position on which every art of the engineer was expended. The water-supply of the town was promptly interrupted, but the river water was quite drinkable.

Meanwhile the French in Metz had been diligently at work. There was no real deficiency of ammunition and stores in the fortress, and provisions for forty days were reported in hand. Bazaine issued orders for a break out to the northward by the right bank of the river, but at the last moment he wavered. Calling a council of war on the heights of Fort St. Julien, he asked the opinion of his subordinates, who were unanimously against the proposed sortie, principally because the artillery "had only ammunition enough for a *single* battle!" Besides, the Germans had long since become aware of the movement in progress, and all chance of surprise was past. It was also raining very heavily. Accordingly the scheme was abandoned. On August 29 Bazaine, receiving word of Macmahon's move to his relief, determined to renew the attempt.

At this moment (Aug. 31) the positions of Manteuffel's command (I. Corps and 3rd Landwehr division) were most dangerously extended, and a surprise at daybreak might have had far-reaching results. But the habit of excessive bugling and band-playing betrayed the French design even before daybreak. This time he adhered to his decision, but the concentration was not complete until 1:30 P.M., and not till 4 P.M. did the attack open (battle of Servigny or Noisseville); his opportunity had been allowed to slip, and though his first onset overwhelmed the German outposts, their main line held good, and masses of guns unlimbering over a front of some 4m. rendered all further attempts to break the German cordon abortive. Next morning the fighting was renewed, but the whole French army was disheartened. It was obvious that what they had failed to do by surprise was hopeless now that twenty-four hours had been given in which the Germans could make counter-preparations. Therefore about noon a general retirement under the guns of the forts took place, and the last serious hope of the French army had vanished. Some 120,000 men with 528 guns had been engaged against 60,000 Germans with 222 guns, and had been beaten off with a loss of 3,500 men. The Germans had lost about 3,000.

The investment now resumed its regular course, and as time wore on the conditions in Metz and the surrounding camps became deplorable. Towards the close of September rations had to be reduced, and the troops began slaughtering the cavalry horses for food. Probably to cheer the men by a semblance of activity Bazaine attempted a large sortie on Oct. 1 in the direction of Ladorchamps, and fighting continued into the 2nd, but without prospect of success, and the profound depression following on defeat sent up the sick list rapidly. One other sortie towards Noisseville followed on the 7th, but it was beaten off with the utmost ease by the investing troops, who were well fed and cared for. By this time even the gun-teams had followed the cavalry horses to the slaughter-house, so that the French as an army had ceased to exist. On the recognition of this fact negotiations for capitulation were begun on Oct. 13, and on the 14th the Army of the Rhine surrendered. Had it held out even forty-eight hours longer events before Paris and Orleans might have taken a different turn. The investment of Metz had lasted 54 days, and the death-roll of the civil population had risen to 3,587 against 1,200 in the corresponding period of a normal year. The army itself had only lost from sickness 2,600 men.

MEUDON, a town of northern France, in the department of Seine-et-Oise, 6 m. E. of Versailles by rail and about 2½ m. S.W. of Paris. Pop. (1926) 17,537. The remains of a castle (17th century) burned during the siege of Paris in 1871 have since been adapted as an observatory. In the 16th century the cardinal, Charles of Lorraine, built at Meudon a magnificent château destroyed in 1803.

MEULEN, ADAM FRANS VAN DER (1632–1690), Flemish painter, born in Brussels. He was a pupil of the battle painter Peter Snayers, and was called to Paris about 1666 by Colbert, at the instance of Le Brun, to fill the post of battle painter to Louis XIV. His paintings during the campaigns of Flanders (1667) so delighted Louis that from that date Van der Meulen was ordered to accompany him in all his expeditions. In 1673 he was received into the French Academy, attained the grade of councillor in 1681, and died full of honours in Paris in 1690. He is best represented by the series of 20 paintings, executed for Louis XIV., now in the Louvre.

MEUNIER, CONSTANTIN (1831–1905), Belgian painter and sculptor, was born at Etterbeek, Brussels, on April 12, 1831, and was a pupil at the academy there. His first exhibit was a plaster sketch, "The Garland," at the Brussels Salon in 1851. Soon afterwards, on the advice of the painter, Charles de Croux, he gave up sculpture for painting. Influenced by Millet, he began to absorb socialistic ideas, and chose most of his subjects from the life and surroundings of miners and factory workers. About 1880 he was commissioned to illustrate those parts of Camille Lemonnier's description of Belgium in *Le Tour du Monde* which referred to mines and factories. After a visit to Spain in 1882, where he painted "The Tobacco Factory at Seville" (Brussels gallery), he was appointed professor at the Louvain Academy of Fine Arts, and in 1885 returned to statuary, producing, among other works, "The Puddler," "The Hammerer" (1886), "The Mower" (1891), "The Glebe" (1892), and the "Puddler at the Furnace" (1893); and "The Horse at the Pond." He collaborated with Charles van Stappen in 1893, in the scheme for the decoration of the Botanic garden at Brussels. The "Monument to Labour," an unfinished work for the Brussels gallery, comprises four stone bas-reliefs, "Industry," "The Mine," "Harvest" and the "Harbour"; four bronze statues, "The Sower," "The Smith," "The Miner" and "The Ancestor"; and a bronze group, "Maternity." Meunier died at Brussels on April 4, 1905.

See Lemonnier, *Constantin Meunier* (1904); K. Scheffler, "Constantin Meunier," in Muther's *Die Kunst* (1908).

MEURICE, PAUL (1818–1905), French dramatist, was born in Paris on Feb. 7, 1818. In 1848 he became the editor of the *Evénement,* founded by Victor Hugo, and in 1869 he was one of the promotors of the *Rappel,* a journal on similar lines. He was the literary executor of Victor Hugo, and edited his works (1880–85). In collaboration with Auguste Vacquerie and Théophile Gautier, he produced *Falstaff* (1842), a play in imitation of Shakespeare, and in 1843 an imitation of the *Antigone;* and with Alexandre Dumas a *Hamlet* (1847). He also wrote *Benvenuto Cellini* (1852), *Schamyl* (1854), *Struensée* (1893), and a dramatic version of *Les Misérables* (1878). He died on Dec. 12, 1905.

MEURSIUS (JOHANNES VAN MEURS) (1579–1639), Dutch classical scholar and antiquary, was born at Loosduinen, near The Hague. At the age of 16 he produced a commentary on the *Cassandra* of Lycophron. Political disturbances caused him to leave Leyden, where he was professor of Greek, for Sorö in Denmark, where he died on Sept. 20, 1639. Many of his classical editions and treatises are printed in Gronovius's *Thesaurus Antiquitatum.* Scaliger called him "pedant" and "ignoramus," which he hardly deserves.

Complete edition of his works by J. Lami (1741–63). *See* Van der Aa's *Biographisch Woordenboek der Nederlanden* (1869), and J. E. Sandys *Hist. of Class. Scholarship* (1908), ii. 311. O. 1138

MEURTHE-ET-MOSELLE, a department of north-eastern France, formed in 1871 out of those parts of the old departments of Meurthe and Moselle which continued French. Before 1790 it belonged to Lorraine, or to one or other of the bishoprics of Toul, Metz and Verdun. Pop. (1926) 552,087. Area 2,036 sq. miles. It is bounded east by Lorraine, north by Belgium and the grand-duchy of Luxemburg, west by the department of Meuse, and south by that of Vosges. The department is formed of the basins of Meurthe and Moselle near Nancy, but not of the part of the Moselle basin focussing on Metz, for the department was reconstituted after that city had been taken by the Germans in 1871. It extends northwards to the frontier of Luxemburg along the scarp of the Côtes de Moselle (Oolite), including the Haute Plaine de la Voëvre within its borders. The department is hilly and rises to 2,041 ft. in the south-east near the Vosges. Summers are hot and winters severe. The mean annual temperature is between 48° and 49°. The annual rainfall averages between 28 and 32 in. The chief crops are cereals and potatoes, clover, mangel-wurzels, tobacco, hops and beetroot. The vine is cultivated; the best vintages are in the Toul district. Fruit trees include pear, apple, walnut, cherry and plum. Oak and wych-elm are most frequent in

woods in the west, beech and fir in the Vosges. The French school of forestry has its seat at Nancy. Horse-rearing is important. The salt-workings (chiefly between Nancy and St. Nicolas), and the iron-mines (round Nancy and Longwy) of Meurthe-et-Moselle are very important. Industries include manufacture of boots and shoes, straw and felt hats, pottery, tanning and brewing, cotton and wool spinning, and the manufacture of cotton goods, hosiery, embroidery, chemicals, soap, crystal, mirrors, glass, army clothing and paper. The Eastern railway from Paris to Strasbourg goes through Nancy. The main waterway is the canal between the Marne and the Rhine, communicating with the Moselle, which is navigable from Frouard downwards, and with the Eastern canal, which unites the Meuse and the Moselle with the Saône and the Rhone. The department constitutes the diocese of Nancy, under the archbishop of Besançon, has its court of appeal at Nancy, and forms a part of the district of the VI. (Metz) and the XX. (Nancy) army corps, and of the académie (educational division) of Nancy. There are three arrondissements (Nancy, Briey and Lunéville), with 29 cantons and 600 communes. The principal towns are Nancy, the capital, Lunéville, Toul, Longwy, Pont-à-Mousson and St. Nicolas.

MEUSE, a department of France, formed out of a part of Lorraine and Champagne. Pop. (1926) 218,131. Area, 2,408 sq. miles. It is bounded north by Belgium and the department of Ardennes, east by that of Meurthe-et-Moselle, south by those of Vosges and Haute-Marne, and west by those of Marne and Ardennes.

Oolitic rocks outcrop over most of the surface, and the department has the impervious lower Cretaceous clays beyond its western border and the Lias beyond its eastern one. The Meuse river crosses it from south-south-east to north-north-west, beneath a limestone scarp on the west (1,388 ft. in the south-west), and a ridge rises rapidly on the east (Côte de Meuse) to the high plain of the Woëvre. To the northern part of the western scarp the name of Argonne is given. The east of the Woëvre drains to the Moselle via the Orne and the Made, the valleys of which thus give access to the Meuse from the north-east; this gave St. Mihiel and Verdun very special significance in the World War. West of Verdun the hills of the Argonne diminish rapidly in height northwards. Most of the department save the north-west is over the 600 ft. level.

Its winters are less severe than those of the Vosges, but it is not so temperate as the Seine region. The average annual rainfall is about 30 inches. The chief crops are wheat, oats, rye, barley, clover, potatoes and mangel-wurzels. The vine is grown to some extent, notably at Bar. The forests, occupying more than a quarter of the area, are mainly of oak, and are rich in game, as are the rivers in fish. Baskets are made in the Argonne. Mineral wealth includes good freestone (Euville, Lérouville). It has iron and steel works, wire-works, and manufactories of files, hardware and edge tools. Ligny-en-Barrois manufactures scientific instruments. There are cotton-spinning, wool-weaving, and hemp, flax and jute factories, sawmills, carriage works, leather manufactures, glassworks, paper-mills, distilleries and flour-mills. The department is served by the Eastern railway, the principal lines being that from Paris to Strasbourg through Bar-le-Duc and Commercy, that from Paris to Metz through Verdun, and the branch line of the Meuse valley. The chief waterways are the canal connecting the Marne with the Rhine and the Eastern canal along the Meuse valley; together they are 145 m. long.

The department forms the diocese of Verdun under the archbishop of Besançon; it has its court of appeal and académie (educational division) at Nancy, and forms part of the district of the VI. army corps (Metz). There are 3 arrondissements—Bar-le-Duc, Commercy and Verdun—28 cantons and 586 communes. The principal places in the department are Bar-le-Duc, the capital, Commercy, Verdun and St. Mihiel.

MEUSE (Flem. *Maes*, Du. *Maas*), a river, 560 m. long, rising at Pouilly, 15 m. north of Langres, France, and flowing northward across the zone of Upper Jurassic rocks which are largely calcareous and give a steep-sided valley of some depth. On this section are the war-scarred S. Mihiel and Verdun, the latter where a line of relatively low land going from the Moselle to the Paris basin crosses the line of the Meuse valley. After passing Mézières the river crosses the lower Palaeozoic rocks of the Ardennes in a narrow valley, entering Belgium north of Givet to proceed to Namur. Here it is joined by the Sambre (left) and, now known as the Maas, turns eastward along the Belgium coalfield to Liège where it again turns north to pass Maastricht, forms the frontier for some distance and enters Holland below Maeseyck. After passing Roermond and Venloo it flows into the Waal channel of the Rhine and near Gorinchem it divides into two branches, the northern flowing due west to join the Lek (Rhine) above Rotterdam and the southern turning south passes along the canalized channel of the New Merwede and enters the Hollandsch Diep. It is also canalized between Liége and Visé and below Maastricht.

MEUSE-ARGONNE OPERATION. On Sept. 2, 1918, ten days before the St. Mihiel Battle in the World War, and during the concentration of troops therefor, an agreement was reached that the American I. army should attack on the Meuse-Argonne front immediately after the completion of the St. Mihiel operation. Marshal Foch had proposed the assignment of American divisions to the French II. and IV. armies, but as the American commander-in-chief, Gen. Pershing, adhered to his purpose of employing the main part of the American troops as an integral army unit.

This American operation, supported on the west by the French IV. Army, was strategically associated with the British-French St. Quentin-Cambrai attack and the combined Allied Ypres attack. The conception underlying these simultaneous offensives was to force such dispersion of the enemy reserves as to weaken his defence generally, or compel such concentration at vital points as would jeopardize other parts of his line. The vital portion of the German front was astride the Meuse river because, here, his main supply artery (Carignan-Sedan-Mézières), traversing the difficult Ardennes forest, was closest to the battle line. Withdrawals were accepted on all fronts except the Meuse-Argonne.

While the ultimate objective of the Meuse-Argonne operation was the severance of the German lines of supply, the immediate purpose was the reduction of the fortified area embraced by the Meuse river—Argonne forest and Hindenburg position extending from Brieulles through Romagne to Grandpré. The French high command hardly expected even this result before winter. The region was ideal for defence, commanded on the east by the Côtes de Meuse and west by the Argonne Forest and dominated in the centre by the heights of Montfaucon, Vauquois, Romagne, Bourgogne and Barricourt. With four successive positions, linked together by numerous interlocking strong points and machine gun emplacements, the defence was continuous for the whole area. Four years of occupation had created a zone 22 km. in depth of defensive strength unsurpassed on the western front. A possibility of ending the war in 1918 and full confidence in the fighting qualities of his troops, prompted the American commander-in-chief to risk his partially trained army in this difficult operation. In two weeks, this army was to reduce the St. Mihiel salient, change to a front about 100 km. distant and attack the fortified Meuse-Argonne zone, a task without parallel in the World War.

On Sept. 22, 1918, the American I. Army, Gen. Pershing commanding, took over the entire front from the Moselle river via Verdun to include Argonne Forest at La Harazée. The command embraced the XVII. French Corps and three French divisions north of Verdun. Maintaining a defensive attitude on the new St. Mihiel front with two army corps, the II. and IV., and eight divisions, and an aggressive defence about Verdun with one army corps and three divisions, all available units were assembled for the decisive attack west of the Meuse river by Sept. 25, 1918. The forces consisted of three army corps, the I., V. and III., 15 divisions (9 in front line and 6 in reserve), nearly 2,800 cannon, over 800 aeroplanes, about 180 tanks and necessary munitions, supplies and hospitals, some of the artillery, aviation, tanks and services coming from the French. This concentration, increasing to over 1,000,000 men in October, was accomplished by night movements over limited communications during and immediately after the St. Mihiel battle in less than three weeks. American feints and ruses

east of the Meuse and Moselle rivers led the Germans to expect an extension of the St. Mihiel operation so that the attack was almost a complete surprise. At this time the Germans had in line, Gen. Von Gallwitz's Detachment C, 10 Divisions at St. Mihiel front: Gen. Von der Marwitz's V. Army, eight Divisions, astride the Meuse river, and part of the Crown Prince's III. Army, three Divisions, astride the Aire river and the Argonne Forest.

After three hours of violent artillery preparation, the American I. army advanced at 5:30 A.M. on Sept. 26, between the Meuse river and the Argonne Forest inclusive with Montfaucon-Romagne-Buzancy as the axis of attack. During the first two days a steady advance was made except at Montfaucon, which the German stubbornly held until the second day and thus gained time for the arrival of reserves. By the 28th, the German had been driven back 11 km., when his reinforcements of eight divisions and considerable artillery and aviation launched strong counter-attacks which maintained intact his main Hindenburg position. Cross and flanking fire from the Côtes de Meuse and the Argonne Forest, coupled with severe fighting during the inclement weather after the 27th, inflicted heavy losses necessitating the relief of three American divisions which were experiencing their first battle. While all except a few heavy guns had passed "no man's" land by the 27th, supply and evacuation were difficult through the deep shell-battered zone over the four partially destroyed roads available. The attack of the French IV. Army in the Champagne made such slight progress that the American commander-in-chief granted Marshal Foch's request for two of his needed divisions as reinforcements to that army, desiring its early advance to assist in "pinching out" the Argonne Forest.

Having driven a salient into the centre of the enemy's defensive zone, the Americans with the three fresh divisions proceeded on Oct. 4 to outflank the Argonne Forest and Côtes de Meuse north of Verdun. After the 1st division had captured Fleville, the I. Corps, crossing the Aire river on the night of Oct. 6–7, assaulted the Argonne heights about Cornay. Severe fighting drove the Germans from the forest into Grandpré by the 10th. The French IV. Army on the west then advanced to the line of the Aisne river. In the attack against the Côtes de Meuse on Oct. 8, the enemy lost several important observation and artillery stations and over 3,000 prisoners.

With the danger of flanking fire reduced by these operations, the Americans in the centre again assaulted the vital Romagne heights which commanded the approaches to the Hindenburg line. By Oct. 16, Côte Dame Marie had been captured and the last organized defensive position in this vital area penetrated. By the end of October, the whole army had gained a footing in this position and the penetration at Grandpré and in the centre at Romagne heights had been complete. In the meanwhile, the French IV. Army made several unsuccessful attempts to cross the Aisne river west of the Bois de Bourgogne.

These American successes confirmed the judgment of the American commander-in-chief in declining Marshal Foch's proposal to limit the American I. Army to the Meuse valley and to create a new army (French-American) under French command to operate on both flanks of the Argonne. The American fighting had been incessant, day and night, the weather trying and replacements scarce. Artillery, tanks and transportation were inadequate and gas ammunition extremely short. However, the fortitude, resourcefulness and leadership of this newly organized army insured success. In a month's combat it had advanced 21 km., reducing four German positions and capturing over 18,000 prisoners, 370 cannon, 1,000 machine guns, and had forced the Germans to employ 31 divisions, including their last reserves. The strain on the German was calamitous and his morale was reaching the breaking point. The critical aspect of the situation was depicted by Gen. Von der Marwitz's declaration to his command about this time: . . . "The heaviest part of the task will thus fall on the V. Army . . . and the safety of the Fatherland will be in its hands. It is on the firm resistance of the Verdun front that depends the fate of a great part of the Western Front, perhaps even of our nation. . . ." Hindenburg in his memoirs added: "It was plain that this situation could not last. . . . Moreover the pressure which the American masses were putting upon our sensitive points in the region of the Meuse was too strong."

Preparing for an easterly advance the American commander-in-chief created a second army, placing Lt.-Gen. Hunter Liggett in command of I. Army on Oct. 16, and Lt.-Gen. Robert L. Bullard over the II. Army on the St. Mihiel front, himself retaining personal direction of this army group. While the I. Army continued its advance north and east, the II. Army was in readiness to move toward Briey.

For the first time the I. Army was able to prepare for its next general attack under normal conditions. Practically all its auxiliaries were now manned by Americans, and a new front with its manifold installations and services did not have to be created. Experience had welded the Army into an effective team with decisive striking power. Concentrating artillery and its aerial bombing in support of its V. Corps (centre), the I. Army, on Nov. 1, 1918, broke through the German defences to the north-east of Buzancy, the 2nd Division advancing nearly 9 km. The Germans were demoralized. On Nov. 2, the I. Corps on the left of the army pursued the enemy beyond Boult-aux-Bois clearing a passage of the Aisne River for the French IV. Army, while the centre and right carried the heights of Barricourt. By a night advance on Nov. 2–3 the approaches to Beaumont were cleared and the German Army between the Meuse and Bar Rivers was in full retreat. The following day the advance continued to the line of the Meuse capturing the heights commanding Sedan during the night of Nov. 6–7. With the German supply line (Carignan–Sedan) under heavy artillery fire by Nov. 3, the III. Corps (right) by a brilliant operation forced a crossing of the Meuse south of Dun-sur-Meuse and in conjunction with troops east of the Meuse cleared the northern slopes of the Côtes de Meuse by Nov. 7. Pursuant to Marshal Foch's instructions of Nov. 9 the advance continued to positions commanding the Chiers river, east of Stenay. Only the Armistice saved the German V. Army from complete destruction. American tactics and the American commander-in-chief's firm adherence to open warfare-training, the value of the rifle and bayonet and the possibilities of the offensive were justified by the brilliant successes in these operations.

With the capture of Côte Dame Marie on Oct. 16, the American I. Army penetrated defences covering the vital German supply lines and jeopardized a successful retreat of the German Army in the northern part of the western front. The Germans employed over one fourth of their divisional strength to meet the American attack, *i.e.*, 47 Divisions west and 15 Divisions east of the Meuse river. The American I. Army employed 31 Divisions (24 American and 7 French) on the whole front with a total ration strength in Oct. of 1,031,000. The Americans captured 26,000 prisoners, 847 cannon, 3,000 machine guns and large quantities of material and suffered 117,000 killed and wounded. (J. J. P.)

MEUSE LINE, the chain of French forts which prior to the World War were intended to close the passage of the Meuse between Verdun and Toul. The total length of the line was 31m., and the *forts d'arrêt* were disposed along the right bank. Between Toul and Épinal the frontier districts were designedly left open, and at Épinal the Moselle Line (*q.v.*) began. These lines formed part of the defensive scheme adopted by France in 1873–75.

MEW, CHARLOTTE (1870–1928), English poet. Her work appeared at first in various periodicals, but in 1917 a collection of 17 poems was issued by the Poetry Bookshop. An enlarged volume appeared under the title of *The Farmer's Bride* in 1920, and there are perhaps 20 more in existence. She was extremely critical of her own work, and the very small proportion of it which she allowed to be published is of a high quality. She died on March 24, 1928. For some time before her death she had been in receipt of a Civil List pension granted by the prime minister.

MEWS, PETER (1619–1706), English royalist and divine, was born at Caundle Purse, Dorset, on March 25, 1619, and was educated at the Merchant Taylors' school, and at St. John's college, Oxford, of which he was scholar and fellow. When the Civil War broke out in 1642 he joined the Royalist army. He was taken prisoner at Naseby; but was released, and in 1648 sought refuge in Holland. He became friendly with Charles I.'s secretary, Sir

Edward Nicholas, and made two journeys to Scotland in the king's service in 1653. Before this Mews had been ordained. Regaining his fellowship at Oxford after the Restoration, he received many preferments. In 1667, when at Breda arranging peace between England and Holland, he was chosen president of St. John's college, Oxford, in succession to his father-in-law, Dr. Richard Baylie, and afterwards became vice-chancellor of the university and dean of Rochester. Appointed bishop of Bath and Wells in 1672, Mews resigned his presidency in 1673, and in 1684 was elected bishop of Winchester, a position which he filled until his death on Nov. 9, 1706. Mews lent his carriage horses to pull the cannon at a critical moment during the battle of Sedgemoor. He was, however, in sympathy with the seven bishops, and as visitor of Magdalen college, Oxford, he supported the fellows in their resistance to James II. He took the oaths to William and Mary in 1689.

See S. H. Cassan, *Lives of the Bishops of Winchester* (1827); and the *Nicholas Papers*, ed. G. F. Warner (1886–97).

MEXBOROUGH, an urban district in the West Riding of Yorkshire, England, 11 m. N.E. of Sheffield, on the L.N.E. railway. Pop. (1931), 15,856. Situated on the river Don, which affords water communication with the Humber. The castle hill is crowned with some fine earth works of uncertain date. The large industrial population is mainly employed in glass, pottery and iron works and in the neighbouring stone quarries.

MEXICO, a Federal republic of North America, though belonging partly to Central America, in the geographical sense, and extending from the United States southward to Guatemala and British Honduras. Its northern boundary-line follows the Río Grande del Norte (Río Bravo) from its mouth northwestward to lat. 31° 47′ N., thence on that parallel westwards for 100 m., thence south to lat. 31° 20′ N., thence due west to the 111th meridian, thence in a straight line, nearly west-north-west, to a point on the Colorado river 20 m. below the mouth of the Gila river, thence northward to the mouth of the Gila, and thence nearly due west along the old line between upper and lower California, to a point on the Pacific coast one marine league south of the southernmost point of San Diego bay, this line having a total of 1,810 miles. The boundary-line with Guatemala and British Honduras is even more arbitrary, beginning at the mouth of the Suchiate river, on the Pacific coast, and following that stream to its source, thence determined by the peaks of Tacaná, Buenavista and Ixbul, from there following a parallel to the Chixoy river, which is really the Upper Usumacinta, to a point on the Usumacinta itself about 16 miles S. of Tenosique (Tabasco), thence due east to the San Pedro Mártir river, thence north to lat. 17° 40′ N., which it follows eastward to the border between British Honduras and Guatemala, thence north to the Hondo river which it skirts to Chetumal bay. The length of this border line is not known accurately.

Physical Geography.—Nowhere does the official boundary between Mexico and neighbouring countries coincide with any real barrier between different regions, nor is it a line of demarcation between different tongues, since the Spanish language is still the natural vernacular of thousands of people north of the American border. Mexico is essentially a region of transition through which one passes gradually from North America into Central America.

Mexico consists largely of an elevated plateau, open in the direction of the United States, limited on its two maritime sides by a double chain of mountains, themselves a continuation of American ranges, which meet one another at La Junta, south-east of Puebla. To this plateau must be added a fringe of lowlands extending on both sides between the mountains and the sea; a high region in the south-east which forms part of the Central American plateau; and two peninsulas, one, that of Lower California, which is evidently a continuation of the American coast range, and the other one, Yucatán, made almost entirely of a low calcareous plain.

Heilprin has shown that the great plateau of Mexico is what remains of a folded region, partly eroded, and covered with deposits of volcanic and detritic origin, and that the chains that are left are undoubtedly the continuation of the American Basin ranges deflected towards the south-east. Remains of transverse chains are to be seen in the isolated ridges and peaks, rising above the level of the table-land, and, in some cases, forming well-defined basins. Two such depressions are particularly conspicuous, the Bolsón de Mapimí, in which the resemblance to the American Basin ranges is quite evident, and the Valley of Mexico, formerly provided with large bodies of water, now replaced by small lakes and marshy lagoons.

The Mexican high plateau has a general elevation of about 8,000 ft. in the States of Mexico and Puebla. Its southward slope is abrupt, while the one to the north is gradual, being about 4½ ft. to the mile, as shown by the elevation at Ciudad Juárez, opposite El Paso, which is only 3,600 feet. In a general way the plateau slopes from south to north and from west to east.

Mountains.—The marginal ranges limiting the high tableland on both sides have been called by the Spaniards Sierra Madre Occidental and Sierra Madre Oriental, but such names are more picturesque than scientific and may easily be a cause of confusion since there are other sierras madres, not only in South America, but in Mexico itself. Anyway, such names can only be considered as having a general signification, and Mexicans give a different one to the various ranges forming the sierras madres.

The northern part of the Sierra Madre Occidental consists of several parallel ranges, the most eastern of which are the Sierra Tarahumare and the Sierra de Durango, while the most western are the Sierra del Nazareno, the Sierra Yaquí and the Sierra Fuerte, all of them converging to form the Sierra del Nayarit. The total length of the former ranges is 900 miles. The altitude of this part of the Sierra Madre Occidental rises constantly from north to south, as shown by the height of the culminating peaks, the Álamos, in the north, 5,874 ft.; the Frailecitos, in the centre, 6,840 ft.; and the Cerro del Pimal, in the Sierra del Nayarit, 11,319 feet. At about 20° of latitude, corresponding to the geographical position of the Nevado de Colima, 14,363 ft., and of the Volcán de Colima, 12,750 ft., the great chain again divides, the western part, or Sierra Madre del Sur, following the shore more or less closely as far as the isthmus of Tehuantepec, and the eastern branch crossing the plateau in a south by east direction.

The Sierra Madre Oriental is narrower and lower, except in its southern part. It rises southwest of Tampico, reaching high altitudes along the western frontier of Veracruz with the Cofre de Perote, or Naucampátepetl, 13,419 ft., and the magnificent snow-capped cone of Orizaba, or Citlaltepetl, 18,209 feet.

Crossing the highest part of the Mexican plateau is a broken and chaotic series of ranges, uniting the two *sierras madres,* part of which is sometimes called Cordillera de Anáhuac, where rise the *Malinche*, or Malintzin, 14,636 ft., the gigantic snow-clad cone of the Popocatepetl, 17,888 ft., the Ixtaccihuatl, 17,323 ft., and further west, the Nevado de Toluca, 15,168 feet.

The Sierra Madre del Sur, or Sierra de Oaxaca, of which the only high peak is the Zempoáltepetl (meaning 20 peaks), 11,139 ft., decreases in height from north to south until it reaches the low-lying isthmus of Tehuantepec, the lowest altitude (*portillo*) of which is 787 ft. (Böse), and the highest point, reached by the trans-isthmian railway, 852 feet. After this interruption the chain, now known as Cordillera de Chiapas, or de Soconusco, is seen to rise again, its summits reaching 7,872 ft., with the cone Soconusco, and 14,000 ft. with the Tacaná.

The great peninsula of Lower California, the "fleshless arm of Mexico" (*el brazo descarnado de México*), as the Mexicans call it, is a rugged region, evidently the continuation of the coast range of the United States, the Gulf of California corresponding to the San Joaquín-Sacramento valley. Its frame is made of four successive chains with an especially noticeable break in the middle, where the extinct volcanic group of Tres Virgenes is found. The highest recorded peak is the Calamahue, or Santa Catalina, 10,122 feet. These coastal ranges can be linked with the Sierra Madre del Sur, through the Tres Marías isles and Cape Corrientes, on the mainland (Gabb, Aguilera, Ordóñez, Suess).

Volcanoes and Earthquakes.—Starting almost at the border between the United States and Mexico, we find the beginning of a chain of volcanoes that is practically unbroken until it reaches

the southern end of South America. The Piñacate, of Sonora, 1,656 ft., is the only one, north of the Lerma river, that shows any activity, but south of that river we find the Ceboruco, 7,100 ft., which was still active in 1875, and the Colima volcanic group, of which the Fuego, 14,200 ft., has had frequent eruptions, the latest being the one of 1909. East of Colima rise the Tancítaro, 12,000 ft., and the famous Jorullo, 4,262 ft., whose first eruption took place in 1759; while north-east of this group we find the Nevado de Toluca or Xinantecatl, 15,000 ft., now quiescent, but whose former eruptions must have been formidable. South-east of the Nevado de Toluca is the Popocatepetl, 17,888 ft., not entirely extinct, whose crater is 500 ft. deep and 2½ m. in circumference, the craterless (although of volcanic origin) Ixtaccihuatl, 17,323 ft., the above mentioned Malinche, Cofre de Perote, and, finally, the Orizaba, the highest of all, 18,209 ft., probably the most perfect and beautiful of all volcanoes, and comparable to the Peruvian Misti and the Japanese Fuji. South-east of Veracruz is an isolated volcanic group of which the Tuxtla, 4,900 ft., had a terrific eruption in 1793 but is now quiescent. On the Pacific coast the Soconusco, 7,872 ft., smokes occasionally and, right on the border itself, the Tacaná, 14,000 ft., is still active.

Earthquakes, of which there were terrific ones in 1474, according to Aztec traditions, are particularly frequent in the Pacific region of Mexico, especially from San Blas to the Guatemalan border, the town of Chilpancingo being generally the spot most affected. In 1909 it was reduced to a mass of ruins, while Acapulco was almost as badly treated, partly on account of a tidal wave that followed the shock. The city of Tehuantepec is another place that has been frequently shaken. The Gulf region is rarely affected.

Coastal Region.—The low land, or *tierra caliente* region, which lies between the sierras and the coast, consists of sandy and marshy deposits near the sea, but some sections of the coastal lands, where débris from neighbouring mountains have accumulated, may reach an altitude as great as 3,000 feet, while on the Pacific coast mountain spurs may extend down to the littoral (Cape Corrientes, Cerro del León). In Tabasco and in south-west Campeche the low lands cover a much vaster extension and are made of the alluvial deposits of the Usumacinta and Grijalva net of rivers. The Yucatán peninsula, north of the Petén lagoon, is formed entirely of a white limestone of very low altitude, the geological age of which is quite recent (Sapper, Heilprin, Engerrand).

The difference between the aspect of the Atlantic (Gulf of Mexico) coast and that of the Pacific is as great in Mexico as it is in the United States. The former, 1,080 m. long, is generally low and sandy, and shows no bay of commercial importance except the shallow Tamiahua lagoon, the relatively deep Laguna del Carmen (the only one that has a natural harbour owing to the protection afforded by the islands of Carmen and Puerto Real), and those on the eastern coast of Yucatán, of which almost no use is made because the region itself is still undeveloped. The general lack of secondary articulations, characteristic of the Gulf coast, and the fact that all the rivers which have their mouths there are obstructed by sand-bars, explain why the good ports on the Gulf of Mexico are artificial; and it must also be remembered that this coast is by far the most important in respect to international communications. The leading ports are Tampico and Veracruz; the former, which is a river port, has been considerably improved by the building of breakwaters or jetties, while the latter is almost entirely man-made. Puerto México (Coatzacoalcos), on the river of the same name—a port whose future on account of its situation could hardly be doubted—has been improved in the same way as Tampico. Large boats can go as far up the river as Minatitlán, 26 m. from the coast. Progreso, the henequén (Sisal hemp) port, has taken the place of old Sisal, but can accommodate small vessels only and is losing depth on account of the slow rising of that part of Yucatán. Tuxpan, notwithstanding its growing importance in connection with the oil business, has not been much improved. Frontera, in spite of its favourable location at the entrance of a large river, is almost useless on account of a bar, while Campeche, at the head of a small, artificial harbour, is almost entirely silted.

The Pacific coast, 2,860 m. long, rugged and much better articulated, has excellent bays, one of which, that of Acapulco, is truly magnificent, though they are all cut off from the interior by the rough and abrupt ranges of the Sierra Madre Occidental. The only important ports are those connected with the interior by railway; viz., Guaymas, Topolobampo, Mazatlán, San Blas, Manzanillo and Salina Cruz. Lower California has some excellent natural bays, such as those of Ensenada de Todos Santos, La Magdalena, on the Pacific coast, and Santa Inés and La Paz on the Gulf of California.

There are no islands of great importance belonging to Mexico. El Carmen, with the port of the same name, on the Gulf of Mexico, Isla Mujeres and Cozumel on the east coast of Yucatán, are the only ones worthy of mention on the Atlantic coast, and the Tres Marías in the Pacific near San Blas, are used as a penal colony.

Rivers.—One would hardly expect that a country consisting mostly of a high denuded plateau and enjoying but a scanty rainfall would be provided with important rivers. It was, in fact, on that account that Mexico found it necessary to develop an efficient net of railways. On the Gulf side, where rivers are all obstructed with bars, we find first the Río Grande del Norte or Río Bravo, a river that is much more American than Mexican if we take into consideration the official boundary and the fact that its 1,800 m. of length is mainly in American territory. Ending in a small delta it has lost all the commercial importance it formerly possessed. Its leading branch on the Mexican side is the Conchos. Further south the Soto la Marina river hardly deserves mention because of the undeveloped region it traverses. The Pánuco river is one of the relatively important streams of Mexico owing to its numerous branches and to the fact that its mouth, thanks to a system of jetties, has been much improved, in order to facilitate the considerable commerce of Tampico. It now drains the lakes of the Valley of Mexico. The Papaloapam, whose head waters are in the mountains of Oaxaca, and the San Juan, which flows through one of the richest regions of the *tierra caliente*, finally unite in the lagoon of Alvarado. The Coatzacoalcos, in the isthmus region, owes its importance to the works that have been constructed to improve its entrance, as a means of improving in turn the port of Puerto México (Coatzacoalcos). It is navigable as far as Minatitlán, where there is a large oil refinery.

The Grijalva and the Usumacinta unite in a common delta but nothing has been done to prevent the forming of a bar and, as a result, the port of Frontera has not developed as much as one might have expected bearing in mind the splendid region the two rivers and their many branches pass through. The Grijalva, called Chiapas in its upper course, rises in the State of Chiapas and is navigable for 90 m., its total length being 350 miles. The Usumacinta, which rises in the Altos region of Guatemala, and is navigable as far as Tenosique, is a powerful river of majestic aspect, gathering in the waters of two important branches, one of which, the Río de la Pasión, has its headwaters in British Honduras. Its total length is said to be 330 miles. The Yucatán peninsula has no superficial streams, the whole country being made of a porous limestone through which the rain penetrates and forms subterranean rivers opening either into the coastal lagoon or into the Gulf itself, sometimes at quite a distance from the littoral. As a consequence, all the important villages are near some of the holes, or natural wells, called *cenotes* or rather *tzonotes*, through which one can reach the subterranean water, sometimes at a depth of as much as 400 feet. However, the south-eastern part of the peninsula, the geological constitution of which is somewhat different, has a relatively important river whose source lies in Petén and whose sluggish course has been chosen as the border between Mexico and British Honduras.

On the Pacific coast rivers are, with two exceptions, even less important on account of the narrower coast. The Río de las Balsas, or Mexcala, which rises in the southern part of the plateau (State of Tláxcala) might be termed a torrent during part of its course, then it runs some distance underground, after which it comes to the surface to cross a relatively large extension of *tierra*

MEXICAN SCENES IN CITY AND COUNTRY

1. View of the Merced Market in the Native Ghetto of Mexico City
2. Palm forests near the Tamasopo, in the state of San Luis Potosí
3. The *chinampas,* or floating gardens of Lake Xochimilco, south of Mexico City. The gardens were originally planted on mats of interlaced twigs covered with dirt, and were rowed out on the lake
4. A banana grove in Atoyac, Veracruz
5. Mount Popocatepetl in eruption. The volcano has a height of 17,888 ft., and is one of the highest peaks in the republic of Mexico
6. Part of the court and stairway of the Palacio del Conde de Santiago. This palace, which dates from the years following the Conquest, is among the oldest buildings of the Colonial period in Mexico City
7. El Palacio Nacional, the national palace of Mexico City. Many government offices are housed in this building which occupies a large city block. Its façade extends along the east side of the Plaza Mayor
8. A native home of tropical Mexico. The straw thatched roof is characteristic of this part of the country
9. View overlooking Guanajuato City, capital of the state of Guanajuato. The city is situated in a narrow mountain gorge high above the great plateau and is one of the oldest places in Mexico
10. The ancient Spanish aqueduct of Los Remedios
11. Tamasopo river near Veracruz

caliente, and finally ends in a broad estuary at about the 18th parallel. The Lerma, Río Bravo, Río Grande or Santiago, also begins on the plateau, near the Nevado de Toluca, from which it reaches Lake Chapala, then leaves it and forms a fall 50 ft. high and 430 ft. wide at Juanacatlán not far from Guadalajara, after which it runs through deep canyons till it reaches the Pacific ocean, north of San Blas. Other rivers are the Mezquital, the Fuerte, Yaquí and Sonora.

Lakes.—Mexico has no great lakes, the Chapala being the largest, with a length of 80 m. and a width of 35. In Michoacán are, among others, the superb little lakes of Pátzcuaro and Cuitzeo, but the most interesting of all the Mexican lakes, on account of their historical meaning, are those of the Valley of Mexico, Xalco, Xochimilco, Zumpango, Xaltocán, S. Cristóbal and Texcoco, the latter being the only one whose level is lower (by 4 to 6 ft.) than that of the City of Mexico, and whose shallow waters are brackish. All these lakes are evidently the remains of a former body of water of much greater area. The Xochimilco, whose waters are no more than a few inches deep, would have been transformed into a salty plain years ago, had it not been for its constant reception of the overflow from the higher lakes. For centuries the City of Mexico was again and again flooded during the rainy season by its dangerous neighbours until a system of drainage was established through which the excess of water is sent to a branch of the Pánuco river, together with the sewage of the capital. Lacustrine depressions of great interest are found in other parts of the country, such as the Guzmán and the Sta. María, in the State of Chihuahua, the lagoons of the Bolsón de Mapimí, the Tlahualila lagoon which receives the Nazas river (370 m.) and the Laguna del Muerto, fed by the Río Aguanaval during that part of the year when it reaches that body of water. In the Yucatán peninsula the brackish lagoon of Chichankhanab is a fine example of a greatly varying body of water.

Geology.—The dominant topographic feature in Mexico, as we have seen, is its high plateau, which is made of Cretaceous formations and of detritic and volcanic rocks, the latter being by far the most important. The lowlands on both sides are largely made of recent beds, while folded Cretaceous and Tertiary layers, interspersed with eruptive formations, make the bulk of the region south of the isthmus of Tehuantepec. Yucatán is an immense slab of limestone of recent age. Strangely enough, nowhere in Mexico, with perhaps the exception of the Carboniferous of Chiapas, do we find Primary formations of clearly established age. Some of the oldest eruptive rocks must be of Precambrian and Paleozoic ages, but, so far, it has been impossible to classify them with certainty—this being true even of the so-called gneiss of Oaxaca. The Silurian, Devonian and Carboniferous of Sonora, Chihuahua, and other northern States, are termed doubtful by the best authorities. Mesozoic formations other than Cretaceous are represented in Mexico but the extension covered by them is not considerable. Black schists, greyish clays and greenish sandstones containing ammonites belonging to the *Sirenites, Protrachyceras, Clionites* and *Anatomites* genera, together with pelecypods, such as *Palaeoneilo* and *Aviculidae*, have been found by Burckhardt near Zacatecas and are of Triassic age. The Jurassic, well studied by the same geologist, is represented in northern Mexico, in the states of Veracruz, Zacatecas and San Luis Potosí, showing sometimes an interesting mixture of Russian and Mediterranean species (Sierra de Mazapíl, Zacatecas). The Upper Oolitic of Cerro de Titania (Tlaxiaco) contains an essentially neritic fauna with *Gryphaea* and *Exogyra*, quite similar to the more northerly Jurassic of the Malone mountains (Texas).

The Cretaceous, for knowledge of which we are indebted to Felix, Lenk, Aguilera and especially Böse, is enormously developed in Mexico, the lower one being found little folded near the American border, while it is deeply folded towards the centre of the country. In the Tlaxiaco and Tehuacán regions it shows Mediterranean and Texan affinities. The Middle Cretaceous of the type found in Texas extends as far south-west as the State of Michoacán, but it is also represented in the States of Mexico, Hidalgo, Morelos and Querétaro. The Upper Cretaceous, the lower formations of which are so finely developed in Texas, has not been discovered in Mexico, but the Campanian exists in Central Mexico, while beds of the Laramie type are known in Nuevo León. The Cenozoic era is represented by extensive deposits in the two low coastal regions, especially in the States of Tabasco, Chiapas, Campeche and Yucatán, but there is no doubt that many eruptive rocks and detritic formations of the high table-land are of that age. The Nummulitic is known in Chiapas; the Oligocene in Veracruz and Chiapas, while Miocene faunas have been found in the isthmus by Böse and in Chiapas by Urbina and Engerrand. The Pliocene and the Pleistocene are hard to distinguish, especially on the high plateau. We know enough, however, to be able to state that faunas of mastodons, horses, camelidae and glyptodons lived in Mexico at the end of Tertiary times. Most of the Yucatán peninsula is made of Pliocene and Pleistocene formations. No proof has been found as yet of the existence of man in Mexico before the Holocene.

Volcanic activity must have begun some time during the Cretaceous or at the beginning of the Tertiary era. Many geologists think that the high plateau is a folded region on which enormous quantities of eruptive rocks accumulated, in the first instance andesitic lava; later, after valleys had been cut through it, new eruptions have originated the formation of thick layers of rhyolites and dacites; and, still further, one more period of volcanic activity resulted in the formation of basaltic tables found above all the other rocks.

Climate.—Two causes contribute to make the climate of Mexico among the most varied on earth: one, the great longitudinal extension of the country, which stretches through 17 parallels of latitude, with the tropic of Cancer crossing it about midway, and the other, the fact that the larger part of the country consists of a very high plateau. In order to give an accurate account of the climate of Mexico, we have to resort to the old division into three (even four) vertical zones, *tierra caliente, tierra templada* and *tierra fría*, which, although applicable to other countries, such as Guatemala and Colombia, finds its best possible application in Mexico.

The *tierra caliente* rises from sea-level to an altitude of about 3,280 ft. and includes the coastal zone, 30 to 40 m. wide, the Yucatán peninsula, all of Tabasco, part of Chiapas, the isthmus of Tehuantepec and a relatively small part of Oaxaca, its mean temperature ranging from 77 to 82° F, rarely falling to less than 60°, but reaching 105°, 110° and even higher on many points of the Pacific coast, especially Guaymas (max. 119° F), Mazatlán, Manzanillo and Acapulco though on the Atlantic coast, even in Yucatán, regular breezes make the heat somewhat less oppressive. The maxima, observed anywhere in Mexico, are not higher, however, than those recorded in some parts of Texas and Arizona.

The *tierra templada*, or subtropical zone, rises to an elevation of from 5,500 to 6,000 ft. and comprises "the greatest portion of Coahuila, Nuevo León, San Luis Potosí, nearly half of Tamaulipas, a small part of Veracruz, nearly the whole of Chiapas and Oaxaca, and a large portion of Guerrero, Jalisco, Sinaloa and Sonora." Its mean annual temperature is 75° F and it has justly been called the best of the three zones, even to Europeans, on account of its lacking the anaemiating influences that are found at higher altitudes. Orizaba and Jalapa, in the State of Veracruz, are typical stations.

The so-called *tierra fría*, which ranges from about 5,500 to 9,000 ft., is made of all the higher parts of the plateau, and its average temperature is about 63° F. At such altitudes there is never any real heat, nor are winters cold, although a slight frost during the night is a frequent occurrence. Once in ten years a few snow flakes may be seen falling on the City of Mexico; but during the winter there is a great difference in temperature in the same house between the rooms exposed to the sun and the others less favourably situated, and foreigners find it impossible to stay in the latter without artificial heat. Its climate may be compared to that of Tuscany, but the maxima of heat and cold that can be observed in Florence are never experienced on the Mexican high plateau. In Mexico City the coldest months are December and January while the warmest are April and May.

Some climatologists consider a fourth zone, the *tierra helada,* or frozen land. It is found above the third one and is made of all the mountains and peaks above the high plateau. The term is exaggerated when applied to its lower parts where forests are found and where cereals are cultivated, but it is evident that at a very high altitude polar conditions are encountered. Such zones are, of course, uninhabited except in rare cases, the ranch of Tlamecas on the Popocatepetl, the altitude of which is 12,500 ft. and which is inhabited the whole year round, being one of them. The succession of climates represented by these different zones can be experienced in a few hours by going on the train from Veracruz to Mexico City. Where the plateau is cut by deep valleys, one can admire the marvelous spectacle offered by the three zones in succession with their wheat-fields, maize, coffee trees, light green patches of sugar-cane and finally the banana tree in its finest development.

Rainfall.—As has been mentioned in another part of this article, the annual rainfall is very heavy in the *tierra caliente,* south of the tropic of Cancer, while near the border on the west side, there is almost none. In certain parts of southern Campeche, in Tabasco and in Veracruz the annual rainfall reaches 80, 90 and even 100 in. (Huatusco district). In most of Mexico it is the absence or the presence of the rain that marks the changing seasons. As is the case with many countries of South America, Mexico has only two such seasons, the dry and the rainy. These seasons come at slightly different times according to latitude and altitude. In Mexico City the former which, despite the fact that it is called summer, is characterized by colder weather, during a few months, begins in October and ends in June. The latter corresponds to the rest of the year. Each season shows some short changes for a few days, on regular dates, in connection with astronomical phenomena. The annual rainfall for the whole republic is 59 in.; it is less than 25 in. in the Valley of Mexico.

Flora.—The immense diversity that Mexico offers in environment and climate is the natural explanation of its remarkable variety in plant life, from the desert flora of the north to the luxuriant tropical one. Although three leading divisions would be expected, corresponding to the different climatic areas, it is more accurate to adopt four—one for the plateau and the arid coastal zones, another for the *tierra templada* and the *tierra fria,* a third for the *tierra helada* and the fourth for the humid *tierra caliente.* No fixed limit can be set, however, between one flora and another, since local conditions, determined by a varying amount of sun radiation, wind and humidity, may bring about deviations from the general rule.

The arid regions, especially the desert zones of the north, have their peculiar vegetation, such as yucca trees, hundreds of species of cacti, and many types of agave and mesquite bushes. A few drops of rain change the whole aspect of the country for some days, the whole desert being almost suddenly covered with flowers of the most brilliant colors. Among the cacti the most interesting, perhaps, are the gigantic *pitahaya,* which bears excellent fruits, the strange *órganos* (*Cactus hexagonus*) and the commoner varieties, yielding the ever present *tuna* whose alternate green, yellow and red colours correspond to the successive seasons. Less numerous but economically more important are the agaves, of which the *Agave americana,* from which the *pulque* is extracted, is the most popular, while other varieties give different types of *mescal.* Some plants of the *Agave americana* are said to yield 2,000 pounds of sap in six months. Most vegetable fibres used in Mexico come from some kind of agave, the *ixtle* fibre being produced by *Agave uninvitata,* while the *Agave rigida* var. *elongata* yields the famous *henequén* or Sisal hemp. This particularly valuable variety of agave is grown in the Yucatán peninsula and in the State of Tamaulipas only.

On the central and southern parts of the high plateau, or *tierra fria,* where there is a greater degree of humidity, relatively abundant trees are found on the slopes of the mountains, cereals of Eurasian origin can be cultivated, and all kinds of fruit trees may be grown, together with the local maize. It is hard to say where the exact limit between the *tierra fria* and the *tierra helada* may be determined because the deforestation of the high plateau has allowed the pine trees of the higher altitudes to invade relatively warmer regions. In ascending the slopes of the mountains, one finds an intermediate zone where different varieties of oaks (*Quercus crassifolia, Q. reticulata,* etc.) are found, together with a pine tree of high altitude (*Pinus oocarpa*), the ocote pine, long and short leaved pines and the *oyamel* (*Abies religiosa*).

TAPPING A ZAPOTE CHICO TREE FOR CHICLE, THE BASIS OF CHEWING GUM

On the slopes of the mountains around the Valley of Mexico forests can be seen of the superb *ahuehuete* (*Taxodium distichum*). The extreme upward limit of trees seems to be between 12,500 and 13,500 ft., but juniper bushes occur as high as 14,000 ft.; above that, only grasses are found until one reaches the lower limit of the snow field. The same thing may be said of the limit between the *tierra fría* flora and that of the *tierra templada.* It is only gradually that one passes from the former to the latter and it is only in the presence of the banana, coffee and orange trees that one can feel sure of having reached a lower level. For a long stage the ocote pine and many varieties of oaks are found together, especially on the eastern slopes, with the addition of magnolias, acacias, myrtles, mimosas and bamboos. There are still cacti when the level is reached where the first palm trees appear, but it is only when the latter is found in abundance that one is in the real *tierra caliente.*

The vegetation of the *tierra caliente* is of such variety as to bewilder the stranger. Trees of hundreds of species, themselves half-buried among palms and ferns of all kinds, form the frame on which hang closely interwoven curtains of lianes and epiphytes, while saprophytic and parasitic plants of infinite diversity are found at the foot and on the trunks of the trees, or on the decaying vegetable matter that litters the soil of the forests. To open a way through such an entangled mass, even with a *machete,* is a slow and painful process, more especially, perhaps, because of the oppressive semi-darkness that surrounds the explorer. In the forests of Chiapas are found more than 50 species of cabinet-wood, including the ebony, the mahogany, the rosewood and the Spanish cedar. Other valuable trees of the *tierra caliente* are the log-wood (*Hematoxylon campechianum*), the dividivi tree (*Caesalpinia coriaria*), the *zapote chico* (*Achras sapota*), exploited in Campeche and Chiapas for chicle, as well as rubber trees. There are not less than 17 oil-bearing plants in Mexico and a much larger number of medicinal ones, yielding jalap, arnotto, ginger, licorice, sarsaparilla, ipecac and various gums.

Among the many plants of economic value that America has given to the world, several might with some right claim Mexico as their country of origin. It is perhaps true of the cacao tree, of the maize, probably derived through mutation from the teosinte (*Euchloena mexicana*), or from a hybrid of the teosinte and of some cultivated grass of the sorghum tribe (*Andropogonae*), of the tomato and also of the *aguacate,* or alligator pear. Most of these plants bear either Aztec names or those of Aztec origin. Moreover, many plants of economic value, the origin of which is to be found in the Old World, have encountered conditions favourable to their acclimatization in Mexico; such is the case of the citrus and practically all the temperate fruits and vegetables of Europe. Mexico has 50 varieties of beans, several dozens of green and red pepper; and it grows the potato, sweet potato, yam, sugar-cane, cotton, indigo, coffee, vanilla and banana.

Fauna.—Since Pliocene times—that is to say, since the two Americas were united—the two faunas have merged, and the

Mexican fauna of to-day is made of animals of South and North America, with predominance of the latter. The high plateau attracted the North American fauna (Sonorian fauna: wolf, coyote, buffalo, bear, beaver, etc.) while the low lands, on both sides, and to the South, forced the South American fauna (jaguar, puma, five species of monkeys, etc.) toward and into the United States. Besides the above-mentioned, the Mexican fauna includes the *ocelotl,* a typical Aztec name, the lynx, badger, otter, raccoon, tapir, two species of peccary, the skunk, several species of opossum, the sloth, two species of ant-bears, the armadillo, at least three species of deer, the Mexican big horn (still found in Chihuahua and Lower California), the fur-bearing seal and many different kinds of small rodents. Bats are numerous, among them the dangerous vampire, which makes it so difficult to keep horses in some parts of Chiapas and Campeche.

Mexican birds are extremely numerous, and comprise many beautiful species, while a few (notably the *zenzontle* or mocking-bird) are songsters, the latter being identified with the cold and temperate zones. In the warm zone, on the other hand, as well as in the temperate, are found many varieties of parrots, parrakeets and macaws besides toucans, spoon-bills, boat-bills, ducks, pelicans, cormorants, sandpipers, curlews, grackles, ever-abundant chachalacas (*Ortalina polycephala*), wood peckers, jays, cuckoos, turkeys, partridges, quail and doves (sometimes seen in immense bevies), buzzards, especially the black zopilote which is protected by the Mexican laws as the scavenger of the country, and many humming-birds (*chupaflor, chupamiel*). The gorgeous *quetzal* (*Trogon resplendens*) has almost disappeared from Mexico and is now rarely found even in Guatemala where its love of freedom has made it the emblem of the country. The turkey is the only important domestic animal of Mexican (and American) origin that was added to the European farm-yard.

Reptiles of all denominations can be found anywhere in Mexico. All tropical rivers and lagoons abound in alligators, while the sea gives abode to enormous turtles and the swamps to tortoises and iguanas. One species of iguana, the black one, is largely arboreal. Lizards of many varieties are found everywhere; snakes are equally abundant, some, like the *palanca* (*fer de lance* of Martinique), the *naoyaca* and 13 out of the 15 species of American rattlesnakes being much dreaded. Many interesting varieties of amphibians are also to be found, as, for example, the remarkable tree-climbing frogs and toads and the famous axolotl.

Notwithstanding the great abundance of marine fishes of many varieties which may be had for the effort, there is no real fishing industry in Mexico. Some of the coast lagoons, for example Río Lagartos, in Yucatán, have enormous quantities of fish on which feast numerous alligators and flamingoes.

In the tropical parts of Mexico man's greatest and most dangerous enemies are the insects, especially the many varieties of *garrapatas,* or ticks, *niguas* or chigoe (*Oestrus humanus*), *jején* or gnat, mosquitoes and fleas, the first of these having in some instances wiped out cattle and horses from certain districts. Numerous species of ants are also found, the most famous being the leaf-cutting variety. The most destructive type of insect, however, is the so-called white ant or termite.

Population.—A comparison of the results of the census of 1921 (including some data extending it to 1924) with those of the 1900 census, as well as the density per square mile in each State and in the whole republic, is afforded by the table in next column, showing the distribution by States.

States	Area in square miles	Population 1900	Population 1921	Density per square mile 1921
Aguascalientes .	2,499	102,416	107,581	43·06

Republic . . .	751,743	13,607,219	14,234,799	18·9

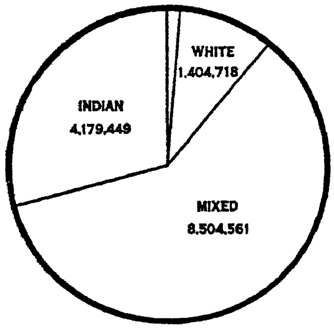
The most important cities of the Republic are Mexico City, 633,000 inhabitants, Guadalajara, 119,468, Puebla, 96,121, Monterrey, 85,000, San Luis Potosí, 85,000, Tampico 80,000 (estimated), León, 80,000 (estimated) and Veracruz, 48,633. The number of foreigners residing in Mexico is relatively small, their proportion to the total population being only 1·41%, more than half of whom are of Spanish tongue. According to the last census the Spaniards, 26,675, are the most numerous and then come Americans, 21,740, Guatemalans 17,473, Chinese, 14,813, about 3,500 Germans, 3,500 French, 3,500 English and 3,000 Italians. Most foreigners live in the large cities, Mexico City having 12,063 Spaniards, 2,382 Americans, 1,652 French, 1,223 Germans, 803 Cubans and 610 English. Most Guatemalans are of the peon class and live in the frontier State of Chiapas. There is a considerable emigration of Mexicans, chiefly unskilled labourers, to the United States, although this is shown by the Mexican official statistics in an indirect way only, 2,392 Mexicans being given as residing in foreign countries, of whom 1,753 are in the United States; on the other hand 83,376 are said to live abroad, without specification of the country of their residence, which is evidently the United States. The total figures for emigration and immigration, between 1911 and 1923, are 752,338 for the former and 1,041,975 for the latter, but they are somewhat open to question and could hardly, therefore, lead to any kind of conclusion.

MEXICAN PEON

Of the Mexican population, the mixed element, partly Indian, partly white, seems to be numerically in the lead, its proportion having passed from 22%, according to the 1810 census, to 40% (1900) and 43% (1921); but the value of such figures must not be put too high. The Indian element has fallen from 62% to 38%, while the white has changed little, mounting from 18% to 19%. Any other racial element is entirely negligible in Mexico. Economic conditions in the republic are not favourable to the settling of large numbers of white workmen or farmers, while the Indian element, being the most ignorant (death rate of Indian children at least 50%) and the least adaptable, has little chance of displacing the more modern and more active mestizo.

Non-Spanish Europeans rarely reached Mexico, since there was a law against their settling there, with a temporary exception for the Portuguese. However, it is known that some Flemish, French and Italians lived in Mexico during colonial times, two or three of whom even played an important rôle, but they had hispanified their names and were supposed to have come from the peninsula. Only men migrated, and, as they were young and intended to stay, they invariably married local women, while the converse could not, of course, take place. The modern half-breed

is therefore a product of this type of crossing. During the colonial régime the name *mexicano* was applied to the Indian only, the creole, or mestizo, being called *americano*. The white man, even when born in Mexico, was always called *español,* though another name *gachupín* (he who wears shoes) was also applied by the other inhabitants. It is easy to understand, on account of the conditions explained above, that few of those *españoles* were of pure white blood, and that the 70,000 who were supposed to be in Mexico in 1811 were simply individuals whose complexions approximated to whiteness.



FIGURES FROM THE STATESMAN'S YEAR BOOK, 1927

COMPOSITION OF THE POPULATION OF MEXICO IN 1921

The small section between Indian and White includes 101,958 "foreigners" and 44,113 not classified

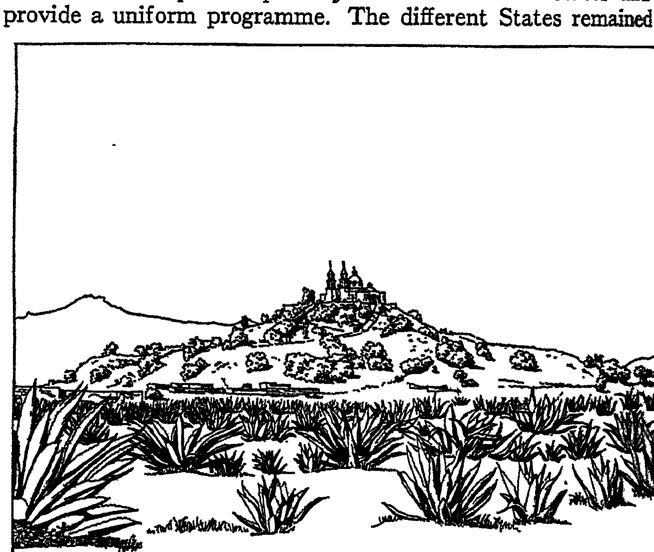
Indians were, from the beginning, classified on the basis of their speech. According to Orozco y Berra there are 192 languages and dialects in Mexico, besides 62 that have become extinct since the conquest. Francisco Belmar reduced this number to a much smaller figure, while, according to Cyrus Thomas and John R. Swanton, whose work is the most recent on the subject, the modern Mexicans speak 59 tongues divided into 20 families. The leading family, by far, is the Nahuatlan, of which the Aztec or Mexican, is a dialect. The latter is spoken by about 650,000 individuals, which means about one-fourth of the Mexican population of Indian tongue, and it is found in the States of Sonora, Chihuahua, Durango, Sinaloa, Zacatecas, part of San Luis Potosí, Nayarit, Jalisco, Guerrero, Morelos, part of México, Puebla, Vera Cruz, Tabasco, Chiapas and extends into Central America as far as Chiriquí. The second group in importance is that of the Maya, spoken by at least 400,000 individuals, if we include the Huastecos in the group, it covers part of Veracruz, Tamaulipas and San Luis Potosí (Huastecas), most of Tabasco and Chiapas and all of Yucatán and Quintana Roo, besides the larger part of Guatemala, British Honduras and a small part of Spanish Honduras. The *Zapotecan,* found in Oaxaca and parts of the neighbouring States, is the language of some 350,000 Indians; while the Otomian, which one hears in the States of San Luis Potosí, Guanajuato, Querétaro, Hidalgo and México, is spoken by about the same number. Other important tongues are the Totonacan, of Veracruz (75,000), and the Tarascan of Michoacán and surrounding States (40,000).

Some dialects are now spoken by only a few individuals and the number of the extinct tongues is constantly increasing. According to R. Bonaparte, more than one-half of Mexico is entirely Hispanified, while the States of Nayarit, Guerrero, Oaxaca, Chiapas, Campeche and Yucatán are still largely Indian, if we take into consideration the use of aboriginal languages. Five of these linguistic groups of Mexican Indians had civilizations of their own at the time of the conquest. One may still find abundant remains of these, such as more or less well-preserved monuments of all kinds. The Mayas reached the highest degree of culture, not only in Mexico, but in America; while the Aztecs, who built up a militaristic empire, came next, to be followed by the Zapotecs, the Tarascos and the Totonacs. In physical characteristics the Mexican Indians differ a great deal, though they all have, with the only exception of the wavy-haired Huauchinangos of Puebla, black, coarse and stiff hair.

Political Organization.—According to the new Mexican constitution, promulgated on Feb. 5, 1917, Mexico is a federated republic of 28 States, each with a considerable degree of home rule, having its own governor, a legislature and judiciary, elected by popular vote. Besides the States, there are two territories and one Federal District, the administration of which is in the hands of the central Government. The States are generally subdivided into *distritos* or *partidos,* and these into *municipios,* but some have adopted special divisions with other names. The State of Nuevo León has *municipios* only. The Federal legislative power is vested in a Congress, consisting of a Chamber of Deputies, elected for two years, on the basis of one for each 60,000 inhabitants, or fraction of more than 20,000, and of a Senate of 58 members, two for each State and the Federal District, half of which number must be renewed every other year. The president is elected for four years (six years, 1928) and is not eligible for immediate re-election. He appoints a cabinet composed of seven secretaries. He must be a Mexican by birth, as well as son of a Mexican by birth, and he shall not have taken part, directly or indirectly, in any military uprising, riot or *coup*. Each State has but one representative body which is called Cámara de Diputados.

The new Constitution contains a large number of provisions touching education, religion and the exploitation of the mineral resources of the country—matters that will be treated elsewhere. There are some laws protecting workmen against undue exploitation; for example, no man can be forced to work more than eight hours in daytime or seven at night; he may claim a share in the profits of his employer and he has the right to strike. The number of clerks, or officers, employed by the Federal Government was 38,212 in 1924, instead of 32,693 in 1923. Public expenses have been, however, reduced a great deal, largely through a diminution of military expenditure, as shown by the total amount paid for salaries to Government employees and soldiers, which in 1918, 1922 and 1926, respectively, was $137,889,386, $199,730,670 and $154,734,772 Mexican pesos. (The peso is worth about 50 U.S. cents.) The judicial power is exercised by district and circuit courts, and a Supreme Court composed of 11 judges elected for life.

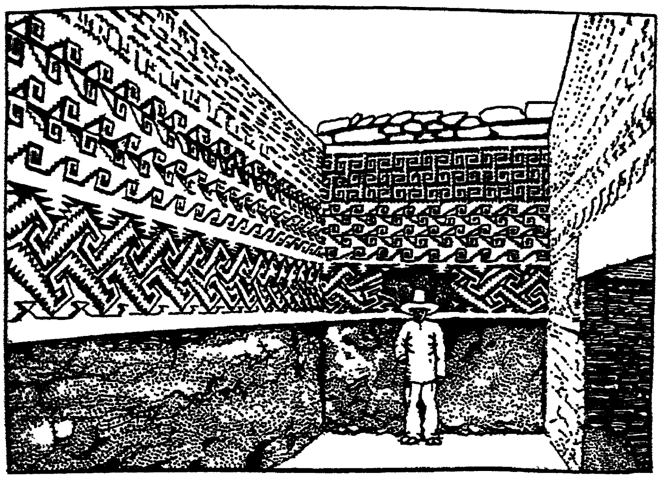
Educational System.—Education is supposed to have been compulsory since 1867 but in spite of efforts to enforce the law, only a small percentage of children have attended schools until recent years. In 1892 and 1896 laws were enacted which vested in the Government the direct control of education in the territories and Federal District, and established a High Board of Education to supervise primary education in the States and to provide a uniform programme. The different States remained in charge of secondary and higher education. Much more attention has been given to the school system in recent years, and progress is evident everywhere. Education is free and compulsory from 6 to 16 years of age and is under Federal control, each State appropriating for schools as much as it deems proper or possible and the Federal Government adding subventions when necessary. Considerable attention is also given to vocational instruction, especially in agriculture, and much further development along this line may be expected in the future. According to the new Constitution, no religious corporation, or minister of any religious creed,



ANCIENT PYRAMID AT CHOLULA, A RELIC OF TOLTEC CIVILIZATION

Constructed of sun-dried bricks and earth, this pyramid is the largest of its kind in the world, being 177 feet high and covering an area of 45 acres. Its summit, now surmounted with a chapel dedicated to the Holy Virgin, was at the time of the Spanish conquest crowned with an imposing temple to the god Quetzalcoatl

shall establish or direct schools of primary education. The total number of public primary schools in Mexico was 9,299 in 1924 and the total number of children who attended them was given as 727,227—actually only one-fourth of the children of school age in the country. On the average it may be said that there is one for every 300 registered children. Of these schools 8,388 were partly supported by the Federal Government. Besides these



SIDE HALL IN THE TEMPLE RUINS OF MITLA, SOUTHERN MEXICO
The five clusters of buildings at Oaxaca, known as Mitla, are believed to have been a centre of Zapotecan culture until a short time before the Spanish conquest

schools there are 460 public schools for workmen, 46 kindergartens and 1,822 private primary schools. The total number of teachers in 1925 was 18,499, of which 4,104 had graduated from some normal school.

There are two universities in the republic, at Mérida, Yucatán, and Mexico City, respectively, the latter having been founded in 1553 and reorganized in 1910. The University of Mexico City holds a summer session that is attracting a large number of American students every year. Several scientific institutions, some attaining world reputation, are located in the capital, such as the National observatory (Tacubaya), the Geological Institute, the National Museum of Archaeology, Ethnology and History and the School of Mines. To these must be added the National Conservatory of Music, the School of Aviation, the Military academy (Chapultepec) and a number of other establishments doing research along many lines of human knowledge. The Escuela Preparatoria can be compared to the best European secondary schools. In Mexico City one also finds the headquarters of the leading learned societies, the best known ones being the Society of Geography and Statistics, the Antonio Alzate Scientific Society, the Academy of Medicine, the Academy of Law and Jurisprudence, the Mexican Geological Society and the Society of Natural History. The National library has 400,000 volumes.

Religion.—The number of Protestants in the Republic, most of whom are not Mexicans, is so small that the Catholic is practically the only church. Mexico has been Catholic since the Conquest, although many Indians have still a very pagan conception of Christianity. The church is administered by three archbishops and 23 suffragan bishops. The first official bishopric, which was that of the capital, was created in 1530 and was occupied by the famous Fray Juan de Zumárraga. Fifteen years later it was elevated to the rank of archbishopric and in 1863 it was divided into the three archdioceses of México, Guadalajara and Michoacán. In the 19th century the church grew immensely wealthy until in 1859 it owned practically one-third of the republic. Juárez, the great Indian president, inspired the laws of La Reforma, which nationalized its property, deprived it of State support and forbade it any participation in political affairs. The Constitution of 1917 and the interpretation given it by President Calles further restricted the power of the church. Places of public worship must be at all times under governmental supervision. The church can not own property, and priests, who must all be Mexican-born, may not participate in politics. There are several Protestant missions in Mexico, but their growth has been slow.

Finance.—The Mexican monetary unit is the gold peso, and coins are made of 2·5, 5, 10, 20 and 50 pesos, respectively. Gold or silver the peso is theoretically worth 50 (American) cents, although the silver standard varies slightly in accordance with the market value of that metal. The amount of gold coined by the Government in 1923 totalled $15,644,619. Of the 34 chartered banks existing in Mexico in 1908, 29 had the right of issuing bank-notes, the total value of which amounted to $97,787,878 at that time. Since the Constitution of 1917 was promulgated banks have no longer been allowed to issue notes, this right being reserved to one "State Bank" (*Banco Unico*) and they have accordingly become only institutions of discount and deposit. In 1925 the Banco de México was founded by the Government and in 1926 the Banco de Crédito Agrícola. The exchange value of the old notes varied (1926) between $2\frac{1}{2}$ and $22\frac{1}{2}$ cents of peso ($1\frac{1}{4}$ to $11\frac{1}{4}$ cents of dollar) per nominal peso, according to the metallic reserves of the bank that had issued them. As a demonstration of the confidence of the Mexican people in their Government, the fact may be mentioned that deposits in the banks passed from $45,951,487 (pesos) in 1925 to $134,672,271 in 1926. The assets of all the Mexican banks were said to be $738,386,696.

In 1923 Federal revenues amounted to $256,259,123, while in 1925 they rose to $309,306,011. State revenues passed from $53,155,299 to $64,849,218, and municipal from $47,281,836 to $46,037,877. Taxes per capita amounted to $21.36 in 1926 (Great Britain $177.55). The following figures show the variations in revenues and expenditures for a certain number of years:

Year	Revenues	Expenditures
1906–07	$114,286,122	$ 85,076,641
1908–09	98,775,511	92,967,393
1910–11	111,142,402	100,913,924
1923	237,876,206	246,837,134
1926*	315,000,000	305,000,000
1927*	334,000,000	327,000,000

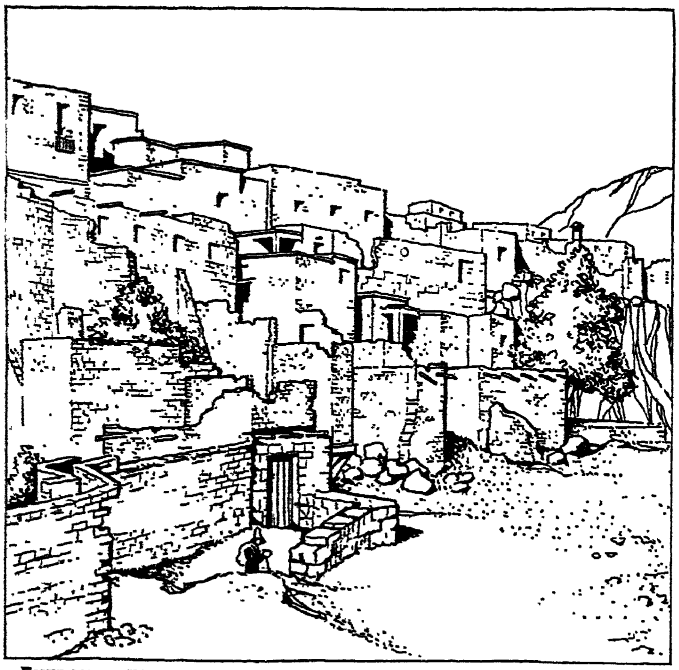
*Estimated.

The total Mexican external debt amounted to $500,000,000 plus $200,000,000 for interest in arrears in 1922. According to an agreement, signed on June 16, 1922, by Adolfo de la Huerta and the International Committee of Bankers, a payment of $15,000,000 was made on Dec. 8, 1923, for the year 1923, but owing to a revolutionary outbreak no other payment was made. In 1925 the Lamont-Pani Agreement was signed which excluded the National Railways from Mexico's external debt.

Defence.—The revolution has thoroughly changed the defensive organization of the country. Military education (including defensive exercises) is compulsory for all citizens. Besides this emergency force there is a regular army, nominally numbering 50,000 men and commanded by officers, who in many cases have received their military training at the Escuela Militar de Aspirantes (Military academy) located in the Chapultepec castle. Five gunboats and a few smaller vessels protect the long coast and there is a naval academy at Veracruz. There is also an aviation school at Mexico City.

Mineral Wealth.—Mexico is one of the richest countries in the world, if not the richest, in metals of many different kinds. From 1521 to 1922 Mexico yielded 155,000 metric tons of silver of a total value of $3,000,000,000. This was then two-thirds of the world's production and the output is still (1927) one-third. The total American capital invested in Mexican mines amounts to $500,000,000. It is highly probable that if Mexico ever drops to a low rank among the petroleum-producing nations, it will still be one of the leading ones in mining. Metals make two-thirds of the Mexican export trade. There are more than 75,000 property-titles, covering a mining territory of 520,000 hectares and 80,000 men are engaged in the mining and ore-smelting industries. Gold is especially abundant in Lower California, Chihuahua, Durango, Michoacán, Puebla, Sinaloa and Sonora, the total production having varied between 20 and 24 tons between 1919 and

1926, one-third of which was exported and the rest coined in the capital. Silver is mined in Guanajuato, Zacatecas, San Luis Potosí, etc., and gold is frequently found with it. The annual production of silver is generally between 2,500 and 3,000 tons, of which six-sevenths are exported while the rest is left to be coined in Mexico. Lead is next in importance and is found in the States of Hidalgo, Oaxaca, Querétaro, Jalisco, Puebla, etc.,



ENTRANCE TO GUANAJUATO, CENTRE OF SILVER MINING INDUSTRY
Guanajuato, founded in 1554, is composed of many hillside mining hamlets grouped about the central town. The silver deposits are among the richest in Mexico

its output having passed from 5,703 tons in 1915 to 60,513 in 1921, 110,455 in 1922, 164,140 in 1924 and 171,767 in 1925. Copper, mined in Michoacán, México, Guerrero, Lower California, Sonora, etc., yielded 205 tons in 1915, 70,223 in 1918, 26,978 in 1922, 49,112 in 1924 and 51,336 in 1925. Zinc mines gave 5,806 tons in 1915, 45,000 in 1917, 6,142 in 1922, 18,937 in 1924, 45,770 in 1925 and 106,367 in 1926, the great variations in the amount of the output being due to political conditions of the country. Other mining products of importance are graphite, arsenic, mercury, antimony, tin, tungsten and molybdenum. Mexico has very little anthracite but much low-grade coal in the northern part of the country, the supply of which is estimated at 300,000,000 tons, the annual output varying between 739,980 tons in 1921 and 1,335,780 in 1925. The value of the metals mined during the first semester of 1924 is given in the following table, in Mexican pesos:

Metals	Production	Exportation
Silver	$59,628,586	$45,075,031
Lead	28,602,451	28,602,451
Gold	16,756,506	5,587,622
Copper	14,363,124	14,363,124
Zinc	1,967,425	1,967,425
Arsenic	415,886	415,886
Graphite	388,487	388,487
Mercury	57,364	57,364
Antimony	25,969	25,969
Tin	9,977	9,977
Molybdenum	9,369	9,369

Iron is found everywhere in Mexico, the Cerro del Mercado, in Durango, being assumed to be entirely made of that metal (500,000,000 tons). The total value of the iron smelted by the Compañía Fundidora de Fierro y Acero de Monterrey and others is estimated at $11,433,038 in 1925 against $8,273,236 in 1921.

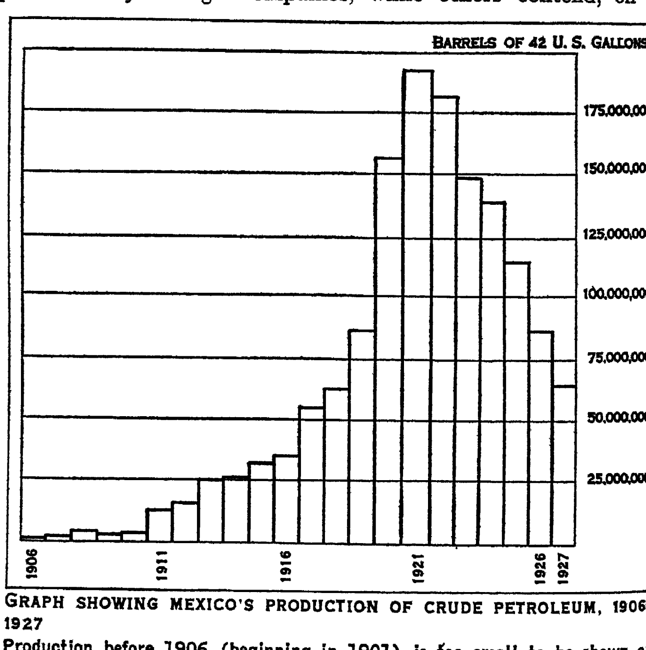
More than anything else, the production of petroleum in Mexico has called the world's attention to that country. Despite the spectacular aspect of that production and although a small part only of the country has been explored by the oil geologists, there are indications that no other oil-fields of importance may be found outside of the Gulf coast regions. Mexican oil is produced in considerable quantities in the State of Veracruz, in those portions of Tamaulipas and San Luis Potosí which are near Tampico and, in small quantities, in some regions of Tabasco and Chiapas. Much of it is heavy oil, suitable for fuel, but some of the lighter variety is found in Tabasco (Macuspana) and in the Isthmus of Tehuantepec. The following figures give, in Mexican pesos, the amount of foreign and Mexican capital invested in the Mexican oil-fields: United States, $614,487,263; Great Britain, $356,776,199; Netherlands, $75,758,960; Mexico, $11,582,405; other countries, $6,943,253; total, $1,065,548,110.

The history of the oil production in Mexico has been most remarkable, not only with regard to the annual output, but also on account of the enormous and prolonged yield of certain wells. Annual Mexican oil production is as follows:—

Year	Number of barrels	Value
1901	10,345	..
1911	12,553,798	..
1921	193,398,587	$365,873,625
1923	149,585,856	285,920,299
1924	139,878,294	232,084,563
1925	115,515,700	299,268,632
1926	90,421,973	225,122,242
1927	64,200,000	..

The total production from 1901 to 1927 was 1,400,927,297 bbl. valued at $2,469,924,580.

The striking decrease in production, noticeable in recent years —a phenomenon which brought Mexico down from second to fourth place among oil-producing countries (thus following the United States, Russia and Venezuela)—is by some associated with disturbed political conditions which have discouraged exploitation by foreign companies, while others contend, on the other hand, that the richest fields are, to all appearance, becoming exhausted. Many wells in the Tepetate pool and in the Pánuco field were affected by salt water in 1919 and 1920. At all events the average production of the new wells is much smaller—a fact easily proved by comparing the average daily production of 10 bbl. for the wells drilled between 1923–26 to that of 40 bbl. corresponding to the wells drilled between 1920–1922. The output of the Naranjos field in 1920, 90,000,000 barrels, is the largest in the history of the World.



GRAPH SHOWING MEXICO'S PRODUCTION OF CRUDE PETROLEUM, 1906–1927
Production before 1906 (beginning in 1901) is too small to be shown on this scale. Total for the 5 years 1901–05 was 502,000 barrels. Total from 1901 through 1928 was 1,465,127,000 barrels, 9.3% of the world production

Agriculture.—The proportion of Mexican land that can be

cultivated under present conditions, according to modern methods, is relatively small. On the high plateau nothing can be done without expensive irrigation; for the best soil elements have been washed down in a few valleys where fertility is remarkable. At least one-fifth of Mexico is unfit for agriculture. At present, indeed, no more than 30,000,000 ac. are under cultivation, 20,000,000 of which require irrigation. Outside the plateau there are only grazing lands and forested areas, all of which would require vast expenditure of capital if they were to be adapted to agricultural purposes. Moreover, in many parts of the country, the lack of adequate transportation is a serious drawback. However, in recent years, a great effort has been made in order to improve conditions. Important irrigation works, whose total cost will be 60,000,000 pesos have been begun in different parts of the Republic, and the sum of 22,000,000 pesos is being spent in building modern highways.

According to a law enacted in 1923 every Mexican citizen, over 18 years of age, is entitled to a plot of land of no more than 25 ha. of irrigable land, or a maximum of 100 ha. of dry land, or up to 500 ha. of grazing land; but the sale of such a plot to a foreigner or to a Mexican owning as much is prohibited. A serious effort is being made to teach modern methods to the Mexican farmer and there is no doubt that, assuming a state of domestic peace, the output of Mexican agriculture, which is not very large now, could be considerably increased. As a proof of the interest shown in agricultural work by the people of Mexico let the fact be mentioned that in 1925 farm implements to the value of $4,178,000 were bought in the United States, as against $843,742 in 1909. In 1925 the increase in the cultivated area was 47·66% for cotton, 876·60% for alfalfa, 258% for rice, 70% for potatoes, 159% for bananas, 88% for wheat, 26% for Indian corn and 1848% for oranges. Indian corn is one of the most important agricultural products of Mexico, though the crop is still inadequate as some has to be imported year after year. Production in metric tons for the leading crops is given in the following table:—

Crop	1910	1921	1923	1925
Indian corn	2,059,242	1,550,000	2,573,682	..
Beans	176,069	71,034	118,685	..
Sugar cane	2,200,794	2,185,365	2,769,960	3,879,626
Wheat	258,177	138,508	371,684	..
Sisal hemp	113,088	115,684	123,184	267,916
Coffee	35,789	34,424	39,986	48,206
Bananas	36,510	..	86,318	160,344
Tobacco	14,396	8,000	11,035	10,497
Cotton	..	31,938	38,025	47,070
Rice	..	29,776	31,963	106,601
Cacao	..	8,646	2,024	4,249
Oranges	..	..	11,435	210,456

The Laguna district (Coahuila, Durango) used to be the leading cotton-producing area, but since 1922 Lower California has outranked it. The value of the cotton crop for 1923 was $57,791,064. Yucatán produces seven-eighths of the Sisal hemp of the world; the value of the 1925 crop was more than $47,000,000. Indian corn is grown everywhere in Mexico and the value of the crop is generally around $200,000,000. Veracruz is the leading State in sugar production, its output being more than double that of Sinaloa, the next ranking State.

The total value of the lumber, including precious woods, from the forests in 1925 was about $1,800,000. The chicle production passed from 2,110 tons in 1921 to 4,412 tons in 1925, the market value of the latter being $7,895,516.

Manufactures.—Considering the possibilities of the country, especially its abundance of raw materials, its water power, and cheap labour, Mexico is far from being industrially developed. Nevertheless a large proportion of the needs of the country can already be met by existing local manufactures. Some of these wares, such as pottery, some forms of tobacco, saddles, candles, soap, chocolate and others, are still fashioned as they were before the Conquest or in the first years of the Spanish occupation. Others such as zarapes, rebozos, glass and shoes, are made according to more or less modern methods. For other categories of articles the mode of manufacture is quite up-to-date, as for example, cigars, cigarettes, sugar, beer, broadcloth, cassimeres, blankets, underwear, hosiery, percales, calicoes, matches, explosives, paper, furniture, metallurgical products, etc.

Besides the iron and steel works (at Monterey) and the tobacco factories, the cotton mills may be considered among the most important agencies of production. In 1923 there were 109 of these with a working personnel of 39,629 and provided with 29,668 looms, having 802,363 spindles; altogether they consumed 23,343,701 kilos of cotton yielding 28,567,596 kilos of products sold for $97,562,594. In 1925 the figures were 130 mills, 43,199 workmen, 30,800 looms, 831,524 spindles, 40,996,834 kilos of cotton consumed and 33,576,583 kilos of products worth $108,395,604.

Commerce.—According to official Government statistics foreign trade in pesos was as follows for the years 1921–25:—

	Imports	Exports
1921	$493,161,741	$756,823,697
1922	308,499,612	643,549,695
1923	315,108,526	568,471,114
1924	321,371,605	614,712,515
1925	390,996,172	682,484,832
1926	381,263,640	691,769,739

The increase in 1926, compared with the figures for the prerevolutionary years is about 115·65%, although, of course, the decreased purchasing power of the peso has to be considered. The leading articles of exportation, as might be expected, were minerals such as oil, silver, gold, copper, zinc; the vegetable ones, sisal hemp, coffee, rubber, chicle, cabinet woods, tobacco, sugar, cattle and hides. Imports consist largely of manufactured articles, such as machinery and tools, textiles, cotton, grain, automobiles, drugs, furniture, coal, etc. Trade with the United States was as follows in millions of pesos:—

	1922	1923	1924	1925
United States Imports	197	235	232·2	274·5
United States Exports	517	471	493·5	516·9

With Great Britain it was:—

	1922	1923	1924	1925
Imports	23·8	21·5	22·5	30·7
Exports	49·7	34·8	34·6	44·6

Germany, France and Spain following in order of importance. Although the commercial balance seems to be in favour of Mexico, it must not be forgotten that most of the companies, exploiting Mexican wealth, are foreign and that their profits are of relatively small advantage to the republic. Here are some comparative data, in pesos, on the exportation of Mexican products for the years 1921 and 1925:—

	1921	1925
Sugar	$ 9,116	$ 1,687,410
Cattle	411,344	996,185
Chicle	4,200,861	7,895,516
Cotton	5,982,846	8,868,289
Coffee	10,206,843	24,428,722
Beans	102,936	2,379,937
Fresh fruits	496,350	3,147,120
Chick-pea*	80,245	3,405,131
Sisal hemp	29,392,833	31,406,528
Ixtle	1,197,983	6,406,845
Fresh vegetables	1,166,384	13,703,048

*Exported to Spain.

The importance still attached to alimentary products brought from foreign countries is an evident proof that agriculture is not yet sufficiently developed in Mexico. For the year 1925 Mexico paid $5,379,333 for Indian corn, $5,261,008 for wheat, $3,621,827 for flour, $4,571,084 for preserves of all kinds, $2,224,015 for eggs, etc. It was also necessary to import lumber to the value of about $9,000,000; but the bulk of the imports, as said above, is made of manufactured products. In 1923 Mexico bought 9,363 automo-

biles, worth $7,801,822, in 1924, 9,124, worth $11,892,131 and in 1925, 23,501, worth $25,935,032.

Communications and Transportation.—In 1925 Mexico had 20,972 m. of railways (19,719 in 1910)—the second highest mileage in Latin America, though still very inadequate to the needs of a country of so few navigable rivers. The development of the Mexican railways is due almost entirely to the statesmanship of Porfirio Diaz. The first railroad, built in 1854, was the line connecting Mexico City with its suburb, Guadalupe. In 1909 most lines were put under direct Federal control under the name of National Railways of Mexico (National, Inter-oceanic, Inter-national, Veracruz-Pacific, Central and some others, totalling about 14,000 m.). Other lines are the Northern Mexico, Kansas City-Mexico & Orient, United Railways of Yucatán, etc. Freight carried by the different lines, with returns, amounted to:

	Metric tons	Returns
1923	6,719,236	$103,206,704
1924	6,664,855	117,864,842
1925	7,291,893	121,567,600

The total revenues derived from these lines was $118,429,234 in 1923, as against $150,622,239 in 1922. More railways are necessary, the Yucatán peninsula, among other regions, being without railway connection with the rest of the country. Modern tramway lines are found in all the important cities. The tramways of Mexico City carried 48,553,048 passengers in 1924 and earned $5,247,397.

Airmail service between San Antonio, Dallas, Laredo and Fort Worth, Texas, in the United States, and cities in the interior of Mexico was inaugurated Oct. 1, 1928.

At the end of 1925 there were 53,554 automobiles in Mexico. Telegraph and telephone lines, under Federal control, totalled 55,394 m. of wire in 1921, while the State-owned and private lines added 20,706 m. of wire to the former. 5,698,026 telegrams went over the lines in 1924. There are 24 radio-telegraphic stations in the republic, through which 250,392 communications were sent in 1924. Mexico City has 24,500 telephones and there are 50,360 in the whole country.

COLONIAL PERIOD. 1519–1821

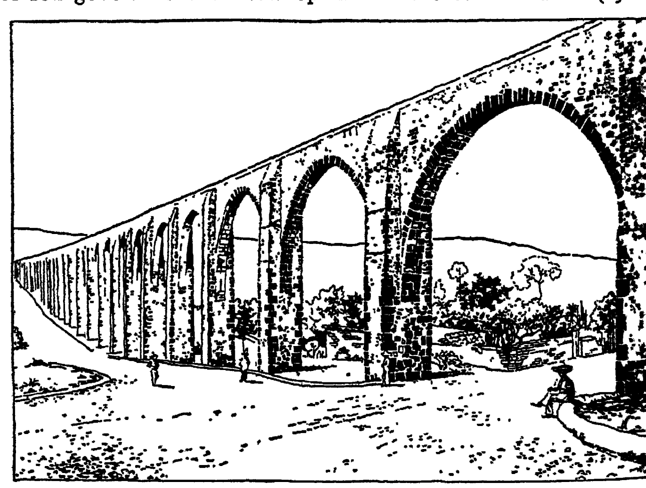
For ancient Mexico before the Spanish Conquest *see* the articles Central America, *Archaeology, Ethnology;* and North America, *Anthropology*.

The overthrow of the Aztec empire by a Spanish force under Hernando Cortés between 1519 and 1521, the execution of the last Aztec emperor, Cuauhtemoc, and the rapid extension of the Spanish conquest from Mexico City as a base, introduced the colonial period of Mexican history. Beginning in 1523 and continuing until the forced resignation of the last viceroy in 1821, New Spain was administered by royal governors until Dec. 1528; by *audiencias* from 1528 to 1535; and by viceroys and *audiencias* after 1535. In all, 61 individuals were appointed viceroys of New Spain, one of whom served a second term. Because of either the death or disability of a viceroy, the *audiencia* at Mexico City assumed administrative powers on 14 different occasions.

New Spain: Extent.—New Spain was one of the four viceroyalties comprising the over-seas possessions of the Crown of Spain known as the Kingdom of the Indies. As modified soon after its establishment in 1535, the viceroyalty of New Spain included and stretched northward from Central America above present Panama. It also included the Spanish West Indies, Venezuela for a number of years, and the Philippines from 1565 to 1584. The north-eastern boundary of New Spain, by a treaty with England in 1670, was fixed just south of Charlestown, S.C.; at the same time its most northern occupied outpost was Taos, New Mexico. Later, New Spain was delimited in the east by the English occupation of Georgia, and, further west, between 1699 and 1763, by the French occupation of Louisiana. New Spain expanded greatly when Western Louisiana was ceded in 1763 by France to Spain, who held it until its retrocession to France in 1800. On the other hand New Spain suffered territorial loss in the east when Spain ceded Florida to England in 1763. Twenty years later Spain acquired West Florida and regained East Florida from England; both provinces were acquired by the United States between 1810 and 1819. In the west, California was occupied between 1769 and 1776.

New Spain was delimited on the north in 1776 when the provinces from Texas to California were erected into a military and political jurisdiction known as the *Comandancia General de las Provincias Internas,* administered by a commandant general. Many changes in organization were subsequently made.

Government and Organization.—The chief administrative subdivisions of the viceroyalty of New Spain at the close of the 18th century were the captaincies-general of Guatemala and Havana. The former included all of the present Mexican State of Chiapas and all of Central America north of Panama; the latter included the Spanish West Indies, Louisiana and Florida. Over the captains-general the viceroy exercised only general supervisory and administrative authority. The viceroyalty proper and the captaincies-general were sub-divided for local administrative purposes into provinces. They were administered by governors, who were appointed by the king and were responsible to him through either the viceroy or the captains-general. The only institution of self-government in New Spain was the town council (*ayuntamiento,* or *cabildo*), composed of municipal judges (*alcaldes ordinarios*) and councilmen (*regidores*).



ONE OF THE AQUEDUCTS CONSTRUCTED IN MEXICO BY THE EARLY SPANIARDS AND STILL IN A STATE OF GOOD PRESERVATION

Aside from its administrative organization, New Spain was divided into four judicial districts, at the head of each of which was an *audiencia.* Such a body functioned primarily as a court of appeals, but it also exercised extensive administrative powers. The seats of the *audiencias* were Mexico City, Guatemala, Santo Domingo (moved to Puerto Príncipe, Cuba, after 1793) and Guadalajara. At Mexico City the *audiencia* served as a viceregal council, although the viceroy was not obliged to follow its advice. The viceroy could preside over the judicial sessions of the audi-

encia but did not have a vote in judicial matters. Similar relations existed between the *audiencia* and the captains-general at Guatemala. The *audiencia* of Santo Domingo exercised administrative authority over all of the Spanish West Indies until 1784, when it lost that authority over the captaincy-general of Havana; it continued to exercise administrative authority over the rest of the Spanish West Indies until 1793, at which time France came into possession of the entire island of Española (Haiti). This *audiencia* also exercised administrative authority over Venezuela for many years. The judicial authority of the *audiencia* of Santo Domingo extended over all of the Spanish West Indies, Florida, Louisiana after 1763, and Venezuela until 1786. The *audiencia* of Guadalajara, in addition to exercising judicial jurisdiction over western and north-western New Spain, including the *Provincias Internas* after 1776, exercised administrative authority in the province of Nueva Galicia.

On the military side the viceroy of New Spain was captain-general of the entire viceroyalty. In practice, however, he exercised merely supervisory military authority in the captaincies-general of Guatemala and Havana. In the *audiencia* districts of Mexico and Guadalajara he exercised direct military authority. The powers of the subordinate or local captain-general were exercised by some provincial governors. At first the viceroy was in charge of the fiscal administration of New Spain. In 1786, however, a separate fiscal administration, dependent upon the viceroy, was introduced with the establishment of the intendancy system. Under this system the viceroyalty proper was divided into twelve intendancies and three provinces. Each intendant was ruled by a governor-intendant, who assisted in the collection of revenues and, in addition, was charged with certain administrative, judicial and military authority in his intendancy.

The Church and the People.—The regular and secular clergy, particularly the former, supplemented the work of the conquerors. The Franciscans were the first regulars to enter New Spain with papal sanction, three of them arriving in May 1522. The members of this order were noted for their charitable work among the Indians and for their missionary work on the northern frontier from Florida to California. Regulars of many other orders followed the Franciscans to New Spain, notably the Augustinians, the Dominicans and the Jesuits. The last-named were transferred in 1572 from Florida to western New Spain where they were actively engaged until 1767 in missionary and educational work and in advancing and holding the frontier. Each of the orders had its own organization, the principal unit of which was the province, which was administered by a provincial. The various orders in 1805 were maintaining 254 convents in New Spain proper. Secular organization began with the nominal creation of the bishopric of Yucatán in 1519; actually it began with the creation of the bishopric of Tlaxcala in 1526. Juan de Zumárraga arrived as first bishop of Mexico City in 1528; in 1547 Mexico City became the seat of an archbishopric. In 1805 there were in present Mexico one archbishop, eight bishops and 1,703 parishes. The Council of the Indies, a joint body of clergy and laity, exercised sovereign authority. Through special concessions of the papacy the king of Spain became virtually the administrative head of the colonial church. As such, the Crown appointed to all ecclesiastical holdings, supervised the conduct of the clergy, and controlled ecclesiastical revenues. The liberal policy of the Crown was such that the church became immensely wealthy and early attained preponderant power and influence. Alamán states that its wealth in 1821 included not less than one-half of the real property and capital of the country. Its power may be judged from the petition of the city council of Mexico to Philip IV. in 1644 to stop the foundation of religious houses, to suspend ordinations because there were more than 6,000 unemployed clerics and to suppress feast days because there were at least two each week. To assist the church a tribunal of the Inquisition was established in Mexico in 1571. By the Crown the church was delegated almost exclusive control over education, but this it was unable to diffuse widely, though Humboldt said that in certain respects Mexico surpassed England. According to authoritative estimates, out of a population of about 6,000,000 at the beginning of Mexican independence, only 30,000 were literate. On the other hand the church established a number of higher institutions of learning, the underlying aims of which were to equip young men of the upper classes for the priesthood and the practice of law. The most noted of these institutions was the Royal and Pontifical University of Mexico which was inaugurated in 1553. The Church also had charge of charitable institutions, as hospitals and orphanages.

Three distinct races were represented in New Spain—the European, the Indian and the negro. The most important of these races was the European, with Spaniards overwhelmingly predominating. They were divided into two classes—gachupines, or European-born Spaniards, and creoles, or American-born Spaniards. For the gachupines were reserved most of the political, commercial and social preferments. The total number of Europeans in New Spain in 1800 probably was about 885,000, of which number approximately 15,000 were gachupines. The native race remained the most numerous. In 1800, in New Spain proper, the Indians probably numbered 3,000,000, or approximately 50% of the total population. Negroes were early brought to New Spain to work as slaves on the coastal agricultural lands. Prior to 1575 they probably outnumbered the whites, but by 1821 they had largely been absorbed or else had bought their freedom and had disappeared. Few Spanish women came to America at first, and at the close of the colonial period they probably did not total more than one-tenth of the European-born Spaniards. As a result, there were many classes of mixed blood, the most important being the mestizo (Indian and European); the sambos (negro and Indian), and the mulattoes (negro and white). The number of persons of mixed race in 1800 was approximately 2,000,000. A few Chinese and Malays were settled on the Pacific coast.

On the theory that the Indians were its wards, the Crown felt obliged to protect, convert and civilize them, and justified in utilizing their labour. The chief means by which it was hoped to attain these ends was the *encomienda* system. Allotments (*repartimientos*) were made to conquerors, to whom the Indians living thereon were given in trust (*encomienda*). Such a grantee (*encomendero*) was obligated to protect his Indians and to provide missionaries and teachers for them; he was also empowered to exact tribute of them. Not all Indians were given in *encomienda*, those living on royal lands being under overseers, appointed by the king, known as *corregidores* and *alcaldes mayores*. These officials after 1786 were replaced by assistants of the governors-intendant known as sub-delegates. While the theory of the *encomienda* system was benevolent, it resulted, in practice, in the abject enslavement of many of the natives. The system was introduced in New Spain by Cortés. Steps looking toward its correction and final abolition were taken in 1542 but it was not finally abolished until the 18th century. It should be recorded that the first church council in Mexico protested against the abuse of power over the Indians. This was an early subject of difference between church and State.

Expansion of the State.—The most continuous development in New Spain—one of dramatic interest and international importance alike—was the northward advance of the frontier of settlement. For the first decade after the capture of Mexico City, the Spaniards, except for the founding of Pánuco (Tampico) in 1522, confined their activities to the regions south and west of the capital. The creation of royal provinces in Central America between 1525 and 1527 cut off opportunities for expansion there. The heroic age of exploration followed, being ushered in by the journey of Cabeza de Vaca from the Florida and Texas coasts to the Gulf of California between 1528 and 1536. Soon afterward the Coronado and De Soto expeditions made known northern Mexico and the southern half of the present United States; the Cabrillo-Ferrelo expedition coasted as far north as Oregon; and the Villalobos expedition from New Spain to the Philippines gave Spain title to those islands.

For nearly two decades following the founding of Culiacán, Sinaloa, in 1531, the frontier of settlement in New Spain extended in an irregular semi-circle, with the base resting on Guadalajara and Mexico City, from Culiacán, on the Gulf of California, to Pánuco, on the Gulf of Mexico. Led by wealthy miners and

cattle barons and by humble missionaries, the northernmost outposts in both the east and the west by 1590 advanced still farther north, while the arc of the circle, in large measure, was filled in. In that year the frontier stretched from Cerralvo, on the lower Rio Grande, by way of Saltillo and San Bartolomé, to San Felipe at the mouth of the Sinaloa river. Meanwhile, Florida had been permanently settled in 1565 by a large expedition from Spain under Menéndez de Avilés. The purpose was to hold Florida against the French Huguenots who had attempted to colonize it. In 1598 the frontier of New Spain proper moved across 600 m. of desert north of the line of 1590 and halted in the upper valley of the Rio Grande The objects were to make New Mexico a base from which to anticipate other nations in the discovery of a supposed strait (North-west Passage) and to exploit the sedentary Pueblo Indians. New Mexico was thus permanently occupied save for the period of the Pueblo Rebellion (1680–92).

Spanish advances in the later 17th and 18th centuries were occasioned almost altogether by the fear of foreign aggression. The short-lived French settlement in Texas under La Salle (1684–87), although it failed, prompted Spain to occupy temporarily east Texas (1690–93); English aggressions westward from South Carolina prompted Spain to found Pensacola, Fla., in 1698. The founding and expansion of French Louisiana, beginning in 1699, made necessary the permanent occupation of Texas in 1716, title to which France never disputed with Spain after 1722. The boundary between French Louisiana and Spanish Texas came to be regarded as the Arroyo Hondo, midway between Los Adaes, the capital of Texas, and Nachitoches, the westernmost French outpost on the Red river, E. of Los Adaes. In north-western New Spain between 1591 and 1767 the Jesuits were chiefly responsible for the advance of the frontier from the line of settlement of 1590 into southern Arizona, and, beginning in 1697, into Lower California. The most noteworthy advances of the Spanish frontier were made after 1763. Western Louisiana having been acquired from France, it was necessary for the Spaniards to advance to the Mississippi and hold at that stream the Anglo-Americans all the way from New Orleans to and beyond St. Louis. From the acquisition of the Floridas by treaty in 1783, until the retrocession of Louisiana to France in 1800 the frontier of settlement of Spain in America extended from St. Augustine, Florida, to New Orleans, thence north to St. Louis, and thence west, by way of Santa Fe, to San Francisco.

The leading events of the colonial period in New Spain proper can be given only in bare outline here. The first two viceroys, Mendoza and Velasco, are extremely important because by them the course of viceregal administration in New Spain was definitely marked out. Mendoza's administration (1535–50), was made notable by his encouragement of exploration, an attempt to suppress the *encomienda* system, the Mixton Indian uprising, the definite incentive to northward expansion through the development of mining north of the line of settlement of 1531, and by a violent epidemic among the natives. Viceroy Velasco ranks high as a humanitarian and an expansionist. By freeing 150,000 male Indian slaves and a large number of women and children, he earned the titles of "Liberator" and "Father of his Country."

The inordinate vanity of Martín Cortés, son of the Conqueror, and the fear of the *encomenderos* that they would lose their rights, culminated in an abortive and disastrous attempt in 1566 to set up Cortés as king—the only separatist movement prior to the 19th century. In the latter half of the 16th century Hawkins, Drake, Cavendish, and other Protestant freebooters, inspired by hatred of Catholicism and patriotic motives alike, engaged in lucrative smuggling of goods into Spanish America and in even more lucrative preying upon Spanish commerce and coast towns. The establishment of regular galleon service between Acapulco and Manila after 1571 made possible the development of an extensive commerce between Spain and the Far East across New Spain. This and the establishment of extensive woollen and cotton factories in the latter part of the 16th century redounded greatly to the material advantage of New Spain.

The regular and secular clergy had early come into conflict, particularly over the tithes and the control of the Indians. The conflict reached a crisis and merged into one between church and State during the viceregal administration of the Marqués de Gelves, 1621–24. This energetic reformer favoured the appointment of regulars to deal with the natives, and in so doing came into conflict with Archbishop Serna of Mexico, who placed the city under an interdict, excommunicated the viceroy, and constrained him to hide from a mob.

During the reign of Viceroy Albuquerque (1702–11), which coincided with the war of the Spanish Succession, his chief concern was the defence of the coasts from British attacks and the fighting of pirates. By the Treaty of Utrecht (1713) England secured commercial privileges which proved in practice to be an entering wedge for much illicit commerce. Friction that resulted therefrom finally culminated in a commercial war which soon merged into the war of Austrian Succession. During the latter war the raids of Admiral Anson in the Pacific struck a hard blow at the commerce between New Spain and the Philippines. Spain entered the Seven Years' War in 1761, only to lose Havana and Manila to the British. Florida was given to England in exchange for them at the close of the war. During the war of the American Revolution, Spain declared war against England (1779) but declined to make an alliance with the American Colonies. Of considerable aid to the colonists as early as 1776 was the anti-English policy pursued by Don Bernardo Gálvez, Spanish governor at New Orleans. After Spain entered the war he directed offensive operations against the British in the territory north of the Ohio river and personally waged successful campaigns against the British in West and East Florida, thereby obtaining them for Spain at the close of the war.

Viceroy Casafuerte's reign (1722–34) was made notable by the publication of the *Gaceta de México*—published intermittently at first—and the *Mercurio de México*. A formidable negro rebellion in Veracruz and a terrible epidemic among the natives were notable events of 1735 and 1736. Viceroy Ahumada (1755–60) is noted for his many administrative reforms. A few years later, a special royal visitor, clothed with supreme power, José de Gálvez, instituted many important administrative, economic, commercial and fiscal reforms. Not the least result of these was an increase from $6,000,000 to $20,000,000 in the annual royal revenues from New Spain—an accomplishment that was effected without increasing taxes. It was at Gálvez's suggestion that the *Comandancia General de las Provincias Internas* and the system of intendancies were established. One of the notable events of the later 18th century was the expulsion of the Jesuits from New Spain, as from all of the Spanish Dominions, in 1767, under orders of Charles III.—these being carried out in New Spain by Gálvez on the night of June 26. The Jesuits were arrested *en masse*, their property, which some authorities have estimated as high as 10,000,000 pesos, was sequestrated, and they were expelled, their place in the north-west being taken by the Franciscans. The second Count of Revilla Gigedo (1789–94), of all the viceroys of that century, ranks as the greatest reformer, statesman and promoter of industry and commerce.

The Independence of Mexico.—The European situation between the outbreak of the French Revolution in 1789 and the wave of liberalism that swept over the Mediterranean States in 1820 profoundly influenced the movement for the independence of New Spain. At the same time the introduction of the revolutionary doctrines of "liberty, equality and fraternity" spread to Latin America and inspired hope among the creoles, who were ambitious to enjoy commercial, political and social preferments on an equal footing with the gachupines.

The greatest impetus to the independentist movement came when Napoleon deposed the rightful king of Spain in 1808 and placed his own brother Joseph upon the throne. At once a small, politically ambitious minority in New Spain, acting on the theory that with the deposition of Ferdinand VII. sovereignty had reverted to the people, demanded a share in the government of the viceroyalty. For selfish reasons the viceroy, Iturrigaray, lent a willing ear to these suggestions and proposed the convocation of a national congress. Thoroughly alarmed at such suggestions and fearful that they would lose to the creoles some of their privileges

through severance from Spain, the gachupines deposed Iturrigaray and took over the Government. Thus intrenched in power they easily suppressed an abortive separatist movement initiated by the creoles in Michoacán in 1809. When the viceroy, Venegas, arrived in Sept. 1810, the hold of privileged autocracy on New Spain never appeared stronger.

While the jealous gachupines and the ambitious creoles thus quarrelled in New Spain over the question of the extension of privileges a great socio-economic upheaval of the masses developed under the leadership of Father Miguel Hidalgo y Costilla, a member of the lower clergy who had been profoundly influenced by the doctrines of the French Revolution. This movement had as its object the extension of human rights and privileges to the great mass of Indians and mestizos whose claim to such privileges was equally revolutionary to creoles, gachupines and the higher clergy. At the outset the uprising, which assumed the character of a race war under the patronage of the Virgin of Guadalupe, was led by Hidalgo and Allende, a captain of cavalry. Their greatest success was the capture of the wealthy city of Guanajuato, after which they threatened the capital. But the revolutionists were decisively defeated at Calderón in 1811 and soon afterward the leaders were executed. Another liberal member of the lower clergy, Morelos, continued the movement. Although he met with serious reverses in the terrible siege of Cuautla in 1812 he rallied the south to his cause and in 1813 was able to convoke a congress which issued a declaration of independence and drafted a republican Constitution. Morelos was captured and executed at Mexico City in 1815. Thereupon, the revolutionary movement disintegrated into guerrilla warfare. The tide had already begun to turn when in 1820 the liberal Spanish Constitution of 1812 was proclaimed after a military uprising in Spain. Its promulgation in Mexico caused the high clergy and the gachupines to fear that a liberal Government in Spain would force upon them toleration and the loss of privileges, disestablishment and disendowment, all of which they had successfully opposed, first, in the period from 1808–10, when the ambitious creoles had demanded reforms, and second, in the period since 1810, when the social upheaval of the masses had largely caused the creoles and the gachupines temporarily to forget their differences. Accordingly the clerical and gachupine opponents of liberalism resolved upon the absolute separation from the Spanish monarchy as the only means of preserving their position.

The first move of the conservatives was the selection of a suitable military leader in the person of Agustín de Iturbide, a creole ex-officer in the Spanish army. He easily induced the unsuspecting viceroy to send him into the field against the rebels. His real purpose, however, in case he could not defeat Guerrero, was to win him over to the separatist movement. This was finally accomplished when, without informing the viceroy, Iturbide signed with Guerrero on Feb. 24, 1821, the Plan de Iguala—a crude *pronunciamiento* which laid down as the bases of the new State the continuation of the Roman Catholic Church as the established church of Mexico, the establishment of an independent limited monarchy, and the equality of rights for Spaniards and native-born Mexicans. Thus the Plan de Iguala was, in theory, a compromise, but one which was destined to bid successfully for the support of the various classes in New Spain. In the interest of the proposed plan, Iturbide first sought the co-operation of the viceroy, Apodaca, who refused, but was powerless to stem the flood of spontaneous support given the plan. When Juan O'Donojú, the last viceroy, arrived in July he was unable to get beyond Veracruz, and, accordingly, recognized the independence of Mexico in the Treaty of Córdoba. Iturbide triumphantly entered Mexico City on Sept. 27, 1821. The following day a provisional governing Junta, named by Iturbide, signed the "Act of Independence of the Mexican Empire," and appointed a regency of five, with Iturbide as its president. These acts marked the beginning of the national period of Mexican history.

INDEPENDENT MEXICO

Mexico has had a turbulent existence since independence. In 1823 the monarchy was repudiated in favour of a republic. From 1823 until 1860 a bitter contest was waged between adherents of federalism and centralism. A Federal republic was definitely established in 1857 but federalism was on the defensive for ten more years, first, in a three-year civil war and, second, during the period of the French intervention and the empire of Maximilian. Since 1867 there has been no organized opposition to federalism in Mexico, but during nearly one-half of that period the Díaz dictatorship prevailed in the guise of Federal institutions. Indecision concerning the form of government was accompanied by political instability. Between 1821 and the rise of Díaz in 1876, there were two regencies, two emperors, several dictators, and enough presidents and acting or provisional executives to make no fewer than 74 governments. Furthermore, the last 100 years have witnessed approximately that number of revolutions. Most of these, however, have been political or personal in character. In fact, since 1810 there have been only three general upheavals in Mexico, each of which has been socio-economic in character and more or less beneficent in its results. The first, begun in 1810 by Hidalgo, substituted the creoles for the gachupines and resulted in greater power and wealth for the church, which in 1807 had been debarred from inheriting real estate. The second, begun in 1854, disendowed and disestablished the church, but worked to the advantage of the great landowners The third, begun in 1910 and continuing down to the present time, was directed chiefly against the landed aristocracy and is strongly nationalistic.

The Mexican empire was of short duration. In the first Mexican Constituent Congress, which met on Feb. 24, 1822, the republicans were in the majority and between them and Iturbide a conflict soon developed. This was terminated on May 18 by a military *pronunciamiento* in favour of Iturbide, and by his extra-legal election as emperor by a minority in Congress. Iturbide was crowned on July 21, 1822, but fresh conflicts broke out between him and the Congress which were only terminated by his forcible dissolution of that body. This arbitrary procedure reacted in favour of a republican armed movement, initiated by Santa Anna. Finally, convinced of the hopelessness of his position, Iturbide abdicated on March 19, 1823. The Congress deported him to Italy, and granted him a pension. He returned with political ambitions the following year, and on landing (having been previously outlawed) was arrested and executed (July 15, 1824). The Congress, left in absolute control after the abdication of Iturbide, created a provisional executive triumvirate; announced (June 12) the adoption of the federal form of government; and issued a decree (June 23) convoking a new Constituent Congress. This body drafted a Federal Constitution which was promulgated Oct. 4, 1824, and Guadalupe Victoria was inaugurated as first president.

The First Federalist Régime, 1824–34.—Confronted by manifold difficulties, the Federalists were able to remain in power and to retain the federal form of government for only one decade after 1824. At the outset, Centralist and Federalist organizations as such disappeared, their places being taken by two Masonic organizations. The Conservatives, Monarchists and Centralists affiliated with lodges of Scottish-Rite Masons (*Escoceses*), and the Liberals, Republicans and Federalists, encouraged by the American minister Poinsett, organized rival lodges of York-Rite Masons (*Yorkinos*). Through boisterous professions of fraternal and political creeds members of the rival lodges kept the country profoundly agitated. An attempt at revolt by Vice President Bravo, the grand master of the Escoceses, was suppressed. The thoroughly discredited and demoralized Escoceses thereupon refrained from naming a presidential candidate in 1828 and instead threw their support to Gómez Pedraza, the Liberal contender for the presidency with Vicente Guerrero, the grand master of the Yorkinos. Gómez Pedraza was declared elected but as a result of an appeal to arms Guerrero was inaugurated for the second presidential term beginning April 1, 1829. Shortly afterward Spain made a final attempt to reconquer Mexico, but the invaders were repelled at Tampico by Santa Anna (Sept. 1829). During the invasion, Vice President Anastasio Bustamante seized the opportunity to declare against President Guerrero and was joined by the bulk of the army. Guerrero was deposed, after having served as president less than nine months, and finally retired to Acapulco, where

he was treacherously seized, tried and executed (Jan. to Feb. 1831). The next year Santa Anna headed a successful revolution against Bustamante in behalf of Gómez Pedraza, thereby enabling him to serve the last three months of the term for which he had been elected in 1828. In the deferred elections, held early in 1833, Santa Anna and Gómez Farías were elected president and vice president, respectively, for the term beginning April 1 of that year. During the greater part of the next 13 months Gómez Farías, serving as acting president, was responsible for many liberal changes, including the laicization of education, the relaxation of monastic vows, the discontinuance by the State of the collection of tithes, and the right of the State to appoint church officers. The Liberals were Whigs rather than Populists. Their dominant desire was to seize the privileges of the Conservatives, in the control of government, the ownership of land and the profits of foreign trade, which had been a Government monopoly. They were little concerned about the welfare of the masses. The liberal measures aroused the opposition of the Clericals and Conservatives, and Santa Anna, taking advantage of the situation to act as their defender, assumed the presidency on April 24, 1834. The following month, as virtual dictator, he dissolved Congress and the State legislatures, and substituted creatures of his own for the governors of the States and mayors. By such action he undid the liberal reforms of Gómez Farías and reduced to a nullity the federal system of which he had been the chief original defender.

The Conservatives and Clericals who thus came into power indirectly with Santa Anna retained control until 1846 under a centralized form of government. A new Congress discarded federalism (Oct. 3, 1835) and framed a centralist Constitution (Dec. 30, 1836), known as the *Siete Leyes* or Seven Laws. By it the States were converted into departments, ruled by governors appointed by the central authority, and popular representation was considerably reduced. Anastasio Bustamante became the first Centralist president. When he failed to satisfy questionable damage claims of French nationals in Mexico a French fleet in 1838 blockaded the coast, bombarded the fortress of San Juan de Ulua, and temporarily occupied Veracruz. This gave Santa Anna the longed-for opportunity to pose as the country's defender which, in turn, reawakened his political ambitions. Full opportunity to realize them, however, was deferred until 1841, when he joined a successful revolution against Bustamante. The Plan of Tacubaya (Sept. 28, 1841), put forward by the revolutionists, abolished all but the judicial provisions of the *Siete Leyes*, conferred upon Santa Anna power of reorganizing the administration, and provided for a new constituent assembly. When it met in June, 1842, the Federalists were in the majority, much to Santa Anna's chagrin. Accordingly he retired, leaving the reins to Nicolás Bravo. He dissolved the Federalist assembly and convened a hand-picked one which adopted an ultra-centralist Constitution (June 12, 1843). Santa Anna was inaugurated first president under it on Jan. 2, 1844, but because of his mal-administration, extravagance and profligacy, was overthrown before the end of the year and exiled. José Joaquín Herrera, who succeeded him (Dec. 1844), was a constructive statesman and adopted conciliatory foreign and internal policies but was overthrown (Jan. 1846) by Ultra-Centralists, Monarchists and anti-Americans led by Gen. Mariano Paredes. Seven months later, in order to solidify public opinion during the war with the United States the Federalist Constitution of 1824 was restored (Aug. 5, 1846). Recalled from his exile to oppose the foreign invaders, Santa Anna was elected president (Dec. 1846) under the Constitution which he had repudiated.

The substitution of a central for a federal form of government was the occasion for uprisings in various parts of Mexico, all of which were finally suppressed except that in Texas, which had been settled principally by colonists from the United States in consequence of contracts granted to immigration agents (*empresarios*) to introduce colonists. The first such contract was granted to Moses Austin, in 1821, and was carried out by his son Stephen. Because of the incompatibility of Mexican and American settlers in Texas and their mutual distrust, Texas gradually drifted toward inevitable rebellion. Various specific grievances developed after 1826 that widened the breach, but the pretext for the rebellion of the Texans was the centralization policy inaugurated by Santa Anna in 1835, culminating in the abolishment by the Mexican Congress of the federal form of government. A provisional revolutionary government, which professed to be acting in defence of the Constitution of 1824, functioned in Texas from Nov. 3, 1835, until March 1, 1836; on the following day the unqualified declaration of Texan independence was issued. Santa Anna attempted to reduce Texas, showing great severity, but was eventually defeated and captured by Houston at the battle of San Jacinto. There he signed an agreement pledging himself to work for the recognition of Texan independence upon his return to Mexico. The Mexican Government, however, repudiated Santa Anna, and a nominal state of war continued between Mexico and Texas, whose independence was recognized by the United States, Belgium, the Netherlands, France and England (1837–41).

War with United States, 1846–48.—The Texas question was chiefly responsible for war between the United States and Mexico. Texas had applied for admission into the American Union in 1836 but annexation was delayed by those in the United States who were opposed to acquiring more slave territory. Fearful of British and French influence in Texas, however, the U.S. Congress early in 1845 adopted a resolution providing for annexation. Texas agreed, and on Dec. 29, 1845, was formally admitted to the Union. The Mexican minister withdrew from Washington following the adoption of the annexation resolution and the U.S. minister was recalled from Mexico. Nevertheless, President Polk was conciliatory, and late in 1845 sent Slidell to Mexico to attempt to settle all differences between the two countries—the chief ones arising from the disputed Texas boundary and the unsettled damage claims of U.S. citizens against Mexico—and also to purchase, if possible, California and New Mexico. Slidell's mission might have been successful, in part, but for the triumph of the war party in Mexico under Paredes. It was not until President Polk was informed that Mexico desired war, that he ordered American troops into the disputed region between the Nueces and the Rio Grande rivers. Hostilities inevitably followed and a state of war with Mexico was declared by the U.S. in May 1846.

The original plans of the U.S. general staff called for (1) an invasion by Gen. Taylor of northern Mexico, which it was hoped would overawe the Mexicans and induce them to come to terms; (2) the military occupation by Gen. Kearny of the territory from New Mexico to California, which was to be held as an indemnity; and (3) the blockade of both coasts of Mexico by the United States fleet. The two last-named plans materialized fully; in addition, Gen. Doniphan led a side expedition from Santa Fe, New Mexico, to Chihuahua and Monterrey. Gen. Taylor's campaign, however, won all military engagements but failed of its object. The Mexicans, instead of submitting as the American army advanced, put up a vigorous defence, and at Buena Vista, on Feb. 22 and 23, 1847, Santa Anna opposed the Americans in the best-fought engagement of the war and the last one in the north. When the spirit of the Mexicans was revealed, a campaign from Veracruz to Mexico City under Gen. Scott was decided upon. Veracruz was captured after a three-weeks' siege (March 7 to 29, 1847), Santa Anna was decisively defeated at Cerro Gordo (April 18) and Gen. Scott, with greatly superior forces fought his way into the Valley of Mexico, and entered Mexico City Sept. 13, 1847. Peace was formally re-established with the Treaty of Guadalupe Hidalgo, concluded on Feb. 2, 1848. By it the Rio Grande was fixed as the southern boundary of Texas and the territory north of an irregular line extending from El Paso, by way of the Gila river to the Pacific ocean, was ceded to the United States; in return the United States paid Mexico $15,000,000 and assumed all claims of her citizens against Mexico.

Second Federalist Régime, 1846–53.—The Federalists, responsible for the conduct of the war against the United States, remained in power six more years after Santa Anna had been defeated and left the country. President Herrera (1848–51) attempted to reorganize the Government, restore order and establish credit. This programme was realized only in part, due to military and political disorders. However, when Arista succeeded Herrera, Mexico witnessed for the first time the peaceful transfer

of executive authority from a constitutional president to his constitutionally elected successor. The experiment was not to be repeated soon, for Arista, cognizant of his general unpopularity, gave way (Jan. 1853) before a movement promoted by Clericals and Conservatives, who favoured the convocation of a constituent assembly. After an interregnum (Jan.–March 1853) a group of militarists succeeded in effecting the recall of Santa Anna. Installed as president on April 20, 1853, he surrounded himself with Conservatives. On Dec. 16, disregarding all restraints, he declared himself dictator, with the title of "most serene highness." A few days later the sale of Mesilla valley (present Arizona, south of the Gila river) to the United States was negotiated, but the purchase money was soon dissipated. Santa Anna's zero hour, however, had already arrived. While Federalist and Centralist office seekers and doctrinaries wrestled for control after 1824, the mestizo and Indian masses, in social and economic degradation and misery, were either ignored or used as pawns. In practice, haughty creoles had merely usurped the places of haughtier gachupines. The church owned in 1854 a great part of all urban property, controlled or owned much of the rural property, had an annual income greater than that of the National Government, and acted as unofficial banker for the people. The gaze of the land-hungry masses fell upon this great domain. Therefore, the recall of the faithless Santa Anna by the Conservatives, his seizure of dictatorial power, and his alienation of the national domain, were but pretexts and not fundamental causes for the revolution of Ayutla, which swept him into perpetual political exile, and provided a liberal Constitution. This revolution was initiated by the mestizo revolutionary patriot, Juan Álvarez, and was formally proclaimed on March 1, 1854. It was soon joined by a future galaxy of heroes, including Comonfort, Juárez and Díaz, and as it spread Santa Anna left the country in Aug. 1855. On Oct. 4, Álvarez was installed as provisional president. He soon resigned and was succeeded by Comonfort, who served as provisional president.

The presidencies of Álvarez and Comonfort were signalized by the promulgation of two laws and the adoption of the Constitution of 1857. The enactment (Nov. 23, 1855) of the first law was secured by Juárez, the Zapotec Indian minister of justice in Álvarez's cabinet, from whom it takes its name (Ley Juárez). By limiting the jurisdiction of ecclesiastical and military courts to offences of the clergy and military, the law for the first time provided for the legal equality of all citizens. Feeling that religion was being attacked, the Clericals opposed the law. Equally noteworthy was the Ley Lerdo (June 25, 1856), so called from its author, Miguel Lerdo de Tejada, minister of finance in Comonfort's cabinet. This law prohibited religious and civil corporations from acquiring or owning rural or urban property not used for the specific object of the corporation, and obliged corporations then owning such property to sell the same to the tenants or usufructuaries on reasonable fixed terms, for the benefit, however, of the owners. In practice neither law accomplished its full object. Nevertheless, they were both incorporated substantially in the new Federal Constitution (promulgated Feb. 12, and effective Sept. 16, 1857) along with other clauses recognizing the natural and inalienable rights of man and providing for religious toleration and agrarian reform—all of which made the new Constitution appear extremely liberal in comparison with that of 1824. The Liberals, however, were still working for the interests of the middle class, rather than of the masses.

As the Constitution of 1857 went into effect, opposition increased. Comonfort was installed as constitutional president on Dec. 1, but within less than three weeks, vainly hoping to reconcile the two hostile political groups, accepted the Plan de Tacubaya (Dec. 17, 1857), which repudiated the new Constitution. He was promptly made dictator by the Conservatives, who took steps to draft a new Constitution under his auspices. Having used Comonfort, the Conservatives soon deposed and exiled him (Jan. 21, 1858) and named as his successor a thorough Conservative, Zuloaga. For the next three years Mexico was the prey of civil war between two rival Governments—the Constitutionalists at Veracruz under Juárez, who, as chief justice of the Supreme Court had succeeded Comonfort, and the Conservatives at the capital. The latter were better organized and early inflicted serious defeats upon the Constitutionalists. Juárez won a great moral victory, however, when he was recognized by the United States (April, 1859); this allowed him to draw supplies of arms and volunteers thence. In July 1859, Juárez published decrees suppressing the religious orders, nationalizing ecclesiastical real property (of the estimated value of more than $125,000,000, exclusive of churches, monasteries, schools, hospitals, libraries and art treasures), establishing civil marriage and registration, transferring the cemeteries to civil control—in short, disestablishing and disendowing the church. In 1859, each of the rival governments made transactions that were humiliating to Mexican sovereignty or provocative of future trouble; they can only be explained by the desperate straits of each party. In return for promised aid, the Conservative president, Miramón, approved a treaty with Spain, which recognized unjust claims of Spanish nationals against Mexico. The same year Miramón, pressed for funds, made a transaction with Jecker, a Swiss banker settled in Mexico, whereby he was to lend Miramón $15,000,000 on such terms that the latter was liable for $16,800,000. Bonds to that amount were issued to Jecker who went into bankruptcy after he had delivered to Miramón only $1,470,000. Soon, however, he bribed French officials to press, in behalf of his French creditors, for the settlement of the bonds at their face value. Also Juárez, in the hope of securing a loan, and desirous of forestalling threatened European intervention, concluded with the United States a treaty which gave the latter, in virtual derogation of Mexican sovereignty, rights of transit by diverse routes across México, and unusual guarantees for U.S. nationals residing there. This treaty was not ratified by the U.S. Senate. Until 1860 the Constitutionalists were on the defensive. In March of that year, however, the U.S. Government gave Juárez, on the ground that his Government was *de jure,* both moral and material aid, and thereby frustrated the plans of the Conservatives to attack Veracruz. Henceforth, they were on the defensive. During the war both sides levied forced contributions on much foreign property, the Conservatives being the worst offenders. The United States withdrew recognition from their Government in 1858; the following year outrages on British subjects caused the British minister to break off diplomatic relations. Finally, on Nov. 17, 1860, Miramón, under the plea of necessity, seized $660,000 which had been left under seal at the British legation. Dec. 22 his forces were routed by the Juarist Gen. Ortega and his Government overthrown.

European Intervention, 1861.—Juárez entered Mexico City on Jan. 11, 1861, and at once took under consideration Mexico's internal problems. The Spanish minister, the papal legate and members of the episcopate were expelled. In return for British recognition Juárez acknowledged as valid British claims—including a new loan—totalling nearly $70,000,000. Steps were taken to enforce the decrees of 1859 disestablishing and disendowing the church. The financial difficulties, however, seemed insuperable. Mexico's acknowledged indebtedness to Europe alone exceeded $82,000,000. In addition there were the indefensible Jecker claims which the French Government now backed up. Juárez, however, would recognize as valid only the cash actually received by Miramón from Jecker. Finally, the Congress decreed (July 17, 1861) the suspension for two years of interest payments on the external national debt. This was the occasion for the French minister to ask for his passports and for the British minister to suspend diplomatic intercourse with the Juárez Government. These events fitted in with the ulterior designs of Napoleon III., who was influenced by his Spanish wife, by the great landowners and by the exiled Mexican Clericals to interest himself in the cause of centralized monarchy and the church; in addition, he was ambitious for political and commercial reasons to establish French hegemony in Spanish America. Finally a convention between Great Britain, France and Spain for joint intervention in Mexico was signed in London on Oct. 30, 1861. Juárez succeeded in negotiating a separate arrangement of the British claims but this was rejected by the Mexican Congress; the assistance of the United States with a small loan, Mexican territory being demanded as security, was also rejected. In mid-December

Veracruz was occupied by Spanish troops; the French fleet and troops arrived soon after, with instructions to seize and hold the Gulf ports until claims were satisfied by collection of duties; Great Britain sent ships, and landed 700 marines. In view of the unhealthiness of Veracruz, the convention of Soledad was concluded with the Mexican Government; it permitted the foreign troops to advance inland to more healthful sites pending a claims conference in April, and incidentally recognized the Juárez Government. But as the French harboured leaders of the Mexican Conservatives, pressed the Jecker claims and showed an unauthorized disposition to interfere in Mexican domestic politics, Great Britain and Spain withdrew their forces in April 1862. More troops were sent from France. Their advance was checked by Zaragoza and Díaz at Puebla on May 5 (Battle of Cinco de Mayo); and in Sept. 30,000 more French troops arrived under Gen. Forey. Wintering at Orizaba, they recommenced their advance (Feb. 17, 1863), reduced Puebla, and on June 7 entered Mexico City which had been abandoned by the Juárez Government. A provisional government of Mexican Conservatives, nominated by the French minister Saligny, adopted monarchy, offered the crown, at Napoleon's instance, to Maximilian of Austria, brother of Emperor Francis Joseph, and, in case of his refusal, left its disposal to Napoleon III.

Maximilian Emperor.—Maximilian, after being endorsed in a nominal Mexican plebiscite, renounced his Hapsburg rights of succession and accepted the Mexican crown. He reached Mexico City on June 12, 1864, where he found the greater part of the country already occupied by the French and reactionary troops, the Juárez Government finally being obliged to transfer to Paso del Norte on the Rio Grande. But the empire was unstable from the beginning and gradually Maximilian came to realize that he was little more than a pawn of a political faction sustained by foreign troops. Maximilian had liberal ideals and his efforts to conciliate the republican opposition and to form a coalition cabinet of Liberals and Monarchists, together with his refusal to restore the church property that had been nationalized by Juárez, cost him the support of his original backers; and, when pressed for funds, he could obtain loans only on the most disadvantageous terms. Nevertheless, Maximilian's troops met with some notable successes. In the south Díaz was driven from Oaxaca in Feb. 1865 and in the north the condition of the Juarists became desperate. But no matter how hard pressed, Juárez was unyielding and the Republicans, defeated in open battle, resorted to guerrilla war. In desperation, Maximilian issued a decree on Oct. 3, 1865, which authorized the court-martial and summary execution of any rebel and the fining and imprisonment of anyone aiding the rebel cause. This decree was later made the basis for convicting Maximilian of murder and thus prepared his own fate.

Maximilian's rule was short but primarily for reasons disassociated with Mexican internal affairs. In view of the Monroe Doctrine, the realization of Napoleon's dream and Maximilian's tenure alike depended on the triumph of the Southern Confederacy. With the Union triumphant in 1865, the Secretary of State, Seward delivered an ultimatum to Napoleon that wrung from him early in 1866 a promise to withdraw his soldiers from Mexico. Other factors contributed to influence Napoleon to yield: the anticipated commercial returns from the Mexican venture had not materialized and the French tax-payers loudly protested against its cost; at the same time Bismarck's aggressions against Austria caused Napoleon to desire to have his troops at home. In desperation Maximilian vainly attempted to placate estranged Clericals; then his wife, Charlotte of Belgium undertook to dissuade Napoleon from withdrawing his support. Finding Napoleon obdurate and the pope, to whom she appealed, unable to aid her, she became permanently insane, dying in 1927. With the last of the French troops withdrawn early in 1867, Maximilian's downfall was hastened. Díaz pushed north to Mexico City while the forces of Juárez besieged Maximilian in Querétaro. There, betrayed as he was attempting to flee, Maximilian was captured (May 15, 1867). He was court-martialled and executed on June 19, 1867.

Juárez President.—The downfall of Maximilian made possible the definite establishment of a republican and federal form of government in Mexico; notwithstanding, political stability was longer deferred. Juárez was re-elected in 1867, but his proposal for an extra-legal amending of the Constitution met with popular disapproval; and his reduction of the army aroused discontent among the soldiery. A crop of revolutions followed, but after a partial restoration of order, a general amnesty was decreed (Oct. 13, 1870). A claims convention was signed with the United States (July 4, 1868) and friendly relations were resumed with some European nations. When Juárez stood for re-election in 1871, he was accused of seeking to make himself dictator, and when, after an indecisive election, Congress declared him president, one of the defeated candidates, Díaz, appealed to arms. His revolution was unpopular and had been virtually suppressed when the sudden death of Juárez removed its chief *raison d'être* (July 18, 1872). Sebastián Lerdo de Tejada, as president *ad interim*, granted general amnesty and called a special presidential election, in which he overwhelmingly defeated Díaz. During his administration, commendable progress in suppressing banditry was made, the Veracruz-Mexico railroad was opened, the Juárez measures disendowing the church and separating it from the State were incorporated in the Constitution, and diplomatic relations were renewed with France and Spain. Trouble developed in 1876 when the Lerdists laid plans to control the elections of that year. Díaz again appealed to arms, declaring in the Plan de Palo Blanco for the sanctity of the Constitution and the principle of no re-election. Lerdo was declared re-elected, but was overthrown by Díaz, after a campaign of dramatic incidents that culminated in the battle of Tecoac (Nov. 16, 1876), and was forced into exile together with the dissenting president of the Supreme Court, Iglesias. After a short provisional term, Díaz was installed as president on May 5, 1877. The following year the Constitution was amended so as to prevent the re-election of executives.

Díaz President.—Except for the term of González (1880–84), Díaz was president until 1911. He thus violated one of the fundamental bases of the Plan of Palo Blanco, but not without first having the Constitution conveniently amended. With Díaz a new era was unconsciously ushered in. In addition to political instability, economic progress had been slow. The number of rural holdings had only increased since 1810 from 14,382 to 19,500; there were only 430 m. of railroad in the country; financial conditions were deplorable. Social conditions had not been greatly changed. Eighty-five per cent of the population of 10,000,000 were Indian and Indian-like people. Only 350,000 children were in the public schools and fully 75% of the population was illiterate.

In marked contrast to the political instability of the past, the history of Mexico from 1876 to 1910 was almost void of politico-military strife. Díaz's policy was to keep down disorder; to centralize authority in his own hands; to foster railway development and economic progress—in large measure by attractive concessions to foreign capital; to develop native manufactures by protective tariffs; to introduce new industries; to promote forestry; to improve education—principally in urban centres; and, above all, to place the national credit on a sound basis. By 1910 most of these aims had been realized. Summary extra-legal executions of malefactors and political conspirators—notably a group of alleged conspirators in 1879—and the policing of the country by a unique and efficient rural gendarmerie contributed to the disappearance of the old revolutions. Also several formidable uprisings of Indians—as the Mayas in Yucatán and the Yaquis in Sonora—were suppressed with great severity. Centralization was effected by Díaz assuming the right to nominate either directly or indirectly, for all Federal, State and municipal offices; by his influence upon bills while being drafted and considered in Congress; and by the deference to his wishes of the members of the Supreme Court in all cases affecting the Government or political matters. Railroad mileage increased to more than 15,000 m. by 1910. Textile factories in 1910 numbered 135 and employed 33,000 hands. Mexico's foreign trade in 1910, totalling more than 450,000,000 pesos, was nearly ten times that of 1873; the modern harbour of Veracruz was finished in 1902; nearly a billion dollars of gold were mined between 1870 and 1909; in 1910 Mexico ranked second in the production of copper; the oil industry at the close of Díaz's

administration was a growing industry. The number of children in the public schools by 1906 had increased to 615,134, and, for the year 1910, in addition to State support, the Federal Government appropriated 7,000,000 pesos or 6¾% of its total budget, for education. In the realm of public finance notable progress was made. Foreign obligations were adjusted and refunded; the tariff was made protectionist; the monetary standard was changed from silver to gold; the hated tax on sales (*alcabala*) was abolished; the budget was balanced, reserves created and new loans effected.

Finally, Díaz, through his conduct of foreign relations, had raised Mexico to a proud position among the nations. In 1877 only six and in 1910 no fewer than 42 foreign Governments had representatives in Mexico. Early relations between Díaz and the United States were strained, due to the temporary refusal of the United States to accord recognition and to border disturbances. These differences were satisfactorily adjusted and after 1888 disputes with the United States were transient. A crisis with Guatemala over the boundary was averted in 1895. The same year, in the difficulty between the United States and England over the Venezuelan boundary, Díaz expressed strong adherence to the Monroe Doctrine in principle, and suggested that its maintenance should be undertaken by all American Powers. In 1906 and 1907 Díaz co-operated with President Roosevelt in mediating successfully between Central American belligerents and took part in the establishment of the Central American Court of Justice. The second Pan American Congress met in Mexico City in 1901.

Successful and beneficent as had been some of the policies of Díaz, others had been reactionary and prejudicial to the best interests of the country. Particularly disastrous in their effect were the land policies of Díaz. A presidential decree in 1890 expropriated and allotted in severalty the theretofore inalienable tillable lands of the villages known as *ejidos*—or communal lands which had long constituted the principal means of independent support of the majority of the sedentary Mexican Indians. The reactionary land law of 1894 legalized the squandering within a few years of a vast national domain. The combined effect of the above-cited decree and law was highly favourable to the landed aristocracy and unfortunate to the masses. By 1910 a total of 96·9% of the rural heads of families owned no real property. Of that in the possession of the other 3·1% was owned by fewer than 1,000 powerful landholders whose estates varied in size up to 6,000,000 acres. Furthermore, approximately 10,000,000 Indians (probably three-fifths of the population), in addition to losing their communal lands, had become serfs. In short, the condition of the masses in 1910 was even more deplorable than it had ever been. Under such conditions Mexico's third great socio-economic upheaval was inevitable and at hand. Other errors of Díaz may be briefly described. Rural education was almost completely ignored. The reform laws were not observed. The church made a partial economic and political recovery, living a precarious existence by executive clemency. Foreign concessionaires were so favoured that national resentment was deeply stirred. An historic principle that had been followed continuously during the colonial and national periods down to 1884 was reversed and by the mining laws of that year, 1892, and 1909, surface owners were given the right, without governmental approval, to exploit subsoil deposits which formerly had belonged first to the king and later to the nation. Finally, the Díaz Government had become a closed political corporation, although there were many who were qualified for participation in governmental affairs.

Revolution of 1910.—Political discontent finally culminated in armed rebellion, and this, in turn, was the occasion for a general upheaval. Díaz's announcement in 1908 that he would welcome opposition in the next campaign was the inspiration of Francisco I. Madero to initiate a political crusade in which he condemned presidential succession and demanded effective suffrage. Madero was nominated by the anti-re-electionists, but was arrested for sedition in June 1910. Escaping to Texas he issued a plan which, in addition to his original proposals for political reforms, included a demand for agrarian reforms. The incorporation of this plank caught the ear of the downtrodden masses who promptly gave Madero their support upon his return to Mexico. Henceforth the aims of the revolution were chiefly socio-economic and not political in character. Díaz attempted to suppress the revolution by force, but failing resorted to promises and belated reforms. These likewise were futile, and he resigned on May 25, 1911, and soon left Mexico forever.

After a short provisional presidency, Madero was inaugurated as constitutional president on Nov. 6, 1911. His administration was characterized by weakness and blunders. When he made concessions to the old Díaz party he lost the support of those who had rebelled to secure political reforms; when he did nothing to achieve agrarian reforms, he aroused the active antagonism of the masses. Rebellions flared up, resulting in chaotic conditions by 1912. President Taft prohibited the shipment of arms to Madero's opponents and advised Americans to leave Mexico.

A Conservative counter-revolution, headed by Victoriano Huerta, met with success in Feb. 1913. The forced resignations of President Madero and Vice President Suárez on Feb. 19, enabled Huerta to seize executive power through constitutional forms. Three days later Madero and Suárez were executed. Huerta, however, faced insuperable obstacles. President Wilson refused to recognize him because of his usurpation of authority and because of holding him responsible for the political executions. From within he was opposed by the disappointed masses, led by Carranza, Villa and Zapata, who had joined the revolution to obtain social and agrarian reforms. They were aided indirectly by the troubles of Huerta with the United States. At Tampico an affront to an American naval officer prompted an official demand that the United States flag be saluted. Huerta's refusal was followed by the American seizure of Veracruz (April 21, 1914). Huerta had already been embarrassed by the mission of John Lind, who had been sent to Mexico by President Wilson to induce him to assent to his own elimination, and the seizure of Veracruz led to the severance of diplomatic relations with the United States. Argentina, Brazil and Chile proffered their good offices, which were accepted, but the Niagara Falls Conference that followed failed to agree on a provisional president. Huerta was finally forced to resign on July 14, 1914.

Carranza President.—Between the revolutionary leaders who co-operated to overthrow Huerta, a dreary and sanguinary civil war developed which produced a flock of presidential pretenders and further delayed much-needed agrarian reforms. These came finally in a provisional decree issued by Carranza on Jan 6, 1915. It provided, where practicable, for the restitution to villages of *ejidos* illegally alienated in the past and for the expropriation of lands necessary to endow with *ejidos* other villages in need of them. The effect of this, the first constructive act of the revolution, was the crystallization of revolutionary sentiment in support of Carranza which, in turn, won for him the recognition of the United States and eight associated Latin-American republics as *de facto* president of Mexico. This success piqued Villa, who, in a deliberate attempt to involve Carranza in international difficulties, perpetrated the massacre of 18 American miners at Santa Isabel (Jan. 10, 1916) and the raid on Columbus, New Mexico (March 9), in which 17 Americans were killed. The Pershing punitive expedition of 12,000 troops immediately but ineffectually pursued Villa far into northern Mexico, much to the embarrassment of Carranza. The American expedition was finally withdrawn (Feb. 5, 1917) but not before it had been attacked by Carranza's forces, at which time several Americans were killed and a score captured (June 21, 1916). Meanwhile, the success of Carranza made possible the crystallization of other revolutionary aims less urgent than those relating to agrarian reforms. Accordingly, when a constituent assembly at Querétaro drafted a new Constitution early in 1917, it not only incorporated substantially the Carranza provisional decree of 1915, but made provision for the realization of the less urgent revolutionary aims, namely, the return to the national ownership of subsoil deposits, the limitation of the acquisition of agricultural property by foreigners, and the effecting of reforms similar in principle to the reform laws of Juárez and Lerdo de Tejada.

Carranza's administration as first president under the new Constitution was disappointing. Little was realized in the way of

effective agrarian reforms. Decrees, charged with being confiscatory in character, by which Carranza sought to enforce the constitutional provisions relating to the national ownership of subsoil deposits in which foreigners were interested, involved him in diplomatic controversies with foreign powers. In the United States intervention was loudly demanded, danger of which was augmented prior to the close of the World War by Carranza's anti-American and pro-German attitude. Finally, through threats of curtailing production, the petroleum companies forced Carranza (Jan. 1920) to suspend his objectionable decrees, but without prejudice to the final adjudication of the dispute. During 1919 Carranza's hold on the country weakened. Rebel activities were wide-spread, corruption prevailed in the army and banditry was general. This situation, together with the non-enforcement of the Constitution and the avowed intention of Carranza, in conformity with his pledge, to impose a civilian, I. Bonillas, as his successor in the presidency, inspired an armed rebellion that was soon dominated by the so-called Sonora triumvirate, composed of De la Huerta, Obregón and Calles. The rebel movement got under way in Sonora early in April 1920 and on May 8 Obregón entered Mexico City on the heels of the fleeing Carranza who was assassinated 13 days later. Following De la Huerta's provisional presidency, Obregón was installed Dec. 1, 1920.

Administration of Obregón, 1920–24.—The many aims of the revolution began effectively to be realized during Obregón's administration. The prompt application of the agrarian laws enabled the Government to re-establish peace throughout the country. Supreme Court decisions upholding some of the contentions of the petroleum companies stimulated their activities and in 1921 production reached the record-breaking total of 193,397,587 barrels. Efforts to refund the Mexican debt which were begun in 1921 were successful in June 1922. Mexico assumed full obligation for the $500,000,000 principal of the debt, the $200,000,000 of defaulted interest, and certain internal debts, and agreed to resume service on the debt, beginning Jan. 1, 1923. The debt agreement was temporarily suspended on July 1, 1924. Education was encouraged among the rural classes, largely Indians, for whom 960 schools were built, many of them large, conspicuous buildings. One of the outstanding events of 1923 was the expulsion of the papal delegate, Mgr. Filippi, whose permission to conduct open air religious exercises, granted by the State authorities of Guanajuato, was not recognized by the Federal Government. The Vatican and Catholic organizations in general protested against this action. An exciting presidential campaign followed late in 1923 and when Obregón threw his support to Calles, De la Huerta and his followers rebelled. Their initial successes menaced the Government and Obregón took the field and conducted a campaign on three fronts. Material and moral aid from the U.S. enabled Obregón to triumph, after which Calles was elected president and inaugurated on Dec. 1, 1924.

The agrarian and petroleum policies of the Obregón Government were responsible for strained relations with the United States. Secretary of State Hughes, who was interested in the general problem of protecting American property rights in Mexico, first endeavoured to negotiate with Obregón a treaty of amity and commerce that would adequately guarantee such protection. Failing in this, Charles B. Warren and John B. Payne, as members of a joint commission, were sent to Mexico with instructions to secure the restoration or proper reparation for the taking of lands owned by Americans, to obtain satisfactory assurances against confiscation of subsoil interests owned by Americans prior to the promulgation of the Constitution on May 1, 1917, and to negotiate appropriate claims conventions. Hughes wished also to raise the question of religious liberty in Mexico; this issue was dropped, by the wish of Mexico, as a purely domestic concern. The joint commission (in session from May 14 to Aug. 15, 1923) reached satisfactory understandings on the most important questions at issue. Under certain conditions American owners of lands expropriated by the Mexican Government for *ejidos* for villages were obligated to accept 20 year 5% bonds for a maximum of 1755 hectares and a just value, paid in cash, for any excess taken. At the same time the Mexican Government recognized the unqualified right of owners who were U.S. citizens, and had suffered losses or damage because of acts resulting in injustice in carrying out the agrarian policy of the Mexican Government, to have recourse to a general claims commission. On the theory that the mining laws of the Díaz régime, through the reversal of an historic principle, had in reality conferred a gift of the subsoil on surface owners, and on the argument that under Napoleonic and Mexican law a gift was not a gift until the donee had performed some positive act indicative of his intention to accept the gift, the Mexican Government recognized the right to the subsoil of all surface owners who, before May 1, 1917, had performed some positive act indicating their intention to exploit the deposits beneath their surface lands. It refused, however, to do more than grant preferential rights to the oil in the subsoil to surface owners who before May 1, 1917, had not performed the afore-described positive act. Nevertheless, because the U.S. Government refused to admit the above distinction, the Mexican Government recognized the former's right "to make any reservation of or in behalf of its citizens." On the basis of the above understandings, as mutually approved by Presidents Obregón and Coolidge, the Obregón Government was recognized by that of the United States on Aug. 31, 1923. A special claims commission whose report was signed on Sept. 10, provided for the adjudication of all claims against Mexico of citizens of the United States suffered "through revolutionary acts" between Nov. 20, 1910, and May 31, 1920 A general claims convention signed on Sept. 8, provided for the adjudication of all other claims of the citizens of either country that originated between July 4, 1868, and the date of the termination of the commission. Obregón had the support of the Agrarians.

President Calles, who was a strong supporter of the programme of 1917, came into power pledged to maintain order, to practice economy, and to promote the economic and social welfare of the Mexican people. He was supported by the Labour Party. A heavy hand was promptly laid on trouble makers, but the programme of economic and social development was impeded by the deplorable financial condition of the Government and by its inability to obtain a loan. Accordingly, President Calles adopted a drastic policy of retrenchment, and in less than eight months an actual saving of over 60,000,000 pesos had been effected. In Oct. 1925 the debt agreement of 1922 was modified to Mexico's advantage—chiefly by the separation of the debt of the national railways, which were returned to private ownership, from the national debt—and arrangements were made for the resumption of interest payments beginning Jan. 1, 1926. Toward labour, which had steadily grown more aggressive and radical, President Calles adopted a firm attitude. The railway service was federalized, thereby reducing the likelihood of strikes, and in the spring of 1925 presidential action prevented a national sympathetic strike called by the Tampico Federation of Labour Unions. Upon the recommendation of President Calles the Mexican Congress, in Dec. 1925, passed the alien land and petroleum laws. The first was an enabling act designed to put into operation the theretofore unfulfilled constitutional provisions relating to the limitation of the acquisition by foreigners of agricultural land in Mexico; the second law was designed to put into operation by legislative action, as opposed to presidential decrees, the constitutional provisions relating to the national ownership of subsoil deposits. Early in Jan. 1926, just as a spirited diplomatic controversy with the United States concerning these laws reached an apparent crisis, the Mexican Catholic episcopate took a positive stand against the theretofore almost wholly unenforced religious and educational provisions of the Constitution and thus precipitated a conflict between church and State. An apostolic letter of Pope Pius XI. (Feb. 2, 1926) which voiced sympathy for the Mexican clergy because of the "wicked . . . regulations and laws . . . against the Catholic citizens of Mexico," intensified the uncompromising attitude of both the Government and the episcopate. The conflict reached a crisis on July 31, at which time the clergy, in preference to submitting to an executive decree designed to enforce the religious and educational provisions of the Constitution, which they regarded as imposing impossible conditions for the practice of their ministry, withdrew from the churches, and thus suspended reli-

gious exercises requiring the services of priests. The Government maintained its position. Churches, as well as all other church property, which had been nationalized, were taken in charge by Government agents, but the churches in most cases were kept open for individual worship. The Government expressed a willingness to transfer the custody of the churches to the clergy if they agreed to recognize the law. Opposition to the law resulted in several outbreaks, which were suppressed. In addition, many members of the episcopate were deported (since April 1927) on the ground that they had encouraged the Catholic uprisings.

Despite international and internal troubles the Calles Government made notable progress in developing irrigation projects, in building roads and in promoting education, particularly among the rural classes. In 1926 a total of 46,000,000 pesos was spent on education. This sum was equivalent to 8½% of the Federal budget plus about 40% of the total budgets of all the States. A politico-military rebellion late in 1927, headed by two presidential candidates, Generals Gómez and Serrano, was suppressed with rigour.

The alien land and petroleum laws were vigorously protested against by the U.S. Government, chiefly because of their alleged retroactive and confiscatory character. The controversy apparently reached a crisis with the official promulgation of both laws early in 1926. The diplomatic exchanges yielded no agreements but the tension was relieved in March. At that time, Secretary of State Kellogg, in answer to various questions concerning the proposed application of specific provisions of the alien land law, received apparently satisfactory replies from the Mexican Government; at the same time Kellogg apparently indicated a willingness to be content with the petroleum law provided American owners who had performed an above-described positive act before May 1, 1917, were confirmed in their rights to the subsoil. The second phase of the diplomatic controversy was opened by Kellogg on July 31, 1926. Vigorous complaints against specific provisions of both land and petroleum laws were made and when the Mexican replies showed that the two Governments differed fundamentally on all specific points raised by Kellogg, the United States in a virtual ultimatum (Oct. 30) warned Mexico not to deprive American owners in Mexico of any of their property rights. The Mexican Government countered by requesting that violations of recognized principles of international law be indicated. Since then neither law has been the subject of public diplomatic representations. The petroleum law in theory went into effect on Jan. 1, and the alien land law on Jan. 21, 1927. The latter, apparently, was quite generally accepted by aliens in Mexico. Articles 14 and 15 of the petroleum law, which were among those vigorously protested against by Kellogg, required owners of the surface who acquired their titles prior to May 1, 1917, to exchange them for "confirmatory concessions," good for 50 years, and, under certain conditions, renewable. Property of owners not complying with the law before Jan. 1, 1927, was to revert to the Mexican nation. On the latter date, however, the Mexican Government made no move to take over such property, and, instead, merely cancelled drilling permits of non-conforming companies on the ground that they had not complied with articles 14 and 15. This made possible a test of the constitutionality of the two articles, and a decision of the Mexican Supreme Court (Nov. 17, 1927) declared that they were unconstitutional. The decision was at once accepted by the Mexican Government and before adjournment in December the Mexican Congress re-enacted the petroleum law with the two controverted articles amended so as to conform with the Supreme Court decision. Authorized executive regulations governing the new law promptly met with the approval of the United States Government when they were issued on March 27, 1928. Thus two, but only two, of the various provisions of the law that are objectionable to the American interests upheld by Kellogg have been eliminated by the Supreme Court decision. Relations between the United States and Mexico have shown marked improvement since the arrival (Oct. 1927) of Dwight W. Morrow as United States Ambassador to Mexico. The mainsprings of his diplomacy have been respect for Mexican sovereignty and personal contacts designed to show interest in and respect for the Mexican people and their Government.

On July 17, 1928, President-elect Obregón was assassinated by a fanatic, José de León Toral. At the special session of the Mexican Congress, on Sept. 1, President Calles declared that he would not again seek election. The Congress elected Emilio Portes Gil, secretary of the interior, provisional president, who took office on Dec. 1, 1928.

On Mar. 3, 1929 a concerted revolutionary *coup d' état* broke out in Vera Cruz and in the northern States, engineered by military and civil leaders, professing themselves loyal to the memory of Obregon but not in sympathy with Calles or Portes Gil. Calles was immediately appointed Secretary of War and took control of operations. Within a week the revolt in Vera Cruz collapsed and, the rebel power was broken at the battles of Jimenez and La Reforma. Pascual Ortiz Rubio was elected President of Mexico in Nov. 1929; he visited the United States in December, and, returning to Mexico, was inaugurated on February 5, 1930.

Bibliography.—For English readers the standard work is still H. H. Bancroft, *History of Mexico, 1516–1887* (San Francisco, 1883–88), and supplementary histories. The best one-volume history of Mexico in English is H. I. Priestley, *The Mexican Nation, A History* (New York, 1923). Standard Mexican authorities are: Lucas Alamán, *Historia de Méjico* (Mexico, 1849–52) I. Álvarez, *Estudios sobre la historia general de México* . . . (Zacatecas, 1875–77); V. Riva Palacio, ed., *México á través de los siglos* (Barcelona, 1888–89); N. de Zamacois, *Historia de Méjico desde sus tiempos mas remotos* . . . (Mexico, 1876–82). Important documents relating to the Colonial period, the struggle for independence and the French intervention are found in *Documentos inéditos ó muy raros para la historia de México* . . . (Mexico, 1905–11), published under the editorship of Genaro García and Carlos Pereyra. A large and informative illustrated work, edited by Justo Sierra, sumptuously produced but inadequately translated, is *Mexico, its Social Evolution* (Barcelona, 1900–04). For colonial institutions and administration *see* G. Desdevises du Desert, *L'Espagne de l'Ancien Régime: les Institutions* (Paris, 1899); Juan de Solórzano y Pereyra, *Politica Indiana* (Madrid, 1629–39, 1776); L. S. Fisher, *Viceregal Administration in the Spanish-American Colonies* (Berkeley, 1926); and Alexander von Humboldt, *Essai politique sur le royaume de la Nouvelle Espagne* (Paris, 1811; English trans., New York, 1811).

H. G. Ward's *Mexico* (London, 1829) is excellent for the history and description of Mexico during the first decade after independence. For Mexico just before the war with the United States, *see* Mme. Calderón de la Barca, *Life in Mexico* (Boston, 1843); and W. Thompson, *Recollections of Mexico* (New York, 1847). For the war with the United States the standard authority is J. H. Smith, *The War with Mexico* (New York, 1919). A valuable study of the liberal movement during its early stages is W. H. Callcott, *Church and State in Mexico, 1822–1857* (Durham, 1926). For Maximilian, the Bluebooks on Mexican affairs contained in *Accounts and Papers* (presented to parliament), vol. lxv. (1862) and vol. lxiv. (1863) are valuable; E. de Kératry, *La Créance Jecker; l'empereur Maximilien son élévation et sa chute* (Eng. trans. by Venables); *La Contre-guérilla française au Mexique*, are especially noteworthy; Prince Felix Salm-Salm's *Diary* gives valuable information as to Maximilian's decline and fall. Also J. F. Domenech, *L'Empire mexicain* (Mexico, 1866), and *Le Mexique tel qu'il est* (Paris, 1867); Daran, *El General Miguel Miramón* (Rome, 1886). For a recent scholarly study *see* J. Musser, *The Establishment of Maximilian's Empire in Mexico* (Menasha, 1918). *See* also F. Bulnes, *El verdadero Juárez* (Mexico, 1904) and G. García, *Juárez; refutación . . . a Bulnes* (Mexico, 1904). For an impartial and well-written account of the Díaz régime *see* D. Hannay, *Díaz* (New York, 1917).

For the background of the socio-economic upheaval that began in 1910 *see* H. Phipps, *Some Aspects of the Agrarian Question in Mexico* (Austin, 1925); G. M. McBride, *The Land Systems of Mexico* (New York, 1923); A. Molina Enríquez, *Los grandes problemas nacionales* (Mexico, 1909); F. González Roa, *Las cuestiones fundamentales de actualidad en Mexico* (Mexico, 1927). For events in Mexico since 1910 the following works are useful: H. Baerlein, *Mexico, the Land of Unrest* (Philadelphia, 1913); M. Márques Sterling, *Los últimos dias del Presidente Madero* (Havana, 1917); E. L. Bell, *The Political Shame of Mexico* (New York, 1914); L. Gutiérrez de Lara and E. Pinchón, *The Mexican People; their Struggle for Freedom* (Garden City, 1914); E. O'Shaughnessy, *A Diplomat's Wife in Mexico* (New York, 1916); E. D. Trowbridge, *Mexico To-day and To-morrow* (New York, 1919); S. G. Inman, *Intervention in Mexico* (New York, 1919); G. H. Blakeslee, ed., *Mexico and the Caribbean* (New York, 1920); Wallace Thompson, *The People of Mexico* (New York, 1921); C. L. Jones, *Mexico and its Reconstruction* (New York, 1921); C. Beals, *Mexico—an Interpretation* (New York, 1923); E. A. Ross, *The Social Revolution in Mexico* (New York, 1923); M. Sáenz and H. I. Priestley, *Some Mexican Problems* (Chicago, 1926).

For the early Constitutions of the republic *see* I. A. Montiel y Duarte, *Derecho público mexicano* . . . (Mexico, 1871–82). A study of the Constitution of 1857 by B. Moses is in the *Annals of the Ameri-*

can Academy of Political Science II., i. (1891). An English translation of the Constitution of 1917 by H. N. Branch, published in parallel columns with that of 1857, is in a supplement to the *Annals* of the same academy, published in Philadelphia (May, 1917). MEXICO, a central plateau State of the Republic of Mexico. Pop. (1921) 884,617, largely Indian. Area, 8,262 sq. miles. Enclosed within its boundaries, except on the south, is the Federal District and capital city of Mexico with an area of 572·5 sq. m., which is not included in that of the State. The State is divided into two unequal parts by the Sierra de Ajusco and Montes de las Cruces, which form a wooded ridge across it from east to west, with a general elevation of about 10,000 ft. above sea-level, or about 2,500 above the plateau level.

A considerable part of the northern section of the State consists of the Valley of Mexico, a nearly circular flat-floored basin, once the bed of a great lake but now covered with swamps, sodden meadows and small lakes. The surrounding country drains into this depression, but an artificial outlet has been created by the opening of the Tequixquiac tunnel. Beyond its margin the plateau drains west to the Pacific through the Lerma, and north-east to the Gulf through the San Juan and Pánuco. South of the Sierra de Ajusco the country is roughly mountainous and drains to the Pacific through tributaries of the Balsas. Within the depression of the north are the lakes of Zumpango, San Cristóbal, Xaltocán, Chalco, Xochimilco and Texcoco, the last-named three lying partly or wholly in the Federal District. Texcoco has the lowest level and its water is brackish and undrinkable, though that of the streams flowing into it and of the other lakes is fresh. Lake Xochimilco is celebrated for its "floating gardens" or *chinampas* (*see* MEXICO, FEDERAL DISTRICT OF). The principal industries of the State are mining and agriculture. The principal agricultural products are cereals, sugar, *maguey* (from which "pulque" is made), coffee and fruit. In recent years the mining of gold and silver has taken high rank, particularly in the district of El Oro in the western part of the State. Stock-raising has also had a profitable development, owing to the proximity of the national capital. The manufacturing industries are important; among the manufactures are cotton and woollen fabrics, flour, dairy products, glass-ware, pottery, bricks, wines and spirits. The making of "pulque" is one of the chief industries of the State, and the product is sent in large quantities to the national capital. The State is traversed by the Central, National, Mexican International and Interoceanic railways, and by short lines from the national capital to neighbouring towns. The capital is Toluca, and other important towns are El Oro de Hidalgo (pop. 14,804 in 1921); Amecameca de Juárez (pop. 6,974 in 1921); Zumpango (pop. 5,405 in 1921), 30 m. N. of the national capital; and Tenango del Valle (5,824 in 1921), 15 m. S.E. of Toluca.

MEXICO, FEDERAL DISTRICT OF, a territory set apart for the independent and exclusive use of the Mexican Federal Government, occupying the south-eastern part of the Valley of Mexico, and taken from and lying within the State of Mexico, which forms its boundaries on all sides except the south where it touches the State of Morelos. Pop. (1921) 906,063, largely Indian; area, 572·5 sq. miles. The district is very irregular in outline, its greatest length (north-west to south-east) being 30 m., and its greatest breadth 25 miles. It is divided into 13 municipalities, México, Guadalupe-Hidalgo, Atzcapotzalco, Tacuba, Tacubaya, Mixcoac, Cuajimalpa, San Angel, Coyoacán, Tlálpam, Xochimilco, Milpa Alta, Ixtapalapa, General Anaya and Ixtalco; the first of these comprises the national capital and its immediate suburbs, and the other 12 the unequal divisions of the district with a considerable number of towns and villages. Indians and half-breeds form more than one-half of the rural population being engaged in agriculture, gardening, manufacturing and trade. The government of the district is exercised by the national executive in accordance with the organic law of 1903, though some measure of popular government is vested in municipal councils (*ayuntamientos*) elected by popular vote for terms of four years. The administrative officers, who are appointed by the national executive, consist of a governor of the Federal District, the director-general of public works and the president of the superior board of health. The governor represents the national Government, and has special charge of the fire and police departments, prisons, imposition of penalties for violation of ordinances, public diversions and festivities, civil registry, street traffic, inspection of weights and measures, and the sale of intoxicating liquors. The director-general of public works has special charge of the water supply, streets and roads, parks, monuments, public lighting, drainage, street cleaning, public buildings not under Federal control, cemeteries, slaughter-houses and markets, building operations and all municipal or communal property. The president of the superior board of health has charge of all sanitary works, general sanitary inspection, the sanitary administration of markets, slaughter-houses and cemeteries, and the introduction of meats from other localities. The government of the district is copied, in part, from that of the District of Columbia in the United States, but its citizens are not disfranchised.

The principal towns of the district are merely suburbs of the capital. Within the municipal limits of Mexico City are Chapultepec, Santa Anita and the hot springs of El Peñón, which are popular suburban resorts easily reached by the ordinary urban tramway service. Chapultepec (Grasshopper Hill) is an isolated rock nearly 200 ft. high surrounded by a beautiful park and surmounted by a fortified structure called the "Castle," containing the summer residence of the president. A finely graded road leads to the summit. The park contains a grove of old cypress trees (*Taxodium distichum*, called "ahuehuetes" by the natives), one of which is 45 ft. in circumference and nearly 200 ft. high. The hill is nearly 3 m. south-west of the centre of the city and once commanded one of its principal causeway approaches. It was assaulted and captured by the American forces under Gen. Winfield Scott on Sept. 13, 1847, after a stubborn resistance. A monument to the cadets of the military school who died in this battle stands in the park. The castle, which was planned by the viceroys, was built and decorated by the Emperor Maximilian, who planned for it the drive known as the Paseo de la Reforma. Guadalupe or Guadalupe-Hidalgo (pop. 11,473 in 1921), 2½ m. north by east from the plaza of Mexico City, near the shore of Lake Texcoco, is chiefly known for its shrine to Our Lady of Guadalupe, who is said to have appeared there to the Indian Juan Diego in 1531. The shrine stands on the principal plaza and is visited by many thousands of pilgrims during the year, whose pious contributions have so enriched the church that its sacred vessels, altar-rails, candelabra and other accessories are estimated to contain 50 tons of silver. The treaty of peace between Mexico and the United States was signed here Feb. 2, 1848. Tacubaya (pop. 54,775 in 1921), about 5 m. west-south-west of the plaza, is noted for its old residences and beautiful gardens. The National Astronomical observatory occupies a modern edifice. At Popotla, now well within the city of Mexico, is an aged tree under which, according to tradition, Cortés sat and wept after his terrible retreat from the Aztec capital on the *noche triste*. Farther south, on the lowest slopes of the mountain range are San Angel, Coyoacán and Tlálpam, favourite country residences of the richer citizens. Xochimilco (field of flowers) (pop. 8,936 in 1921), on the west shore of the lake of that name and 10 m. south by east of the city, is an Indian town dating long before the discovery of America.

MEXICO, a city of Missouri, U.S.A., 110 m. N.W. of Saint Louis; the county seat of Audrain county. It is on Federal highway 54, and is served by the Burlington Route, the Chicago and Alton and the Wabash railways. Pop. 6,013 in 1920 (15% negroes); 8,290, 1930 by Federal census. It is in the blue-grass region of the State, which produces especially horses and mules, grain, hay, cattle and hogs. The city has large deposits of high-

grade fire-clay. It manufactures shoes, flour, fire-brick and stove-linings; and is the seat of Hardin college for girls (Baptist, 1873).

MEXICO, GULF OF, a mediterranean gulf almost surrounded by the coasts of the United States and Mexico, and forming the northern division of the extension westward of the west Atlantic trench (*see* ATLANTIC OCEAN). Its southern boundary is defined by the partly submerged ridge which extends eastwards from the peninsula of Yucatán, and on which the island of Cuba is situated; to the east it communicates directly with the Atlantic by the Strait of Florida. On the western side of Yucatán a southerly embayment is formed by the Gulf of Campeachy. The U. S. coast closely follows the parallel of 30° N., while the parallel of 20° N. cuts across the Gulf of Campeachy; the greatest length—Veracruz to Florida—is 1,120m., and greatest width—Galveston to Campeachy—680 miles. The total area is approximately 716,000sq. miles.

The deepest part of the Gulf of Mexico, the so-called Sigsbee deep, lies below the line of 2,000 fathoms, between 23° and 25½° N., and 84½° to 95° W. It is widest to the west, where the breadth is about 120m., and narrows to 25m. at its greatest depth (2,119 fathoms) between 86° and 88° W., widening again to some 80m. farther eastward. The continental shelf is for the most part narrow; its breadth is 6m. at Cape Florida, 120m. along the west coast of Florida, 10m. at the southern pass of the Mississippi, 130m. near the boundary of Texas and Louisiana, and 15m. off Veracruz. The shores are low, sandy, and marshy, the coast-line being frequently doubled by lagoons. There are no islands except the "Keys" of Florida and Yucatán, and Cuba.

The tides in the Gulf of Mexico are of comparatively small range (springs rarely exceed 4ft. and neaps 2½ft.), but a remarkable feature is the exaggeration of the diurnal inequality to such an extent as almost to extinguish the semi-diurnal tide in the inner parts of the gulf, giving high and low water only once daily. The mean level of the water in the Gulf of Mexico was formerly given as about 40in. above that of mean sea-level at New York, but later reports on precise levellings from New York to Biloxi through St. Louis describe it vaguely as "somewhat higher." The current movement in the Gulf of Mexico consists of a rotational movement in the direction of the hands of a watch, the branch of the equatorial current which enters the Caribbean sea passing into the gulf by the Strait of Yucatán and issuing from it by the Strait of Florida as the Gulf Stream.

From March to September the prevailing winds are the north-east trades; these undergo considerable modification on account of the configuration of the surrounding land, and the rains which accompany them are interrupted by spells of calm thick weather, and rarely by northerly winds known as *Nortes del hueso colorado* and *Chocolateros*. In the colder dry season, from October to April, the climatic situation is dominated by the relatively high temperature of the surface of the gulf, causing a cyclonic inflow of air which is associated with the strong northerly winds or "northers" prevailing on the western side, more particularly along the Mexican coast. The northers sometimes blow with terrific force and are at times accompanied by rain. The form and position of the Gulf of Mexico exercise a profound influence on the climate of the United States. (H. N. D.)

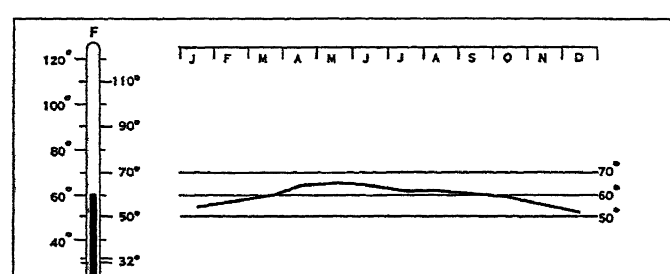
MEXICO CITY, capital and metropolis of the Republic of Mexico, and chief town of the Federal District, near the southern margin of the great central plateau of Mexico, in lat. 19° 25′ 45″ N., long. 99° 7′ W. It is about 200 m. in a direct line W. by N. of Veracruz, its nearest port on the Gulf of Mexico, with which it is connected by two railway lines, one of which is 264 m. long; and about 181 m. in a direct line N.N.E. of Acapulco, its nearest port on the Pacific, with which it is connected partly by rail and partly by a motor road. The city had a population of 615,367 at the census of 1921 (271,956 males and 343,411 females), of whom 23,668 were foreign-born; estimate for 1924, 880,000. The majority of the inhabitants is composed of Indians and mestizos, from whom come the factory workers, labourers, servants, porters and other wage-earners. The foreign population includes many capitalists and industrial managers, who are doing much to develop the country, the large American colony being concentrated in a fine modern residential district in the south-west.

The city stands on a small plain occupying the south-western part of a large lacustrine depression known as the Valley of Mexico (*El Valle de México*), about 3 m. from the western shore of Lake Texcoco, whose waters once covered a considerable part of the ground now occupied by the city. The valley, including the drainage basin of Lake Zumpango, has an area of 2,219 sq.m. (1,627 sq.m. without that basin). The elevation of the city above sea-level is 7,415 ft., only a few feet above the level of Lake Texcoco. The general elevation of the valley is about 7,500 ft., that of Lake Zumpango being 7,493 ft., and of Lake Chalco 7,480 feet. The rim of the valley is formed by spurs of the cordillera on all sides—the Sierra de Guadalupe (650 to 750 ft. above the city) on the north, the Sierra Nevada, with its snow-clad peaks of Popocatépetl and Ixtaccíhuatl farther away to the south-east, the Sierra de Ajusco, and the Montes de las Cruces bordering the depression on the south and west. Earthquake shocks are of frequent occurrence, but the city rarely suffers any material damage. The great earthquake shocks of July 30 and 31, 1909, however, caused considerable damage in the city, and a few lives were lost.

Lake Texcoco is a shallow body of brackish water, with area of about 11½ sq.m., and is fed by a number of small streams from the neighbouring mountains, and by the overflow of the other lakes. Its shores are swampy and desolate and show considerable belts of saline incrustations with the fall of its level. The Aztecs settled there because of the security afforded by its islands and shallow waters.

The Chalco and Xochimilco lakes, 8 or 9 m. to the southward, which are separated by a narrow ridge of land, are connected with the lower part of the city by an artificial canal called "La Viga," 16 m. long and 30 ft. wide, which serves as an outlet for the overflow of those lakes and as a waterway for the natives, who bring in flowers and vegetables for sale. Lake Xochimilco, celebrated for its *chinampas* or "floating gardens" (*see* MEXICO, FEDERAL DISTRICT OF), is supplied largely by fresh-water springs opening within the lake itself. Lake Chalco is greatly reduced in size by railway fillings and irrigation works.

Climate and Health.—The climate of the city is temperate, dry and healthy. The temperature ranges from a minimum of



WEATHER GRAPH OF MEXICO CITY. THE THERMOMETER INDICATES THE ANNUAL MEAN TEMPERATURE. THE CURVE SHOWS THE MONTHLY MEAN TEMPERATURE, AND THE COLUMN, THE NORMAL MONTHLY PRECIPITATION

about 35° F in winter, to a maximum of 79° in summer. The nights are always cool, and there is a marked difference between sun and shade. The year is divided into a wet and dry season, the former from April to September, the latter from October to March. The rainfall, however, is light, about 20 to 25 in., but, with the assistance of irrigation, it serves to sustain a considerable degree of cultivation in the neighbourhood of the city. The health of the city, unfortunately, does not correspond with its favourable climatic conditions. The death-rate has been notoriously high, though the completion of the valley drainage works in

1900, supplemented by underground sewers in the better parts of the city, by a more adequate water supply, and by better sanitation, have improved matters. The annual death-rate per 1,000 was 54 for the Federal district in the year 1901, 50 in 1902, 48 in 1903, 46 in 1904, and 56 in 1905; the increase for the last-mentioned year being due to an epidemic of typhus fever. During the year 1915 a disastrous epidemic of typhoid fever, that caused an appalling number of deaths, developed in the city, due to the neglect of public services brought about by the revolutionary disturbances, and within the next few years frequent recurrences of influenza raised the death-rate. The mortality during 1924 reached 57·40 per 1,000.

Streets and Plazas.—The city is laid out with almost unbroken regularity, and is compactly built. The newer and better residential sections are on the south-western side; the poorer districts are on the eastern side, nearer the swampy shores of Lake Texcoco. As the name of a street changes with almost every block, according to the old Spanish custom, a list of street names is sometimes mistakenly accepted as the number of continuous thoroughfares in the city, so that it has been said that Mexico has 600 to 900 streets and alleys.

Several new residential suburbs have been created by cutting up adjacent estates (*haciendas*) into building lots; many new modern streets have been cut, and old dirty squares have been transformed into neat flower-decked plazas. In 1923 the area of the city was about 15 sq.m., divided into eight sections (*cuarteles* or *demarcaciones*), and sub-divided into about 1,000 squares. There are over 200 m. of tramways, and tram service, furnished by an English company and managed by English and Canadians, is efficient. Outside the Indian districts of the eastern and southern outskirts the streets are paved with asphalt or stone, lighted with electricity and gas, and served with a good street railway service. The political and commercial centre of the city is the *Plaza Mayor*, or *Plaza de la Constitución*, on which face the cathedral, national palace, and municipal palace. Grouped about the *Plaza de Santo Domingo* are the old convent and church of Santo Domingo, the court of the Inquisition, now occupied by the School of Medicine, the offices of the *Departamento de Comunicaciones*, and the old custom-house (*aduana*). Close by are the old church of the Jesuits and the school of mechanic arts (*artes y oficios*) with its large and well-equipped shops. Among other well-known *plazas* are: Loreto, on which faces the great enclosed market of the city; Guardiola, in the midst of handsome private residences; San Fernando, with its statue of Vincente Guerrero; and Morelos, with its marble statue of the national hero of that name. The *Paseo de la Reforma*, the finest avenue of the city, is a broad boulevard extending from the *Avenida Juárez* south-west to Chapultepec, a distance of nearly 3 miles. At intervals are circular spaces, called *glorietas*, with statues (the famous bronze equestrian statue of Charles IV., the magnificent Independence column and the monuments to Columbus, Cuauhtemoc, the last of the Aztec emperors, and Juárez). Other notable avenues are Bucareli and Juárez, and the *Avenida de la Viga*, which skirts the canal of that name. The principal business street runs westward from the *Plaza Mayor* toward the *Alameda*, and is known as the *Avenida de Francisco I. Madero*, for five squares, and as *Avenida Juárez*, along the south side of the *Alameda* to its junction with the *Paseo*. The *Alameda*, or public garden, ½ m. W. of the *Plaza Mayor*, covers an area of 40 ac., and occupies the site of the old Indian market and place of execution, where occurred the first auto-da-fé in 1574.

Noteworthy Buildings.—The great cathedral stands on or near the site of the Aztec temple (*teocalli*) destroyed by Cortés in 1521. The foundations were laid in 1573 and the church was finished about 1811. Standing close beside the cathedral is the highly ornamented façade of a smaller church, called *El Sagrario Metropolitano*. The city has about 60 church edifices, including *La Profesa, Loreto, Santa Teresa, Santo Domingo* and *San Hipólito*. At the time of the secularization of Church properties there were about 120 religious edifices in the city—churches, convents, monasteries, etc., many of which were turned over to secular uses. The national palace, also on the *Plaza Mayor*, has a frontage of 675 ft. on the east of the *Plaza*, and covers a square of 47,840 sq.yd., or nearly 10 acres. It contains the executive offices of the Government, the Senate chamber, the general archives, national museum, observatory and meteorological bureau. The palace occupies the site of the residence of Montezuma, which was destroyed by the Spaniards, and that of Hernando Cortés, which was also destroyed in 1692. It has three entrances on the *Plaza*, and over its main gateway hangs the "liberty bell" of Mexico, first rung by the humble parish priest, Hidalgo, on the night of Sept. 16, 1810, to call the people of Dolores to arms, and now rung at midnight on each recurring anniversary by the president himself. The national museum, which occupies the east side of the national palace, is rich in Mexican antiquities, among which are the famous "calendar stone," supposed to be of Toltec origin, and the "sacrificial stone" found in the ruins of the great *teocalli* destroyed by Cortéz. Near the cathedral is the *monte de piedad*, or Government pawnshop, endowed in 1775 by Pedro Romero de Terreros (*conde de Regla*) with £75,000, and at one time carrying on a regular banking business, including the issue of bank-notes. The national library, which has upwards of 225,000 volumes, occupies the old St. Augustine church.

Other notable buildings are the general postoffice, begun in 1902 and finished in 1907; the Minería, occupied by the schools of mining and engineering; the military school, occupying a part of the Castle of Chapultepec; the Iturbide palace, now occupied as a hotel; the Chamber of Deputies; the Palace of Justice; the old mint, dating from 1537; the penitentiary, completed in 1900; the Panteón, with its bronze monuments to the most celebrated Mexicans; the general hospital; the Jockey Club on Plaza Guardiola, now an American restaurant; the National university and new school edifices of modern design. The magnificent National Theatre, begun in 1900, has been partially completed, 12,000,000 pesos having been spent on it up to 1922.

Types of Construction.—The old Spanish edifices were very solidly constructed of stone, and private residences were provided with iron gates and window guards strong enough to withstand an ordinary assault. Private houses were also provided with flat roofs (*azoteas*) and battlements, which gave them great defensive strength, as well as a cool, secluded retreat for their inmates in the evening. The old Moorish style of building about an open court, or *patio*, still prevails. The better residences of the old style were commonly of two storeys—the ground-floor being occupied by shops, offices, stables and servants' quarters, the living rooms of the family being on the second floor. The modern constructions, such as those of the *Colonia Juárez* and other new residential districts are more attractive.

Drainage and Water Supply.—Mexico was formerly one of the worst drained large cities of the New World, its subsoil being permanently saturated and its artificial drainage being through open ditches into the San Lázaro canal, which nominally discharged into Lake Texcoco. The difference in level between the city and the lake being less than 6 ft. and the lake having no natural outlet typhoid fever became a common epidemic in its lower and poorer sections. In 1629 the streets of the city were covered to a depth of 3 ft. and remained flooded until 1634. The earliest effort to correct this evil was by the Dutch engineer, Maartens (Span., Martínez), who planned a deep cutting through Nochistongo hill, north of the city, to carry the overflow of Lake Zumpango to the river Tula, a tributary of the Pánuco. The cutting was 13 m. long and is known as the Tajo de Nochistongo. It was begun in 1607 but was not completed until 1789, and then it was found that the city was still subject to partial inundations, although an enormous sum of money and 70,000 lives of Indian labourers had been expended upon it. During the year 1856 President Ignacio Comonfort invited tenders for drainage works conditional on the use of waste waters for irrigation purposes, and the plan executed consists of a canal and tunnel 43 m. long, starting from the east side and 4¼ ft. below the mean level of the city, and running north to Zumpango and thence eastward into a tunnel over 6 m. long, which discharges into a small tributary of the Pánuco river, near the village of Tequixquiac. The greatest depth of the tunnel is 308 ft. The works were completed in 1900.

For the water supply the Aztecs used the main causeway through their city as a dam to separate the fresh water from the hills from the brackish water of Texcoco, and also obtained drinking water from a spring at the base of Chapultepec. The Spaniards added three other springs to the supply and constructed two long aqueducts to bring water into the city. Three other sources were added during the 19th century, and in 1899–1900 steps were taken to secure a further supply from the Río Hondo. Besides these there are 11 public and 1,375 private artesian wells in the city. All these sources are estimated to yield about 220 to 230 litres per head per day.

Educational Institutions.—Considerable attention has always been given to education in Mexico, but in colonial times it was limited in scope, and confined to the dominant classes. The old University of Mexico, with its faculties of theology, law and medicine (founded 1551 and inaugurated 1553), ceased to exist in 1865 and was succeeded by schools of engineering, law and medicine, which have been signally successful. The university, however, was reopened in 1910. A summer school, in connection with it, was established in 1922, designed especially to attract foreign students for the study of Spanish. The Government also maintains schools of agriculture, commerce, fine arts, music, pharmacy, technology and an admirable high school, besides a large number of primary and secondary schools, for which modern school buildings have been erected. Normal and industrial schools for both sexes are maintained, the latter (*artes y oficios*) performing a very important service for the poorer classes.

By the Constitution of 1917 elementary education was made free, compulsory to the age of 15 and secular, but pending the provision of enough secular schools many of the old schools under religious auspices continued to function. There are several good daily papers published in Mexico City. The World War increased the interest of Mexicans in reading, and as a result a number of new periodicals, of a superior quality, were established in the city, which had the first printing press in the New World and the first regularly issued newspaper.

Industries.—Through lack of water-power and cheap fuel, Mexico has never been rated as a manufacturing city. However, the development of electric power, and the possibility of transmitting it for long distances, have worked a noteworthy change in this respect, and a large number of industries have been added in recent years. The largest of the electric-power plants is on the Necaxa and Tenango rivers, in the State of Puebla, 92 m. from the city, which furnishes 40,000 h.p. for industrial and lighting purposes. Another plant is in the suburb of San Lázaro, the current being distributed by over 100 m. of underground mains in the city, and many miles of overhead wires in its outskirts and suburbs. Other plants are at San Ildefonso, 12 m. distant, and on the Churubusco river, 16 miles.

Manufacturing, still relatively unimportant, was represented in 1925 by some 215 establishments, with an annual output valued at 10,000,000 pesos, and employing about 10,000 workers, most of whom were Indians and half-breeds (*mestizos*). Foundries and iron-working shops add much to the prosperity of modern Mexico City. There are also large cotton mills and cigar and cigarette factories. In the suburbs, oils, chemicals, cigarettes and bricks are made at Tacuba; cotton textiles at Contreras, San Angel and Tlálpam; paper and boots at Tacubaya, and bricks at Mixcoac and Coyoacán. A little farther away are the woollen mills of San Ildefonso, the paper-mills of San Rafael, and important works for the manufacture of railway rolling stock.

Railway Communications.—The railway connections include direct communication with one port on the Gulf coast and with two on the Pacific, and indirect communication with two on the Gulf. The Mexican and Inter-oceanic lines connect with Veracruz, the Mexican Central with Manzanillo, via Guadalajara and Colima, and the Veracruz and Pacific (from Córdoba) with the Tehuantepec line and the port of Salina Cruz. The last-mentioned line also gives indirect connection with the port of Coatzacoalcos, and the Mexican Central, via San Luis Potosí, with Tampico. A southern extension of the Mexican Central, via Cuernavaca, has reached the Balsas river and will be extended to Acapulco, once the chief Pacific port of Mexico and the dépôt for the rich Philippine trade. A Mexican extension of the (American) Southern Pacific has been completed from Nogales to Guadalajara, which gives the national capital direct communication with the thriving ports of Mazatlán and Guaymas. In addition to these, the Mexican Central and Mexican National, now consolidated, give communication with the northern capitals and the United States, and the Mexican Southern runs southward, via Puebla, to the city of Oaxaca. These railways, with the shorter lines radiating from the city, connect it with nearly all the State capitals and principal ports.

HISTORY

The Aztecs.—Mexico City dates, traditionally, from the year 1325 or 1327, when the Aztecs settled on an island in Lake Texcoco. The Aztec name of the city was Tenochtitlán, derived either from Tenoch, one of their priests and leaders, or from *tenuch*, the Indian name for the "nopal," which is associated with its foundation. The modern name is derived from Mexitli, one of the names of the Aztec god of war, Huitzilopochtli, which name was later on applied also to the Aztecs themselves. The island settlement which was practically a lake-village built on islets—some of them undoubtedly artificial—grew rapidly with the increasing power and civilization of its inhabitants, who had the remains of an earlier civilization to assist in their development. About the middle of the 15th century their mud-and-rush dwellings were partly replaced by stone structures, grouped around the central enclosure of the great *teocalli* and bordering the causeways leading to the mainland. The town had reached its highest development when the Spaniards appeared in 1519, when it is said to have had, including suburban towns, a total of 60,000 dwellings, representing about 300,000 inhabitants.

Allowance should be made for the habit of exaggeration among the Spanish adventurers of that time, and also for the diplomacy of Cortés in magnifying his exploits to win the favour of his king. The truth is, without doubt, that the dwellings of the lower classes were still built of reeds and mud, and covered the greater part of the city's area, otherwise it is impossible to understand how a mere handful of Spanish soldiers, without tools and explosives, could so easily have levelled it to the ground. After its almost total destruction in Nov. 1521, Cortés employed some 400,000 natives in rebuilding the city on its former site. Since then the lake has decreased greatly in extent, its area being reduced to $11\frac{1}{2}$ sq.m. and its shore-line being more than 3 m. distant from the city it once surrounded. During Spanish rule the only break in the ordinary course of events was the revolt of 1692, which resulted in the destruction of the municipal buildings. The city was not much disturbed by the struggle for independence.

In the war between Mexico and the United States Mexico City was the chief point of attack. The American army, under Gen. Winfield Scott, arrived at Ayotla, 16 m. S.E. of the city on Aug. 10, 1847, moved around the capital on the south side to avoid its heavy fortifications, crossed the difficult terrain of the Pedregal, a field of broken lava, and succeeded in capturing point after point of the city's outlying defences (including the hill of Chapultepec), thus forcing the surrender of the Mexicans on Sept. 13. The city was then occupied by the American army and held until the signing of the Treaty of Guadalupe-Hidalgo, May 1848.

The French intervention of 1861 led to a second occupation by a foreign Power—a French military force under Gen. Forey taking possession in June 1863. Maximilian, archduke of Austria, was crowned emperor of Mexico in the cathedral in June 1864, and held possession of the capital until June 21, 1867, when it was captured by Gen. Porfirio Díaz.

During the revolutionary movements beginning in 1910, Mexico City was taken and re-taken many times, never, however, suffering serious damage. On Sept. 29, 1927, a long distance telephone between Mexico City and Washington, D.C., was inaugurated, the event being celebrated by an exchange of greetings between the chief executives of the two nations. The total length of the Washington–Mexico City circuit is 3,357 miles.

For further description *see* H. H. Bancroft, *History of Mexico* (San Francisco, 1883); R. S. Barrett, *Standard Guide to the City of Mexico*

and Vicinity (Mexico, 1900); T. A. Janvier, *The Mexican Guide* (5th ed., New York, 1890); D. Charnay, *Ancient Cities of the New World* (Eng. ver., New York, 1887); and the *Plano de la ciudad de México,* in the *Diccionario enciclopédico hispano-americano,* xii. 740 (Barcelona, 1893).

MEYER, CONRAD FERDINAND, one of the greatest of Swiss poets and novelists, was born at Zürich on Oct. 11, 1825, and died on Nov. 28, 1896, at Kilchberg (near Zürich), where he had settled in 1875. In his youth he studied law and pursued historical researches in Italy; but he began his career as author comparatively late in life. As compared with Gottfried Keller (*q.v.*), for example, Meyer is more of the cosmopolitan and patrician and less of the democrat. His style is singularly pure and polished, and he appeals strongly to readers of culture. His poems include *Balladen* (1867), *Romanzen und Bilder* (1870), *Huttens letzte Tage* (1871), and *Engelberg* (1873)—the last two powerful narrative poems. His *Gedichte* have been published in at least 20 editions. Of his novels, in which he shows a preference for Renaissance subjects, the most popular are *Jürg Jenatsch* (1876; 312th ed., 1924) and *Der Heilige* (1880; 198th ed., 1924). The latter was translated into English by M. von Wendheim, as *Thomas à Becket, the Saint* (1885). *Die Versuchung des Pescara* (1887) was translated by Mrs. C. Bell (1890). His charming short stories were collected in 1885 (206th ed., 1924).

BIBLIOGRAPHY.—Lives of Meyer have been written by A. Reitler (1885); A. Frey (1900); R. d'Harcourt (1913); M. Nussberger (1919); H. Maync (1925). *See* also L. Frey, *C. F. Meyer's Gedichte und Novellen* (1892); K. E. Franzos, *K. F. Meyer* (1899); B. Meyer, *C. F. Meyer* (1903); A. Bettelheim, *Louise von François und Conrad Ferdinand Meyer* (1905); A. Langmesser, *C. F. Meyer* (1905) and *Conrad Ferdinand Meyer und Julius Rodenberg* (1918); E. Korrodi, *C. F. Meyer; Studien* (1912); W. Brecht, *C. F. Meyer und das Kunstwerk seiner Gedichtsammlung* (1918); E. Brock, *Die Landschaft in C. F. Meyer's Novellen und Gedichten* (1926).

MEYER, EDUARD (1855–1930), German historian, was born at Hamburg on Jan. 25, 1855. He was educated at Bonn and Leipzig, where in 1879 he qualified in ancient history. He afterwards became professor of ancient history at Breslau (1885), Halle (1889) and Berlin (1902). Meyer realized the great importance of folklore, historical monuments and numismatics as aids to the study of ancient history, and the value of his original methods in treating the subject was recognized by the universities of Oxford, St. Andrews and Freiburg from which he received honorary degrees. Meyer's principal works are: *Geschichte des alten Aegyptens* (1887); *Forschungen zur alten Geschichte* (1892–99); *Wirtschaftliche Entwicklung des Altertums* (1895); *Die Entstehung des Judentums* (1896); *Zur Theorie und Methodik der Geschichte* (1902); *Geschichte des Altertums* (3rd. ed. 1909); *Caesars Monarchie und das Principat des Pompeius* (2nd ed. 1919); *Preussen und Athen* (1919); *Ursprung und Anfänge des Christentums* (3 vol., 1921–23). Meyer died August 31, 1930.

MEYER, HEINRICH AUGUST WILHELM (1800–1873), German Protestant divine, born at Gotha on Jan. 10, 1800, spent most of his life at Hanover where he held a pastoral charge and eventually became superintendent. He died there on June 21, 1873. He prepared, with other scholars, the well-known *Kritischexegetischer Kommentar Zum Neuen Testament* (16 vols., 1832–59), since re-edited by later scholars. Meyer's commentary was published in English in Clark's series (20 vols., 1873–82).

MEYER, JULIUS LOTHAR (1830–1895), German chemist, was born on Aug. 19, 1830, at Varel in Oldenburg. He studied medicine at Zürich and Würzburg, and then turned to physiological chemistry at Heidelberg and finally to mathematical physics at Königsberg. After holding various positions as a lecturer he became, in 1876, professor of chemistry at Tübingen, where he died on April 11, 1895. His earliest work was on the chemistry of the blood, but his name is best known for the share he had in the development of the periodic classification of the elements (*see* PERIODIC LAW). He noted, as did J. A. R. Newlands independently in England, that if they are arranged in the order of their atomic weights they fall into groups in which similar chemical and physical properties are repeated at periodic intervals; and in particular he showed that if the atomic weights are plotted as ordinates and the atomic volumes as abscissae, the curve obtained presents a series of maxima and minima, the most electro-positive elements appearing at the peaks of the curve in the order of their atomic weights. His book on *Die modernen Theorien der Chemie,* which was first published in Breslau in 1864 and later translated into English, contains a discussion of relations between the atomic weights and the properties of the elements. In 1882 he received from the Royal Society the Davy medal in recognition of his work on the Periodic Law.

See *Berichte d. Deutsch. Chem. Gess.* vol. 28. p. 1103 and *Journal of the Chem. Soc.* (1896) p. 1403.

MEYER [MARIE], PAUL HYACINTHE (1840–), French philologist, was born in Paris on Jan. 17, 1840. He was educated at the Ecole des Chartes, and in 1863 was attached to the manuscript department of the Bibliothèque Nationale. In 1876 he became professor of the languages and literatures of southern Europe at the Collège de France. In 1882 he was made director of the Ecole des Chartes, and in 1883 became a member of the Academy of Inscriptions. He was one of the founders of the *Revue Critique,* and a founder and the chief contributor to *Romania* (1872). Paul Meyer began with the study of old Provençal literature, but also ranks as a great modern authority on the French language. He edited many old French texts for the *Société des anciens textes français,* and independently.

MEYER, VICTOR (1848–1897), German chemist, was born at Berlin on Sept. 8, 1848. He studied at Heidelberg under R. W. Bunsen, H. F. M. Kopp, G. R. Kirchoff and H. L. F. Helmholtz (*qq.v.*); he also worked under Baeyer (*q.v.*) in Berlin. In 1870 he was appointed extraordinary professor at Stuttgart polytechnic, and in 1872 succeeded J Wislicenus (*q.v.*) at Zürich. In 1885 he obtained the chair of chemistry at Göttingen, and in 1889 he succeeded Bunsen at Heidelberg. He was awarded the Davy medal in 1891. Meyer proved to be not only a great investigator but also a stimulating teacher, with a wonderful command of language. He suffered from ill health and committed suicide on Aug. 8, 1897.

Meyer's first papers dealt with the composition of camphor, chloral hydrate and the structure of benzene (*q.v.*). In 1872 he discovered the aliphatic nitro-compounds (*q.v.*), and this led him on to the study of nitroso-compounds and nitrols. In 1882 he discovered the oximes (*q.v.*) and showed that they can exist in stereo-isomeric forms; he also investigated the chemistry of these compounds very thoroughly. In 1871 he devised a method for determining vapour densities (*see* CHEMISTRY: *Physical*), and this led him on to a series of pyro-chemical studies, in which the vapour densities of inorganic substances were determined at fairly high temperatures. The results of this work, with his brother, Carl Meyer, were collected in *Pyrochemische Untersuchungen* (1885). In the course of a lecture demonstration he made an observation which led him to the discovery of thiophene (*q.v.*) in 1883; he studied the substance and determined its structure; the results are published in *Die Thiophengruppe* (1888).

See C. Meyer, "Victor Meyer" in *Ber. d. deutsch chem. Ges.* (1908); B. Horowitz, "Victor Meyer His Life and Work," *Jnl. Franklin Inst.* (1916); T. E. Thorpe's *Essays in Historical Chemistry* (3rd ed., 1911).

MEYERBEER, GIACOMO (1791–1863), German composer, first known as Jakob Meyer Beer, was born at Berlin Sept. 6, 1791[1] His father, Herz Beer, was a banker; his mother, Amalie (*née* Wulf), was a woman of high intellectual culture; and two of his brothers distinguished themselves in astronomy and literature. He studied the pianoforte, first under Lauska, and afterwards under Lauska's master, Clementi. When seven years old he played Mozart's Concerto in D Minor in public, and at nine he was pronounced the best pianist in Berlin. For composition he was placed under Zelter, and then under Bernard Weber, director of the Berlin opera, by whom he was introduced to the Abbé Vogler. Vogler received him into his house at Darmstadt, where he formed an intimate friendship with Weber. In 1812 the grand duke appointed Meyerbeer court composer. His first opera, *Jeptha's Gelübde,* failed lamentably at Darmstadt in 1811 and his second, *Wirth und Gast* (*Alimelek*), at Vienna in 1814. Bitter disappointment over these failures drove him to Italy.

[1]Or, according to some accounts, 1794.

At Venice he was captivated by Rossini, and produced a succession of seven Italian operas—*Romilda e Costanza, Semiramide riconosciuta, Eduardo e Cristina, Emma di Resburgo, Margherita d'Anjou, L'Esule di Granata* and *Il Crociato in Egitto*—which all achieved a success as brilliant as it was unexpected. Against this act of treason to German art Weber protested, and an invitation to Paris in 1826 led him to review his position dispassionately. For several years he produced nothing in public; but, in concert with Scribe, he planned his first French opera, *Robert le Diable* (Grand Opéra, 1831). It was the first grand romantic opera, with situations more theatrically effective than any that had been attempted either by Cherubini or Rossini, and with ballet music such as had never yet been heard, even in Paris.

His next opera, *Les Huguenots*, was first performed in 1836. In gorgeous colouring, rhetorical force, consistency of dramatic treatment, and careful accentuation of individual types, it is at least the equal of *Robert le Diable.* Meyerbeer then spent many years in the preparation of his next greatest works—*L'Africaine* and *Le Prophète.* The libretti of both these operas were furnished by Scribe; and both were subjected to countless changes.

Meanwhile Meyerbeer accepted the appointment of kapellmeister to the king of Prussia, and spent some years at Berlin, where he produced *Ein Feldlager in Schlesien,* a German opera, in which Jenny Lind made her first appearance in Prussia. Here also he composed, in 1846, the overture to his brother Michael's drama, *Struensee.* But his chief care at this period was bestowed upon the worthy presentation of the works of others: Weber's *Euryanthe,* and *Rienzi* and *Der fliegende Holländer,* the first two operas of Richard Wagner, who, then in poverty and exile, would, but for him, have found it impossible to obtain a hearing in Berlin. With Jenny Lind as prima donna and Meyerbeer as conductor, the opera flourished brilliantly in the Prussian capital.

Meyerbeer produced *Le Prophète* at Paris in 1849. In 1854 he brought out *L'Étoile du nord* at the Opéra Comique, and in 1859 *Le Pardon de Ploërmel* (*Dinorah*). His last great work, *L'Africaine,* was in active preparation at the Académie when, on April 23, 1863, he was seized with a sudden illness, and died on May 2.

See lives and studies by J. Weber (1898), J. Dauriac (1913), Hermann Abert (1918) and Julius Kapp (1920).

MEYERHOLD, VSEVOLOD EMILIEVICH (1873–), Russian theatrical producer, was born in Moscow and from 1898–1905 was well known as one of the most distinguished actors of the Moscow Art theatre. He then began to produce plays, adopting a new convention in opposition to the "true-to-life" ideas of Stanislavsky, in which the actor and the stage setting presented a complete harmony. After the Revolution he carried these methods to. an extreme, using no curtain and a bare stage with purely formal scenery. He managed the Revolutionary theatre, Moscow, and also acquired a theatre of his own, and in both produced political propaganda plays. His views are set forth in his book, *The Theatre* (St. Petersburg, 1913).

MEYNELL, ALICE (1849–1922), British poet. By her marriage in 1877 Alice Thompson became Alice Meynell. She had the fortune to find herself in that mid-Victorian era which still held freshly to its heritage from Keats and Shelley, from Wordsworth and Coleridge. It felt its heart torn by the griefs of the Brontës, stirred by their glories, and almost clung to the hand of Elizabeth Browning. Eagerly awaiting every recurring sign of Tennyson's fertility, it yet respected the long pause of Patmore; and took for its own the volumes of Dante and Christina Rossetti, warm from the press. With these two women of song, Elizabeth and Christina, Alice Meynell's name is associated.

Mistress Anne Killigrew had been told by Dryden, "thy father was transfused into thy blood." That girls alike with boys, inherit from fathers as from mothers, was the theme of a verse where Alice Meynell, after the desolations of the World War, gave the comforting signal:—

> The crippled world! Come, then,
> Fathers of women with your honour in trust.
> Approve, accept, know them daughters of men,
> Now that your sons are dust.

Her own father, having left Cambridge and unsuccessfully contested two costly elections for parliament as a free trader, became very much a citizen of the world. After his marriage with Christiana Jane Weller, a beautiful and accomplished girl to whom her adoring friend Charles Dickens fitly introduced him, he made his home much in Italy, devoting himself to the liberal learning of the two daughters: Elizabeth, the elder, afterwards Lady Butler, famous as a war painter; and Alice, who early began to put her rhymed thoughts shyly upon paper.

The volume of *Preludes* was issued (for the girl what an association) by Tennyson's then publisher, Henry S. King, on the word of his "reader"—later his successor—C. Kegan Paul, who, not trusting his own judgment all the way, read some of them aloud to George Eliot, receiving her deciding approbation. The critics were mostly silent; and even those who praised hesitated. But the volume made its own quiet way, Ruskin in all ways first in his soaring praises: "The last verse of that perfectly heavenly 'Letter of a Girl to her own Old Age,' the whole of 'San Lorenzo's Mother' and the end of the 'Sonnet to a Daisy,' are the finest things I have yet seen or felt in modern verse." Rossetti, too, spread the news of the young poet's advent, reciting "Renouncement" by heart to his friends, and saying that it was "one of the three finest sonnets ever written by women." Browning, having read a brief quotation buried in a halting press appreciation, "conceived the desire to read the rest for myself," and found its beauty "even beyond what the indifference of the reviewer should have prepared me for." The volume brought her many a friend—and more. For the reviewer in *The Pall Mall Gazette*—a paper to which she was later to be a conspicuous contributor—quoted the sonnet "My Heart shall be thy Garden," and found for it a reader whom it reached revealingly. A consequent introduction to the sonneteer by a common friend was followed by a marriage that fulfilled for him Crashaw's "heaven-on-earth" for 45 years.

On Mrs. Wilfred Meynell, as she then (1877) became, fell a long silence as a poet. The muse does not ordinarily leave cards on the happily and busily married; the domesticities and the "sweet sense of providing" are not the fashioners of those "sweetest songs" that breed from "saddest thoughts." Eight children were born, one of whom died in infancy: a grief that put into poetry the dread reminder that the giver of life is also the giver of death: "and she who slays is she who bears, who bears." A like sensitiveness to life's cruelties put her, for all her reticence, on political platforms, and marched her in multitudinous processions, in favour of the granting of votes to women and the opening of long closed professional doors. Compassion was the companion of all her walks abroad, for the over-burdened man and animal; for the beggar-woman to whom she cried with her gift, in Portuguese fashion, "Have patience, little saint"; for the underfed in London slums which she at one time sedulously visited; and for the beast in the shambles, in shame for whose martyrdom she refused to eat meat until, after persuasion, she sought by more impersonal methods to further laggard reforms.

Her married life matured her vigilance as a mistress of prose. In W. E. Henley of *The Scots Observer* and *The National Observer,* she encountered an editor who heartened her by his boisterous welcomes: "That woman's taking her place at the steering wheel" was one of his recorded acclaims. Later, in *The Pall Mall Gazette* of Harry Cust's editorship, she was accorded a weekly column which left her a large range in the choice of subjects. George Meredith, reading here her "princely journalism," sought with her an acquaintance that soon became a "dearest friendship." In a magazine—those were still the days of the magazines—he spoke of her words as having the "living tremor in them," just as he had before said that Carinthia's had the "throb beneath them." Of her essays, he wrote: "The surprise coming on us from their combined grace of manner and sanity of thought is like one's dream of what the recognition of a new truth would be. They leave a sense of stilled singing on the mind they fill. The writing is limpid in its depths."

Coventry Patmore, too, her yet warmer admirer, published, when Tennyson died, his unavailing plea for her succession to the laureateship. Her close friendship for such seniors coincided

with that for her contemporaries, and for her juniors, chief among whom was Francis Thompson, who addressed to her his exquisite sequence of poems *Love in Dian's Lap*, of which, Patmore said, Beatrice or Laura might have been proud. Of the homage paid to her, another chosen friend, J. L. Garvin, has well said: "Alice Meynell was in herself a person of her age, sure, as I think, of perpetual remembrance, even if half a dozen of her shining contemporaries had not competed in vain to spoil her with praise. It was what no one could do: recognition only made her humble." And these contemporary praises notwithstanding, G. K. Chesterton predicts: "She was deservedly famous; but I will venture to prophesy that her fullest fame is yet to come. The whole modern world must immeasurably enlarge itself before it comes near the measure of her mind." She died in London on Nov. 27, 1922.

Alice Meynell's *Preludes* (1875), long out of print, re-appeared in a volume of *Poems* (1893) including new ones; and these, together with yet later verses separately issued as *A Father of Women* (1917) and *Last Poems* (1923), are all assembled in the complete volume of *Poems* (1923) now in circulation. Of her prose, several small volumes of essays in the '90s—*The Rhythm of Life* (1893), *The Colour of Life* (1896) and *The Spirit of Place* (1899)—were followed by *Ceres' Runaway* (1909), by *Hearts of Controversy* (1917), by *The Second Person Singular* (1921) and finally by the standard volume of selected *Essays* (1914)—the selection being her own. Other books were *John Ruskin* (1900), *The Children of the Old Masters* (1903), *Mary, the Mother of Jesus* (1912) and *London Impressions* (1898). Two anthologies give her choice among poems—*The Flower of the Mind* (1897) and *The School of Poetry* (1923), the first including Notes and the second Commentaries. She prefaced editions of *The Sonnets from the Portuguese* and Christina Rossetti's *Poems* (1910), as well as a decade of volumes "The Red Letter Library"; she introduced in 1903 a volume of reproductions of Sargent's Portraits; and she made for English readers a Selection from the Poems of J. B. Tabb (1906). (W. Me.)

See Viola Meynell, *Alice Meynell* (1929).

MEYRIFAB, a small semi-nomad tribe of Semitic stock, on the east bank of the Nile near Berber who never marry slaves.

MÉZIÈRES, PHILIPPE DE (*c.* 1327–1405), French soldier and author, was born at the château of Mézières in Picardy. He belonged to the poorer nobility, and served under Lucchino Visconti in Lombardy, and subsequently under Andrew, king of Naples, who was assassinated in September 1345. He then set out for the East in the French army. After the battle of Smyrna in 1346 he was made a knight, and went to Jerusalem. He planned a new order of knighthood, the first sketch of which was drawn up by him in his *Nova religio passionis* (1367–1368; revised and enlarged in 1386 and 1396). From Jerusalem he went in 1347 to Cyprus to the court of Hugo IV., where he met the king's son, Peter of Lusignan, then count of Tripoli; but he soon left Cyprus, and had resumed soldiering when the accession of Peter to the thrones of Cyprus and Jerusalem (Nov. 1358) induced Mézières to return to the island, probably in 1360, when he became chancellor. He came under the influence of the pious legate Peter Thomas (d. 1366), whose friend and biographer he was to be, and Thomas, who became patriarch of Constantinople in 1364, was one of the chief promoters of the crusade of 1365. In June 1366 Mézières was delegated to Venice, to Avignon and to the princes of western Europe, to obtain help for Cyprus against the Saracens. His efforts were in vain; even Pope Urban V. advised peace with the sultan. Mézières remained for some time at Avignon, seeking recruits for his order, and writing his *Vita S. Petri Thomasii* (Antwerp, 1659), which is invaluable for the history of the Alexandrian expedition. The *Prefacio* and *Epistola*, which form the first draft of his work on the projected order of the Passion, were written at this time.

Mézières returned to Cyprus in 1368, but was still at Venice when Peter was assassinated at Nicosia at the beginning of 1369, and he remained there until 1372, when he went to the court of the new pope Gregory XI. at Avignon. In 1373 he was in Paris, and he was thenceforward one of the trusted counsellors of Charles V. He was tutor to the future Charles VI., but after the death of Charles V. he was compelled to retire. He lived thenceforward in the convent of the Celestines in Paris, but continued to exert an influence on public affairs. To this period of his life belong most of his writings. Two devotional treatises belong to 1386–1387. In 1389 he wrote his *Songe du vieil pélerin*, an elaborate allegorical voyage in which he described the customs of Europe and the near East, and advocated peace with England and the pursuit of the Crusade. His *Oratio tragedica*, largely autobiographical, was written with similar aims. Mézières died in Paris on May 29, 1405.

See A. Molinier, *Manuel de bibliographie historique* vol. iv. (1904); and especially the researches of N. Jorga, published in the *Bibliothèque de l'école des hautes études* vol. 110 (Paris, 1896); and the same writer's *Philippe de Mézières, et la croisade au xiv. siècle* (1896). Jorga gives a list of his works and of the mss. in which they are preserved, and analyses many of them. On the *Songe du vergier*, see P. Paris, in *Mémoires* vol. xv. (1843) of the Academy of Inscriptions.

MÉZIÈRES, a town of northern France, capital of Ardennes department, 55 m. N.E. of Reims by rail. Pop. (1926) 8,418.

Founded in the 9th century, Mézières was a stronghold belonging to the bishops of Reims, which afterwards became the property of the counts of Rethel. The town was increased by successive immigrations of the people of Liége, flying first from the emperor Otto, and afterwards from Charles the Bold; and also by concessions from the counts of Rethel. Walls were built in the 13th century, and in 1521 it was successfully defended against the Imperialists by the Chevalier Bayard. In 1815 the Germans were kept at bay for six weeks, and in 1871 the town only capitulated after heavy bombardment. Both Mézières and Charleville were taken by the Germans in Aug. 1914. They made Charleville the seat of their High Command in the West, and later the headquarters of the German crown prince.

The town is situated on a peninsula formed by a loop of the Meuse. The river separates it from Arches and the town of Charleville on the north and from the suburb of Pierre on the south. Adjoining Pierre is Mohon, pop. (1926) 7,814, with metallurgical works. The fortifications of Mézières (dismantled in 1886), as well as the citadel still dominating the town on the east, were built under Vauban's direction. Immediately to the east of the citadel runs a canal, which provides river-traffic with a short cut across the isthmus. The parish church (16th cent.) contains inscriptions commemorating the raising of the siege of Mézières in 1521 and the marriage of Charles IX. with the daughter of the emperor Maximilian II. (1570). Mézières is the seat of a prefect and of a court of assizes, and there are manufactures of motor cars, bicycles, and iron and steel castings.

MEZÖTÚR, a town in Hungary near the right bank of the Körös. It is a market and fair town for the cereal and cattle-rearing district in which it lies. It has also small flour mills and important potteries. Pop. (1920) *c.* 27,000.

MEZZOFANTI, GIUSEPPE CASPAR (1774–1849), Italian cardinal and linguist, was born on Sept. 17, 1774, at Bologna, and educated there. He was ordained priest in 1797, and later became professor of Arabic in the university. In 1833 he succeeded Angelo Mai as chief keeper of the Vatican library, and in 1838 was made cardinal and director of studies in the Congregation. He died at Rome on March 15, 1849. He is said to have spoken fluently some fifty or sixty languages.

See Russell, *Life of the Cardinal Mezzofanti* (1857); A. Bellesheim, *Giuseppe Cardinal Mezzofanti* (Würzburg, 1880).

MEZZOTINT or **MEZZO TINTO,** as it was first called, is a process of engraving whereby a copper, or steel, plate is first prepared to produce uniformly black impressions on paper. This is done by pricking the plate with innumerable small holes which will hold ink. In connection with mezzotint, as with all other forms of engraving, the ink used is a thick ink which does not run. After the surface of the mezzotint plate has been prepared, the high lights in the portrait or picture to be produced are obtained by scraping away and burnishing parts of the plate, thus reducing, or obliterating, the small holes, according to the effect desired. The pricking of the plate, originally done with a roulette or small wheel covered with sharp points, was later done with an instrument called a *cradle*, or *rocker*. The

ENGLISH MEZZOTINTS OF THE 18TH CENTURY

1. "Mrs. Carnac." After Sir Joshua Reynolds by John Raphael Smith (1752–1812)
2. "Mary Amelia, Countess of Salisbury." After Sir Joshua Reynolds by Valentine Green (1739–1813)
3. "Lady Hamilton" ("Nature"). After George Romney by John Raphael Smith (1752–1812)
4. "Georgiana, Duchess of Bedford." After John Hoppner by Samuel William Reynolds (1794–1872)

process not only punctures the plate to hold ink, but, at the same time, produces a burr on the surface of the metal, which, cutting into the paper when in the press, causes a deeper absorption of ink, and produces that velvety effect so characteristic of the fine mezzotint engraving in an early impression. The surface of the punctured and roughened plate is left undisturbed where the deepest black is required, and by a graduated scraping of the plate, which removes both burrs and punctures so that ink is held in lesser degrees, middle and light tones are obtained when an impression is taken from it. Dots made with a sharp point on a polished metal surface were long used as an adjunct to engravings. They show on silver plates engraved for Niello (*q.v.*) in the 14th century. Prints on paper from line engravings cut on metal plates, probably copper, were first made about the middle of the 15th century, but dotted, or pointille work does not seem to have been much used for some time after that.

The 17th Century Dutch School.—About the middle of the 17th century, Ludwig von Siegen, a Dutch officer in the Hessian army, who was also an amateur artist, applied the old device of dotted work to a metal plate, by means of a small roulette, and succeeded in producing an excellent print entirely by its use. In 1654, von Siegen met Prince Rupert, count palatine of the Rhine and grandson of James I., at Brussels. Prince Rupert was a skilled amateur artist, and he became deeply interested in von Siegen's invention, which he at once tried. In a short time he produced a very fine piece of rouletting in a print of *The Large Executioner,* after Spagnoletto, a Spanish painter. The curving lines, made by unskilful use of a large roulette, show clearly in the background. William Sherwin was a native of Hertfordshire, and a well known line engraver. He was also a friend of Prince Rupert, who is said to have taught him the new art and presented him with a roulette. Sherwin made mezzotint portraits of Charles II. and of his queen in 1669, both of which were dedicated to Prince Rupert.

The early mezzotinters were mostly Dutchmen, and they did not succeed particularly well. Curiously enough, most of their work was done in England. But eventually, a great Dutch artist, Abraham Blooteling, arrived in England in 1673, and was much attracted by the new art. Blooteling did much splendid work, particularly after Van Dyck, Kneller and Lely. But he did much more for the art of the mezzotint than produce beautiful prints, because he radically changed and improved the technical part of the process. Instead of using only a roulette to produce dark space, he began by roughening the plate all over, so that if printed from, it would show simply a black space, and then he cut away the roughness with a scraper to make the light places as required. This plan produced most brilliant effects. Blooteling also invented a tool, now called a rocker, which is like a very small spade with a toothed edge, and with this powerful instrument a copper or soft steel plate can quickly be roughened all over, rendering the use of the old roulette obsolete. The early users of the rocker roughened their own plates, but now this can be professionally done by the dealers.

The 18th Century English School.—After Blooteling, and during the 18th century, a remarkable school of English mezzotinters became prominent, and did such distinguished work that abroad the process became known as *La manière anglaise.* This pre-eminence was due, not only to their remarkable skill and the great beauty of their work, but also to the fact that there were in England at that time, several portrait painters of the very first rank for them to interpret. We owe the existence of the finest mezzotints ever done to the inspiration of men like Lely, Reynolds, Lawrence, Romney, Hoppner, Constable and several others of lesser reputations.

Early in the 18th century an Irishman, T. Frye, tried several byways of art before he specialized in mezzotint, but he ended by "scraping" a series of large portrait heads after drawings of his own. When in good condition, heads by Frye are extremely decorative. Another Irishman, J. MacArdell, became one of our greatest mezzotinters. Sir Joshua Reynolds had so high an estimation of MacArdell's work that he once declared he would be immortalized by his engravings. This is now beginning to prove true, because Sir Joshua's paintings are in many cases deteriorating badly, whereas a mezzotint, carefully kept under a sunk mount, is extremely long-lived. Richard Earlom (1743–1822) used only the roulette where he wanted shadow. He engraved the *Liber Veritatis* of Claude Lorrain, and by doing so he suggested the *Liber Studiorum* of J. M. W. Turner.

The numerous mezzotints made by Valentine Green (1739–1813) are all of the highest order of excellence. He was especially successful in his rendering of the beautiful full length figures of ladies, painted by Sir Joshua Reynolds, and he frequently printed his engravings in brown ink.

John Raphael Smith began his artistic career as a miniature painter, but eventually became one of the foremost mezzotint engravers. He worked mainly after Sir Joshua Reynolds, but was very happy in his interpretation of Romney's graceful work. Smith made several engravings after his own drawings.

S. W. Reynolds made a series of 357 small mezzotints of portraits by Sir Joshua Reynolds. Mezzotints, however, are not satisfactory when done on a small scale. S. W. Reynolds was, in larger subjects, a highly skilful artist, and engraved many excellent plates after his own work. He did mezzotinting on some of the plates in Turner's *Liber Studiorum.*

William Say used etching as an adjunct to most of his fine mezzotints, but he was never satisfied with the small number of prints that could properly be made from a copper plate. He was the first mezzotinter to experiment with the use of steel instead, but he did not carry his ideas out successfully. Shortly afterwards, however, T. G. Lupton carried farther the experiments, with the use of steel instead of copper. Say seems to have tried with hard steel and Lupton used soft steel very successfully. Instead of being able to print only about 50 proofs of the highest excellence from copper, it was found possible to print about 1,500 from steel, without any appearance of deterioration. The dark places on a mezzotint are those to be looked for in worn prints. They ought to look like black or brown velvet. Steel engravings on mezzotint are often very delicate and charming, but they have a tendency to hardness. The method was also carried out by D. Lucas, but not so successfully as by Lupton. Now copper engravings can be steeled over several times and prints from such plates can never become rare.

Samuel Cousins was an apprentice to S. W. Reynolds, and used etching and line engraving freely with his mezzotint, so much, indeed, that his method is known as the "mixed" style. But his work is effective and very popular. Cousins killed the art of line engraving in England by reason of his fine plate of Bolton Abbey, after Sir Edwin Landseer, published in 1837. This plate proved that such a picture could be produced much more easily and effectively by mezzotint than it could by line engraving.

Among modern mezzotint engravers many are highly skilled, and most of them have chosen particular artists for their especial study. Sir Frank Short has been particularly successful in his interpretation of G. F. Watt's powerful work; C. W. Campbell with the delicate fancies of Sir E. Burne Jones; J. D. Miller follows Lord Leighton; G. P. Robinson, Sir Frank Dicksee; Norman Hirst, W. Draper, and now the process of photogravure has reached such a high state of excellence that little room is left for the earlier art. (*See* also ETCHING; ENGRAVING.)

(C. DA.)

MFUMBIRO or **KIRUNGA,** general names for a chain of volcanic mountains extending across the central African rift-valley immediately north of Lake Kivu. The range completely blocks the valley at this point, forming a divide between the rivers flowing north to the Nile and the waters of Lake Kivu, connected through Tanganyika with the Congo system. The chain consists of two groups of mountains, surrounded by a vast lava field. The lavas belong to a nephelinite suite with leucite and melilite as frequent minerals. The western group lies directly north of Lake Kivu, and contains two active volcanoes, Kirunga-cha-gongo, the nearest to the lake (11,194 ft.), and Kirunga-namlagira (9,711 ft.), 10 m. farther north. The eastern group contains several higher peaks, Karissimbi (14,683 ft.), Mikeno (14,385 ft.) and Muhavuru (13,562 ft.). The latter is the mountain to which the names Mfumbiro and Kirunga were originally applied and its crater contains a lake. Some 6 m. W. of Muhavuru is Sabyino (Sabinjo), 11,881 ft. high. The eastern peaks are snowclad for a part of the year. North of these high mountains is a district, extending towards Lake Albert, containing hundreds of low peaks and extinct volcanoes. It is to this region that the name Umfumbira or Mfumbiro is said properly to belong.

Mfumbiro, *i.e.*, Muhavuru, was first seen by a white man in 1861, J. H. Speke obtaining a distant view of the cone, which was also seen by H. M. Stanley in 1876. Its true position was first ascertained by Franz Stuhlmann in 1891. In 1894 Count von Götzen travelled through the region which was subsequently explored by E. S. Grogan, Maj. St. Hill Gibbons, Capt. Herrmann, Dr. R. Kandt, Sir Alfred Sharp (1912) and others, the chief heights being determined in 1903. In 1907–08 the range was geologically and topographically examined by the duke of Mecklenberg's expedition. By the Anglo-German agreement of the 1st of July 1890 "Mount Mfumbiro" was included in the British sphere in East Africa.

Bibliography.—Count von Götzen, *Durch Afrika von Ost nach West* (1895); Captain Herrmann, *Vulkangebiet des zentralafrikanischen Grabens* (Berlin, 1904); Adolf Friedrich, duke of Mecklenburg, *Ins Innerste Afrika* (Leipzig, 1909); Sir Alfred Sharpe, "The Kivu Country," *Geogr. Journ.* (1916).

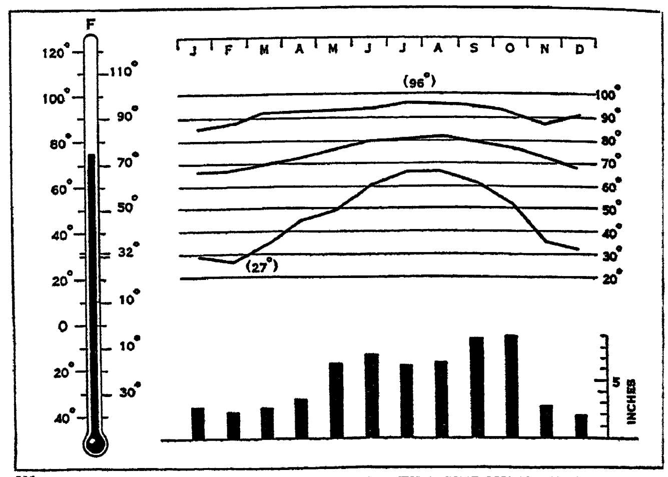
MHOW, a town of Central India, with British military cantonment, within the state of Indore. Pop. (1921), 31,737. It is one of the chief military stations of India. There are two high schools, a Zoroastrian and a Canadian mission, the Dorabji Pestonji dispensary, and a gaol.

MIAGAO, a municipality (with administration centre and 94 *barrios* or districts), on the south coast of the province of Iloilo, island of Panay, Philippine islands, about 25 m. west of Iloilo, the provincial capital. Pop. (1918), 24,556. The climate is comparatively cool and healthy. The most important local industry is the weaving of abacá and *piña* fabrics. In 1918, it had 2,717 household industry establishments with outputs valued at 849,300 pesos; and seven sugar mills. Of the 17 schools, 12 were public. The language spoken is a dialect of Bisayan.

MIAMI, a tribe of North American Indians of Algonquian stock, first found in south-eastern Wisconsin, about 1750. Their civilization was advanced and they lived in stockaded towns.

MIAMI, a town of Gila county, Arizona, U.S.A., 6 m. S.W. of Globe (*q.v.*) on Federal highway 180 and the Southern Pacific railway. Pop. (1920), 6,689; and in 1930 it was 7,693. It is a great copper-mining camp of the Globe-Miami district (which ranks third in the United States in the production of copper), in a cattle-raising and truck-farming region, containing many and varied mineral deposits and much beautiful scenery.

MIAMI, a city of south-eastern Florida, U.S.A., the county seat of Dade county; on Biscayne bay, at the mouth of the Miami river, from which a canal extends to Lake Okeechobee. It is on federal highways 1 and 94; has two municipal and one commercial airport; and is served by the Florida East Coast and the Seaboard Air Line railways, the Pan-American Airway and various steamship lines. The population was 69,754 (32% negroes) in 1925 (State census); 131,286 in 1926, after annexations of territory (special enumeration under the supervision of the Federal Census Bureau); but was 110,637 in 1930 by Federal census. Miami is the metropolis of south-eastern Florida, with a history which justifies its sobriquet "the magic city." Founded in 1896, by 1927 it had an assessed valuation of $389,853,131; its bank clearings in 1926 totalled $855,200,000; and in January 1928, it celebrated the completion of a programme of improvements costing $300,000,000. The city (on latitude 25° 47′) has a sub-tropical climate and vegetation. The average monthly mean temperature ranges from 66·5° F in January to 81·4° in August, and the extremes on record are 27° and 97°. Facilities are at hand



Weather graph of Miami, Florida. The mercury indicates the normal annual mean temperature, the centre curve shows the normal monthly mean temperature, the curves above and below, the highest and lowest temperatures ever recorded, and the columns indicate the normal monthly precipitation

for every conceivable sport and variety of recreation compatible with the climate. The harbour and channel (3·5 m.) to the ocean have been deepened by the Federal Government to 25 ft., accommodating large ocean-going vessels, and improvement of the inland waterway to Jacksonville is under way. Along the bay for 15 m. runs a 100 ft. boulevard, bordered with royal palms, and a water-front park has been created by filling in 43 acres. A 27-story county courthouse was completed in 1927, and office buildings and hotels are on a corresponding scale. Miami has extensive commercial fisheries, and its manufacturing industries (with an output in 1927 valued at $10,249,710) are already important and diversified. It ships large quantities of grapefruit, oranges, limes, pineapples, avocados, and other fruits, coco-nuts, and early vegetables.

In 1896 Henry M. Flagler extended the Florida East Coast railway to Miami (then a little Indian trading post consisting of two dwellings, a storehouse, and the small stone Ft. Dallas, erected in 1836 during the Seminole wars), and began the construction of the Royal Palm hotel. On July 28, 1896, the city was incorporated, with a population of 260. By 1910 it had grown to 5,471; by 1920 to 29,571. It was one of the principal foci in the rush to Florida which began in 1922. At the opening of the winter of 1925–26, when the boom was at its height, adventurers were arriving from all parts of the United States by rail, steamer, automobile, mule and on foot, at the rate of 6,000 a day, and leaving at the rate of 2,000 a day. Shelter was at a premium. Building was pushed at top speed, and tent colonies sprang up until they presented a serious sanitary problem. In September 1926, the city was seriously damaged by a West Indian hurricane, but it escaped with slight loss in the storm of 1928. The city is under a commission-manager form of government.

MIAMI, a city near the north-eastern corner of Oklahoma, U.S.A., on the Neosho river and federal highway 66; the county seat of Ottawa county. It is served by the Frisco, the Kansas, Oklahoma and Gulf, and electric railways. The population was 6,802 in 1920 (93% native white) and was 8,064 in 1930 by the Federal census. It is the metropolis of the principal lead and zinc mining district of the state, which in 1926 produced ores containing 65,473 tons of lead and 253,897 tons of zinc. There are smelters and various other manufacturing industries. Miami was founded in 1893 and incorporated as a city in 1895.

MIAMISBURG, a village of Montgomery county, Ohio, U.S.A., 11 m. S.S.W. of Dayton, on the Miami river and Federal highway 25. It is served by the Baltimore and Ohio, the Big Four and the Erie railways, and by interurban electric and motorbus lines. Pop. 4,383 in 1920; in 1930 it was 5,518. It is in the heart of the tobacco district of the State, and has flour, pulp and paper mills, and various other manufacturing industries.

MIANTONOMO (1565?–1643), chief of the Narraganset tribe of North American Indians, nephew of their grand sachem, Canonicus (d. 1647). He seems to have been friendly to the English colonists of Massachusetts and Connecticut, though he was accused of being treacherous. In 1637 he permitted John Mason to lead his Connecticut expedition against the Pequot Indians through the Narraganset country, and in 1638 he signed for the Narraganset the tripartite treaty between that tribe, the Connecticut colonists and the Mohegan Indians, which provided for a perpetual peace between the parties. In 1643 a quarrel broke out between the Mohegan and the Narraganset, and Miantonomo led his warriors against those of Uncas, the Mohegan sachem. He was defeated and captured at what is now Norwich, Conn., and was later tried at Boston. A committee of five clergymen, to whom his case was referred, recommended that he be executed, and the commissioners accordingly sentenced him to death and chose Uncas as his executioner. Miantonomo, who was kept in ignorance of this sentence, was taken to the scene of his defeat and was there tomahawked in cold blood by Wawequa, the brother of Uncas. There is a monument to Miantonomo in Sachem's Park, Norwich, Conn.

MIANWALI, a town and district of India in the Punjab. The town is situated on the left bank of the Indus, 655 ft. above sea-level. Pop. (1921) 9,115. The district was formed in 1901, after the creation of the North-West Frontier Province, out of the Cis-Indus portions of Bannu and Dera Ismail Khan districts. Area, 5,395 sq.m. Pop. (1921), 358,205. About three-quarters of the district lies to the east of the Indus. Along the river is a low fertile tract, liable to floods. The remaining upland, known as the Thal, is barren and sandy, cultivable only where irrigation is possible. In the north-east the district includes the western flank of the Salt Range. The part of the district west of the Indus is a level and fairly fertile plain. The chief agricultural products are wheat and other grains and oil-seeds. Hides and wool are also exported, together with small quantities of alum (abundant in the Salt Range), salt (from the Salt and Maidani ranges), and coal of poor quality, which is found at several points.

A MIAO OF SOUTH-WESTERN CHINA WITH HIS SON

MIAOTSZE, a hill tribe of southern China, of Northern Burma and Indo-China. At one time they occupied the fertile lands of central China, but were driven into the mountains of the southern provinces. They were driven out of Hunan about 800 B.C. and were finally crushed by the emperor K'ien-Lung. (*See* also MAN.)

See Playfair, *The Miaotzu of Kwei-chow and Yunnan* (1877).

MIAOULIS, ANDREAS VOKOS or BOKOS (1768–1835), Greek admiral and politician, was born in Negropont. He settled in the island of Hydra east of the Morea, and with the islanders took an early and active part in the Greek War of Independence. As early as 1822 Miaoulis was appointed navarch, or admiral, of the swarm of small vessels which formed the insurgent fleet. For the events of the struggle *see* GREEK INDEPENDENCE, WAR OF. He continued to be the naval chief of the Greeks till Lord Dundonald entered their service in 1827, when he retired in order to leave the English officer free to act as commander. When independence had been obtained, Miaoulis in his old age was entangled in the civil conflicts of his country, as an opponent of Capodistrias and the Russian party. He had to employ his skill in the employment of fireships against them at Poros in 1831. He died on June 24, 1835 at Athens.

MICA, a group of widely distributed rock-forming minerals, some of which have important commercial applications. The principal members of the group are muscovite, biotite, phlogopite and lepidolite (*q.v.*). The name is the Lat. *mica,* a grain, but is confused with *micare,* to glitter, the German word for mica, *Glimmer,* having also the meaning of glitter.

Mineralogical Characters.—The micas are characterized by a very easy cleavage in a single direction and by the high degree of flexibility, elasticity and toughness of the extremely thin cleavage flakes. They all crystallize in the monoclinic system, often, however, in forms closely resembling those of the rhombohedral or orthorhombic systems. Crystals have usually the form of hexagonal or rhomb-shaped scales, plates or prisms, with plane angles of 60° and 120°, and, with the exception of the basal planes, are only rarely bounded by smooth and well-defined faces. The different species have very nearly the same forms and interfacial angles, and the crystals not infrequently occur intergrown together in parallel position; those of Vesuvian biotite are the best developed.

When a cleavage flake of mica is struck a sharp blow with a blunt needle-point a "percussion figure" or six-rayed star of cracks is developed; the rays intersect at angles of approximately 60°, and the pair most prominently developed are parallel to the plane of symmetry of the crystal. A similar six-rayed system of cracks, bisecting the angles between the rays of the previous set, is produced when a blunt punch is gradually pressed against a sheet of mica; this is known as the "pressure figure." These cracks coincide with planes of easy separation or of gliding in the crystal; they are especially useful in helping to determine the crystallographic orientation of a cleavage flake when crystal faces are absent. Sheets of mica which have been subjected to earth-movements are frequently cracked and ridged parallel to these directions, and are then valueless for economic purposes.

In their optical characters the micas exhibit considerable variations. The indices of refraction are not high, the mean index being about 1·58–1·60, but the double refraction is very strong (0·04–0·05) and is negative in sign. The angle between the optic axes varies from 70–50° in muscovite and lepidolite to 10–0° in biotite and phlogopite; the latter are thus frequently practically uniaxial. The acute bisectrix of the optic axes never deviates from the normal to the basal plane by more than a degree or two, hence a cleavage flake of mica will always show an optic figure in convergent light when placed on the stage of a polarizing microscope. The plane of the optic axes may be either perpendicular or parallel to the plane of symmetry of the crystal, and according to its position two classes of mica are distinguished. To the first class, with the optic axial plane perpendicular to the plane of symmetry, belong muscovite, lepidolite, paragonite, and a rare variety of biotite called anomite; the second class includes zinnwaldite, phlogopite, lepidomelane and most piotites. Dark coloured micas are strongly pleochroic.

The different kinds of mica vary from perfectly colourless and transparent—as in muscovite—through shades of yellow, green, red and brown to black and opaque—as in lepidomelane; the former have a pearly lustre and the latter a submetallic lustre on the cleavage surfaces. Sheets very often show coloured rings and bands (Newton's rings), due to the interference of light at the surfaces of internal cleavage cracks. The sp.gr. varies between 2·7 and 3·1 in the different species. The hardness is 2–3; smooth cleavage surfaces can be just scratched with the finger-nail. Micas are bad conductors of heat and electricity, and it is on these properties that many of their technical applications depend. Inclusions of other minerals are frequently to be observed, and flattened crystals of garnet, films of quartz, and needles of tourmaline are not uncommon. Cleavage sheets are frequently disfigured and rendered of little value by brown, red or black spots and stains, often with a dendritic arrangement of iron oxides. Minute acicular inclusions, probably of rutile, arranged parallel to the rays of the percussion figure, give rise to the phenomenon of "asterism" in some micas, particularly phlogopite; a candle-flame or spot of light viewed through a cleavage sheet of such mica

appears as a six-rayed star.

Chemical Composition.—The micas are extremely complex and variable in composition. They are silicates, usually orthosilicates, of aluminium together with alkalis (potassium, sodium, lithium, rarely rubidium and caesium), basic hydrogen, and, in some species magnesium, ferrous and ferric iron, rarely chromium, manganese and barium. Fluorine is also often an essential constituent, and titanium is sometimes present.

The composition of the several species of mica is given by the following formulae, some of which are only approximate, and many attempts have been made to explain the variations in composition. It will be seen that they may be divided into two groups—alkali-micas (potash-mica, etc.) and ferromagnesian micas—which correspond roughly with the division into light and dark micas.

Muscovite	$H_2K\ Al_3(SiO_4)_3$
Paragonite	$H_2NaAl_3(SiO_4)_3$
Lepidolite	$KLi[Al(OH,F)_2]Al(SiO_3)_3$
Zinnwaldite	$(K,Li)_3[Al(OH,F)_2]FeAl_2Si_5O_{16}$
Biotite	$(H,K)_2(Mg,Fe)_2(Al,Fe_2(SiO_4)_3$
Phlogopite	$[H,K,(MgF)]_3Mg_3Al(SiO_4)_3$

The water which is present in muscovite to the extent of 4 to 6%, and rather less in the other species, is expelled only at a high temperature; it is therefore water of constitution, existing as basic hydrogen or as hydroxyl replacing fluorine.

Roscoelite is a mica in which the aluminium is largely replaced by vanadium (V_2O_3, 30%); it occurs as brownish-green scaly aggregates, intimately associated with tellurides of gold in California, Colorado and Western Australia.

Occurrence.—Mica occurs as a primary and essential constituent of igneous rocks of almost all kinds; it is also a common product of alteration of many mineral silicates, both by weathering and by contact- and dynamo-metamorphic processes. In sedimentary rocks it occurs as detrital material.

Muscovite and biotite are commonly found in siliceous rocks, whilst phlogopite is characteristic of calcareous rocks. The best crystallized specimens of any mica are afforded by the small brilliant crystals of biotite, which encrust cavities in the limestone blocks ejected from Monte Somma, Vesuvius. Large sheets of muscovite, such as are of commercial value, are found only in the very coarsely crystallized pegmatite veins traversing granite, gneiss or mica-schist. These veins consist of felspar, quartz and mica, often with smaller amounts of other crystallized minerals, such as tourmaline, beryl and garnet; they are worked for mica in India, the United States (South Dakota, Colorado and Alabama), and Brazil (Goyaz, Bahia and Minas Geraes). The commercially valuable micas of Canada and Ceylon are mainly phlogopite (*q.v.*), which has a rather different mode of occurrence. The mica mined in India is practically all muscovite. The principal mining districts are those of Hazāribāgh in Bengal and Nellore in Madras; in the former district the mica has usually a ruby tint, whilst in the latter it is more often greenish. In the Inikūrti mine, Nellore, "books" of mica measuring 10ft. across, and up to 15ft. across the folia have been found, and rectangular sheets measuring 30 by 24in. and free from cracks and flaws have frequently been obtained.

Uses.—On account of its transparency and its resistance to fire and sudden changes of temperature mica has been much used for the windows of stoves and lanterns, for the peep-holes of furnaces, and the chimneys of lamps and gas-burners. At one time it was used for window panes of houses and the port-holes of Russian men-of-war, being commonly known as "Muscovy glass." Spangles of mica are much used for decorative purposes of various kinds, and the mineral was formerly known as *glacies Mariae* (Ger., *Frauenglas*) because of its use for decorating statues of the Virgin. The *lapis specularis* of Pliny, scattered over the Circus Maximus to produce a shining whiteness, was probably mica. Large quantities of ground mica are used in the manufacture of wall-paper, and to produce a frosted effect on toys, stage scenery, etc. Powdered mica is also used in the manufacture of paints and paper, as a lubricant, and as an absorbent

of nitro-glycerine and disinfectants. Sheets of mica are used as a surface for painting, especially in India; for lantern slides; for carrying photographic films; as a protective covering for pictures and historical documents; for mounting soft and collapsible natural history specimens preserved in spirit; for vanes of anemometers; for mirrors of delicate physical instruments; for various optical and many other purposes. Being a bad conductor of heat it is used for the packing and jackets of boilers and steam-pipes. Other applications depend on the strength of its resistance to acids.

The most extensive application of mica at the present day is for electrical purposes. Being a bad conductor of electricity it is of value as an insulator, and the smooth flexible sheets are much used in the construction of armatures of dynamos and in other electrical machinery. "Micanite" or "micanite cloth"—small sheets of mica cemented with shellac or other insulating cement on cloth or paper—is used for various purposes.

Muscovite and phlogopite are practically the only species used commercially. Phlogopite is rarely found as colourless transparent sheets and is therefore almost exclusively used for electrical purposes. Many other uses of mica might be mentioned: the potassium it contains renders it of value as a manure, and the species lepidolite is largely employed in the manufacture of lithium and rubidium salts.

Mining, Preparation and Value.—Mica mining is an industry of considerable importance, especially in India where, however, methods are very primitive and wasteful. In working downwards in open quarries and in tortuous shafts and passages much of the mica is damaged and a large amount of labour is expended in hauling waste material to the surface. Since the mineral occurs

in definite veins a more satisfactory and economical method of working would be that adopted in metalliferous mines, with a vertical shaft, cross-cuts, and levels running along the strike of the vein; the mica could then be extracted by overhead stopping, and the waste material used for filling up the worked-out excavations.

In dressing mica the "books" are split along the cleavage into sheets of the required thickness, and the sheets trimmed into rectangles with a sharp knife, shears or guillotine, stained and damaged portions being rejected. The dressed sheets are sorted according to size, transparency, colour and freedom from spots or stains. Scrap mica is ground to powder or used in the manufacture of micanite.

See Sir T. H. Holland, "The Mica Deposits of India," *Memoirs of the Geological Survey of India* (1902), xxxiv. 11–121; F. Cirkel, *Mica: its Occurrence, Exploitation and Uses* (Canada, Mines Branch, Ottawa; 2nd edit. by H. S. de Schmid, 1912, No. 118); *Mica* Imp. Mineral Resources Bureau, London, 1922. (L. J. S.)

MICA PRODUCTION

From any one mine the percentage of the output of mica that can be manufactured in the sheets seldom exceeds 10%. Formerly the rejected material was mostly wasted; to-day this scrap mica is in active demand for grinding.

The term *vermiculite* is applied to the group of micaceous minerals which generally are alteration products of mica. Until a few years ago the few known deposits were considered a mineral curiosity. Large quantities have recently been discovered in Colorado and Montana, and have attracted attention to the commercial possibilities. The most pronounced characteristic of vermiculite is great expansion by heating which takes place in only one direction, at right angles to the cleavage.

During expansion the volume increases up to sixteen times the original. At the same time the colour changes according to the degree of heat and the exposure to the air. This change is believed to be caused by the oxidation of the iron in the mica and therefore to vary with the amount of oxygen available. The expanded product has been found to be an excellent heat insulator and sound deadener, and to possess possibilities as a paint and calcimine pigment.

MICAH, the sixth in literary order of the "minor prophets" of the Old Testament, is not to be confused with the 9th century Micaiah (1 Kings xxii.; the gloss in verse 28b, quoting Micah i. 2, and absent from the Greek version, shows that such confusion occurred at an early date). Micah was a younger contemporary of Isaiah, living in the closing decades of the 8th century, though, unlike Isaiah, he belonged to the country, not to the city. He is called "the Morashtite" as being a native of Moresheth-Gath (i.14), *i.e.*, a daughter-village of Gath, in the "Shephelah," a district in which his interest is manifest (i. 10–15).

The editorial title of the book of Micah declares that Micah prophesied "in the days of Jotham (739–734), Ahaz (733–721) and Hezekiah (720–693), kings of Judah." Nothing in the book itself can claim to belong to the reign of Jotham, but the prophecy against Samaria (i.5–8) may have been uttered originally before the fall of Samaria in 722, *i.e.*, in the reign of Ahaz. In its present form, however, it has been incorporated in a prophecy against Judah, belonging most probably, to the years shortly before 701, when a new Palestinian rising provoked Sennacherib's campaign. This prophetic activity of Micah under Hezekiah is confirmed by the direct statement of Jer. xxvi. 17 *seq.*, where Mic. iii. 12 is quoted ("Zion shall be plowed as a field," etc.). The verse quoted forms the climax of Mic. i.–iii., from which chapters only any certain conclusions as to the prophetic message of the historic Micah can be drawn; the remaining sections of the present book (iv.–v., vi.–vii.) consist, in whole or in greater part, of writings belonging to a later period.

The subject-matter of i.–iii. consists of a declaration of divine judgment against Israel, a warning to other nations (i.2). This takes the form of a theophany (i.3,4) and issues in the destruction of the northern and southern capitals (i.5), in which the evil to be punished is concentrated, and in the destruction of idols. The prophet wears the garb of a mourner, and loudly laments the fate that befalls Judah as well as Samaria, in a "dirge" that describes the destruction of the country-side, with many plays on names (i.10–16). The moral evils denounced are the rapacity of "land-grabbers" and the eviction of former owners (ii.1–11), the injustice of rulers and the falsity of prophets (iii.1–8), whose selfish interests dictate their conduct (iii.9–12). Their false confidence in the protection of Yahweh can have but one issue—the destruction of Jerusalem and its temple.

Our only evidence as to the reception of Micah's message by his contemporaries is that afforded by Jer. xxvi. 17 *seq.*, both directly, in the recorded effect on Hezekiah and the people; and indirectly, in the fact that the impression created was remembered a century afterwards. Micah resembles Amos, both in his country origin, and in his general character, which expresses itself in strong emphasis on the ethical side of religion. As the last of the four great prophets of the 8th century he undoubtedly contributed to that religious and ethical reformation whose literary monument is the Book of Deuteronomy.

The remainder of the book bearing the name of Micah falls into two main divisions, viz., iv., v. and vi., vii. Each differs from the first division (i.–iii.) in a marked degree. The second consists mainly of prophecies of restoration including eschatological (iv.1 *seq.*) and Messianic (v. 2 *seq.*) hopes. The third is formed of three or four apparently unrelated passages, on the spirituality of true worship (vi. 1–8), social immorality and its doom (vi. 9–16; vii. 1–6), and Israel's future recovery from present adversity through Divine grace (vii.7–20). It is improbable that much, if any, of these chapters can be ascribed to Micah himself, not only because their contents are so different from his undoubted work (i.–iii.), for which he was subsequently remembered (Jer. xxvi. 18), but because they presuppose the historic outlook of the Exile, or a later age (*e.g.*, iv. 6 *seq.; vii. 7 seq.*). It is neither psychologically nor historically impossible for a prophet of judgment to be also a prophet of comfort; but the internal evidence of composite and (in whole or part) later authorship must outweigh the traditional attachment of these passages to a ms. containing the work of Micah. It is noteworthy that the triple division of the book of Micah (i.–iii.; iv., v.; vi., vii.) corresponds with that of the book of Isaiah (i.–xxxix.; xl.–lv.; lvi.–lxvi.) in the character of the three divisions (judgment; coming restoration; prayer for help in adversity) respectively, and in the fact that the first alone gives us pre-exilic writing in the actual words of the prophet to whom the whole book is ascribed. In both cases, it need hardly be said, the great literary and spiritual value of the later passages ought in no way to suffer prejudice from critical conditions as to their date and authorship. Amongst these passages there are two that call for special notice. The first is the prophecy that the little clan of Ephrathah, which includes Bethlehem, the birthplace of David, is destined to be the source from which comes the future Davidic prince who shall "shepherd" the Messianic kingdom (v. 2, 4; the intervening verse is a gloss, connecting this "Messiah" with a Messianic interpretation of Is. vii. 14). The second is the summary of the fundamental principles of prophetic religion—justice, mercy, and humility (vi. 6–8).

MICA-SCHIST, in petrology, a rock composed essentially of mica and quartz, and possessing a foliated or schistose structure due to the parallel arrangement of the mica flakes. Mica-schists differ from gneisses principally by the absence of conspicuous alternations of schistose and granular bands characteristic of the latter rocks, and by the paucity of felspar minerals. Between phyllite and mica-schist there are all gradations. Mica-schists possess a greater variety of constituent minerals and are more coarsely crystallized. The mica may be muscovite or biotite; both are often present. Paragonite and fuchsite are rare. In addition to quartz, minor quantities of albite or oligoclase fel-

spar are frequently found. A great number of accessory minerals are known in mica-schists, and when these are conspicuous they may be regarded as constituting special varieties receiving distinctive names. These minerals include almandine garnet, staurolite, kyanite, andalusite and sillimanite. Many of them are indicators of a special grade of metamorphism. Minor accessories include rutile, hematite, ilmenite, tourmaline and zircon.

In nearly all cases mica-schists are metamorphosed sedimentary rocks of the composition of clays, shales and slates, though examples are known which are clearly transmuted acid igneous rocks, such as rhyolites and porphyries. The origin of these latter types, if not decipherable by their field relations, is usually indicated by their bulk chemical composition.

The common associates of mica-schist are quartzites, quartz-schists and limestones, representing sediments of a siliceous and calcareous nature interstratified with clays and mudstones from which the mica-schists are derived.

Like all metamorphic rocks mica-schists are principally found in areas of pre-Cambrian rocks. In the mountain chains of the Alps, the Himalayas, etc., mica-schists of Palaeozoic and Mesozoic age are known as they are seen to pass into sediments containing recognizable fossils. At Bergen, in Norway, Palaeozoic fossils have been found in mica-schists, and some of the Mesozoic schists of the Alps retain identifiable organic remains. Mica-schists are rarely of economic value, being too fissile for building-stones and too brittle for roofing slates. (*See* also SCHISTS.) (C. E. T.)

MICHAEL, an Old Testament name, synonymous with Micaiah or Micah (Num. xiii. 13; 1 Chron. v. 13, *et passim*). In the book of Daniel the name (which means "Who is like God?") is given to one of the chief "princes" of the heavenly host, the guardian angel or "prince" of Israel (Dan. x. 13, 21; xii. 1; *cf.* Enoch xx. 5 and possibly Mal. iii. 1). He holds the secret of the mighty "word" by which God created heaven and earth (Enoch lxix. 14), and was "the angel who spoke to Moses in the Mount" (Acts vii. 38). It was through Babylonian and Persian influence that names were given to the angels, and Michael finds a parallel in Vohumano, "Ahura's first masterpiece," one of the Zoroastrian Amesha-spentas or arch-angels. It is as guardian angel of Israel, or of the Church, the true Israel, that Michael appears in Jude 9 and Rev. xii. 7.

MICHAEL, the name of nine East-Roman emperors.

MICHAEL I. RHANGABES (d. 845), an obscure nobleman who had married Procopia, the daughter of Nicephorus I. He was made emperor in a revolution against his brother-in-law, Stauracius (811).

Elected as the tool of the orthodox party, Michael diligently persecuted the iconoclasts on the northern and eastern frontiers of the empire, but allowed the Bulgarians to ravage a great part of Macedonia and Thrace; having at last taken the field in the spring of 813, he was defeated near Versinikia, and relegated to a monastery in the island of Prote where he died in 845.

MICHAEL II., called PSELLUS, "the stammerer," emperor 820–829, a native of Amorium in Phrygia, began life as a private soldier, but rose by his talents to the rank of general. He had been sentenced to death in December 820 for a conspiracy against Leo the Armenian; his partisans, however, succeeded in assassinating Leo and called Michael to the throne. The principal features of his reign were a struggle against his brother general, Thomas (822–824); the conquest of Crete by the Saracens in 823; and the beginning of their attacks upon Sicily (827).

MICHAEL III. (839–867), "the drunkard," was grandson of Michael II., and succeeded his father Theophilus when three years old (842). During his minority the empire was governed by his mother Theodora (*q.v.*), who entirely neglected the education of her son. As a result Michael grew up a debauchee, and fell under the sway of his uncle Bardas, who induced him to banish Theodora to a convent, and practically assumed the chief control (857); in the wars of the period Michael himself took a more active part. During a conflict with the Saracens of the Euphrates (856–63), the emperor sustained a personal defeat (860), which was retrieved by a great victory on the part of his uncle Petronas in Asia Minor. In 861 Michael and Bardas invaded Bulgaria and secured the conversion of the king to Christianity. On sea the empire suffered under the ravages of the Cretan corsairs; and in 865 the first pillaging expedition of the Russians endangered the Bosporus. In 867 Michael was assassinated by Basil the Macedonian.

MICHAEL IV. (d. 1041), "the Paphlagonian," owed his elevation to Zoë, the wife of Romanus III., who poisoned her husband and married Michael, her chamberlain (1034). Michael, however, being weak and subject to epileptic fits, left the government in the hands of his brother, John the Eunuch. John's reforms of the army and financial system revived for a while the strength of the Empire. On the eastern frontier the important post of Edessa was relieved. The western Saracens were almost driven out of Sicily (1038–40); but an expedition against the Italian Normans suffered several defeats, and subsequently most of the Sicilian conquests were lost (1041). In the north the Serbs achieved a successful revolt (1040), but a dangerous rising by the Bulgarians and Slavs which threatened the cities of Thrace and Macedonia was repressed by a triumphant campaign which the decrepit emperor undertook in person shortly before his death (1041).

MICHAEL V. CALAPHATES, or "the caulker," nephew and successor of the preceding, surnamed after the early occupation of his father. He owed his elevation (Dec. 1041) to his uncle John, whom along with Zoë he almost immediately banished; this led to a popular tumult in consequence of which he was dethroned after a brief reign of four months, and relegated to a monastery.

MICHAEL VI., "the warlike," was already an old man when chosen by the empress Theodora as her successor shortly before her death in 1056. He was unable to check the disaffection of the feudal aristocracy, who combining with an officer named Isaac Comnenus, dethroned Michael (1057).

MICHAEL VII. DUCAS, or PARAPINACES, was the eldest son of Constantine X. Ducas. After a joint reign with his brothers, Andronicus I. and Constantine XI. (1067–1071), he was made sole emperor through his uncle John Ducas. The feebleness of Michael and the avarice of his ministers, were disastrous to the empire. As the result of anarchy in the army, the Byzantines lost their last possessions in Italy (1071), and were forced to cede a large strip of Asia Minor to the Seljuk Turks (1074). These misfortunes caused widespread dissatisfaction. In 1078 two generals, Nicephorus Bryennius and Nicephorus Botaniates, simultaneously revolted. Michael resigned the throne with hardly a struggle.

MICHAEL VIII. PALAEOLOGUS (1234–1282) was the son of Andronicus Palaeologus Comnenus and Irene Angela, the granddaughter of Alexius Angelus, emperor of Constantinople. At an early age he rose to distinction, and ultimately became commander of the French mercenaries in the employment of the emperors of Nicaea. A few days after the death of Theodore Lascaris II. in 1259, Michael, by the assassination of Muzalon, became guardian of the young emperor, John Lascaris. Afterwards invested with the title of "despot," he was finally proclaimed joint-emperor and crowned alone at Nicaea on Jan. 1, 1260. In July 1261 Michael conquered Constantinople through his general Strategopoulos. He thereupon had John Lascaris blinded and banished. For this last act he was excommunicated by Arsenius, and the ban was not removed until the accession of a new patriarch (1268). In 1263 and 1264 respectively, Michael, with the help of Urban IV., concluded peace with Villehardouin, prince of Achaia, and Michael, despot of Epirus, who had been decisively beaten at Pelagonia in Thessaly (1259); Villehardouin was obliged to cede Mistra, Monemvasia and Maina in the Morea.

Subsequently Michael was involved in wars with the Genoese and Venetians, whose influence in Constantinople he sought to diminish by maintaining the balance of strength between them. In 1269 Charles of Sicily, aided by John of Thessaly, made war with the alleged purpose of restoring Baldwin to the throne of Constantinople, and pressed Michael so hard that he consented to the papal supremacy at the council of Lyons in 1274. The union thus brought about between the two Churches was, however, extremely distasteful to the Greeks, and the persecution of his "schismatic" subjects to which the emperor was compelled to resort weakened his power so much that Martin IV. was tempted to enter into alliance with Charles of Anjou and the Venetians for the purpose of

reconquering Constantinople. The invasion, however, failed, and Michael so far had his revenge in the "Sicilian Vespers," which he helped to bring about. He died in Thrace in December 1282.

MICHAEL IX. PALAEOLOGUS, was the son of Andronicus II. and was associated with him on the throne from 1295, but predeceased him (1320). He took the field against the Turks (1301, 1310) and against the Grand Catalan Company (1305), but was repeatedly defeated.

See Gibbon's *Decline and Fall* (ed. Bury, 1911); G. Finlay, *Hist. of Greece* (ed. 1877); G. Schlumberger, *l'Epopée byzantine* (1896); J. Bury, in *Eng. Hist. Rev.* (1889); Meliarakes, Ἱστορία τοῦ βασιλείου τῆς Νικαίας καὶ τοῦ δεσποτάτου τῆς Ἠπείρου, pp. 539–627 (Athens, 1898).

MICHAEL (1596–1645), tsar of Russia, was the first tsar of the house of Romanov, being the son of Theodore Nekitich Romanov, afterwards the Patriarch Philaret (*q.v.*), and Xenia Chestovaya, afterwards the nun Martha. He was elected unanimously tsar of Russia by a national assembly on Feb. 21, 1613, but not till March 24 did the delegates of the council discover the young tsar and his mother at the Ipatievsky monastery near Kostroma. He was crowned on July 22. The first care of the new tsar was to clear the land of the robbers that infested it. Peace was made with Sweden and Poland by the peace of Stolbova (March 10, 1617) and the truce of Deulina (Feb. 13, 1619). The most important result of the truce of Deulina was the return from exile of the tsar's father, who henceforth took over the government till his death in October 1633. Michael died on July 12, 1645.

See R. Nisbet Bain, *The First Romanovs* (Lond., 1905).

MICHAELIS, GEORG (1857–), German statesman, was born on Sept. 7, 1857 at Haynau. He studied law and for some years lectured at the university of Tokyo. He entered the Prussian administration in 1879, and by 1909 had risen to the grade of under-secretary of state in the Prussian ministry of finance. On the outbreak of the World War he was appointed director of the imperial department for the control of the grain trade, and in Feb. 1917 State commissioner for the national food supply. On the retirement of Bethmann Hollweg in July 1917, the military authorities, with the object of avoiding conflict with the civil administration, advised the appointment of a chancellor who would accommodate his policy to theirs. Michaelis, as a colourless Prussian official, was selected, but even in the first weeks of his chancellorship his weakness became manifest. He was confronted with the demand of the parliamentary majority that he should publicly identify himself with the spirit and letter of the so-called Peace Resolution in favour of a peace "without annexation or indemnities" passed by the Reichstag on July 19, 1917. Under the influence of the military authorities he attempted to evade this obligation by declaring himself, in a phrase that became celebrated, the supporter of the resolution "as he understood it." He had still further to compromise himself over the naval mutiny before it was recognised that his position was untenable. He was succeeded by Count Hertling on Nov. 1, 1917. He was then appointed chief president in the province of Pomerania, an office which he held till 1919.

See his autobiographical *Für Staat und Volk* (1922).

MICHAELIS, JOHANN DAVID (1717–1791), German biblical scholar and teacher, was born at Halle, on Feb. 27, 1717, a member of a family which included several good biblical scholars. He qualified as university lecturer at Halle in 1739–40, but he did not feel at home in the pietistic atmosphere of the university at that time, and was glad to accept a position as *privatdozent* at Göttingen. He became full professor in 1750, and remained there until his death on Aug. 22, 1791. His works include *Supplementa* (1784–92) to the Hebrew lexicons; *Spicilegium geographiae Hebraeorum exterae post Bochartum* (1769–80); an interesting autobiography, *Lebens beschreibung* (1793). He also edited the *Orientalische und exegetische Bibliothek* (24 vols. 1771–79; new series, 8 vols. 1786–91).

MICHAEL OBRENOVIĆ III. (1838–1868), prince of Serbia, was the youngest son of Prince Miloš Obrenović I. (*q.v.*). After the abdication of his father (1839) and the death of his elder brother, Milan Obrenović II. (1840), he ascended the throne of Serbia. He began his reign with an ambitious programme of self-assertion abroad and reform within; but alienated Turkey and Austria, while the heavy taxation imposed multiplied the party which had forced his father to abdicate. In Aug. 1842 Vučić, the leader of the malcontents, forced him to leave the country, Alexander Karageorgević, son of Karageorge (*q.v.*), being elected in his place. He married, in 1856, Julia, Countess Hunyadi.

In 1858 Alexander was dethroned in his turn, and Miloš Obrenović I. recalled to the throne; on whose death (1860) Michael succeeded him. His policy was generally wise and moderate. He abolished the oligarchic Constitution of 1839, limiting the powers of the Senate and increasing that of the Skupština; established a regular national army, and reformed the judicature and administration. Meanwhile, he was planning an ambitious foreign policy, negotiating secretly with Bosnian, Bulgarian and Albanian leaders. Had his plans succeeded a great Yugoslavia would have been formed, including Bulgaria under Serbian leadership. He secured the sympathy of France to his plans, and a promise of neutrality from Austria; but his long diplomatic duel with the Turks only succeeded in obtaining the withdrawal of the last Turkish garrisons from Serbia (1867). Before he could take the next step, he was assassinated in the Topčider, near Belgrade, on the night of June 10, 1868.

MICHALAKOPOULOS, ANDREAS (1875–), Greek statesman, was born at Patras, in 1875, and first joined the military school, but subsequently became a practising lawyer. He entered politics in 1910 as an independent, joined the Liberals, and was minister of national economy under Venizelos in 1912 and 1915, and minister of agriculture in Venizelos' Salonika cabinet of 1916. He accompanied his leader to Paris for the peace negotiations; was out of office during the Royalist reaction of 1920–23, but re-elected in 1923, and negotiated the important Greek Refugees loan. In Nov. 1924 he became prime minister and minister of war, and in Jan. 1925, also minister of foreign affairs, holding office for the record period of eight months, despite the difficult situation (*see* GREECE). In June 1925 he was overthrown by General Pangalos (*q.v.*) and subsequently exiled to Naxos. In the "Oecumenical cabinet" formed on Dec. 4, 1926, he again became minister of foreign affairs, a post for which his long experience, his moderate views and his knowledge of languages peculiarly fitted him.

MICHAUD, JOSEPH FRANÇOIS (1767–1839), French historian and publicist, was born on June 19, 1767, at Albens, Savoy. He was a strong counter-revolutionary, and editor of *La Quotidienne*. He was proscribed more than once during the revolutionary period. He entered the Academy in 1814, and died at Passy, Paris on Sept. 30, 1839. His principal work is an *Histoire des croisades*, which was published in its final form in six volumes in 1840 under the editorship of his friend Poujoulat.

See Sainte-Beuve, *Causeries du lundi*, vol. vii.

MICHAUX, ANDRÉ (1746–1802), French botanist and traveller, was born at Versailles on March 7, 1746. In 1779 he spent some time botanizing in England, and in 1780 explored Auvergne, the Pyrénées and the north of Spain. In 1782 he was sent by the French government on a botanical mission to Persia. After two years he returned with a fine herbarium, and also introduced numerous Eastern plants into France. In 1785 he was sent to North America, but on his return in 1797 he was shipwrecked and lost most of his collections. In 1800 he went to Madagascar where he died on Nov. 16, 1802. His work on the flora of North America was a valuable contribution to American botany.

He wrote *Histoire des chênes de l'Amérique septentrionale* (1801) and the *Flora Boreali-Americana* (2 vols., 1803). His son François published a *Histoire des arbres forestiers de l'Amérique septentrionale* (3 vols., 1810–13, Eng. trans., 1817–19).

MICHEL, CLAUDE, known as CLODION (1738–1814), French sculptor, was born on Dec. 20, 1738 in Nancy. In 1755 he came to Paris and entered the workshop of Lambert Sigisbert Adam, his uncle, and on his death became a pupil of J. B. Pigalle. In 1759 he obtained the grand prize for sculpture at the Académie Royale; and in 1762 he went to Rome. Catherine II.

was eager to secure his presence in St. Petersburg, but he returned to Paris in 1771. Among his many patrons were the chapter of Rouen, the states of Languedoc, and the *Direction générale*. He frequently exhibited at the Salon. The agitation caused by the Revolution drove Clodion in 1792 to Nancy, where he lived until 1798. His works include a statue of Montesquieu, a "Dying Cleopatra," and a chimney-piece at present in the South Kensington Museum. One of his last groups represented Homer as a beggar being driven away by fishermen (1810). Clodion died in Paris on March 29, 1814.

Thirion's *Les Adam et Clodion* (1885) contains a list of the sculptor's works sold between 1767 and 1884. *See* also A. Jacquot, *Les Adam et les Michel et Clodion* (1898).

MICHEL, CLÉMENCE LOUISE (1830–1905), French anarchist, called *la Vierge rouge de Montmartre,* was born at the château of Vroncourt (Haute-Marne) on May 29, 1830, the daughter of a serving-maid, Marianne Michel, and the son of the house, Étienne Charles Demahis. She was brought up by her father's parents, and received a liberal education. After her grandfather's death in 1850 she was trained to teach, but her refusal to acknowledge Napoleon III. prevented her from serving in a state school. She found her way in 1866 to a school in the Montmartre quarter of Paris, where she threw herself ardently into works of charity and revolutionary politics. During the siege of Paris she joined the ambulance service, and untiringly preached resistance to the Prussians. On the establishment of the Commune she joined the National Guard. She was with the Communards who made their last stand in the cemetery of Montmartre, and was closely allied with Théodore Ferré, who was executed in Nov. 1871. This ardent attachment was perhaps one of the sources of the exaltation which marked her career, and gave many handles to her enemies. When she was brought before the 6th council of war in Dec. 1871 she defied her judges and defended the Commune. She was sent as a convict to New Caledonia, among her companions being Henri Rochefort, who remained her friend till the day of her death.

The amnesty of 1880 found her revolutionary ardour unchanged. She travelled throughout France, preaching revolution. For being concerned in a Paris riot in 1883 she was condemned to six years' imprisonment, but was again released in 1886. She was touring France and lecturing on behalf of anarchist propaganda when she died at Marseilles on Jan. 10, 1905.

Her *Mémoires* (1886) contain accounts of her trials. *See* also E. Girault, *La Bonne Louise* (1906).

MICHEL, FRANCISQUE XAVIER (1809–1887), French scholar, was born at Lyons on Jan. 18, 1809. He edited the works of many mediaeval French writers, and the French Government, recognizing their value, sent him to England (1833) and Scotland (1837) to continue his researches there. In 1839 he was appointed professor of foreign literature in the *Faculté des lettres* at Bordeaux. Between 1834 and 1842 he published editions of a large number of works written between the 11th and 14th centuries in French, English and Saxon, including the *Roman de la rose* and the *Chanson de Roland*. He died in Paris on May 18, 1887.

MICHELANGELO (Michelagniolo Buonarroti) (1475–1564), the most famous of the great Florentine artists of the Renaissance, was the son of Ludovico Buonarroti, a poor gentleman of that city, and of his wife Francesca dei Neri. The Buonarroti Simoni were an old and pure Florentine stock of the Guelf faction. Ludovico was barely able to live on the income of his estate, but boasted that he had never stooped to add to it by mercantile or mechanical pursuits. He held the appointment of podestà or resident magistrate for six months, from the autumn of 1474, at Castello di Chiusi and Caprese in the Casentino. At Caprese, on March 6, 1475, his second son Michelagniolo or Michelangelo was born. The child was put to nurse with a marble-worker's wife of Settignano. His mother died a few years later, after bearing three more sons. While still a young boy Michelangelo determined, in spite of his father's opposition, to be an artist. He had sucked in the passion, as he used to say, with his foster-mother's milk. After a sharp struggle his stubborn will overcame his father's pride and at thirteen he was articled as a paid assistant in the workshop of the brothers Ghirlandaio. Domenico Ghirlandaio, bred a jeweller, had become by this time the foremost painter of Florence. Michelangelo studied also, like all the Florentine artists of that age, in the Brancacci chapel, where the frescoes of Masaccio, painted some sixty years before, still held their own; and here, in reply, to a taunt he had flung at a fellow-student, Torrigiano, he received the blow on the nose which disfigured him for life.

Sculpture.—Though Michelangelo's earliest studies were directed towards painting, he was by nature and predilection much more inclined to sculpture. In that art he presently received encouragement and training under the eye of Lorenzo dei Medici. On the recommendation, it is said, of Ghirlandaio, he was transferred, before the term of his apprenticeship as a painter had expired, to the school of sculpture established by Lorenzo in the Medici gardens. Here he could learn to match himself against his great predecessor, Donatello, one of whose pupils and assistants, the aged Bertoldo, was director of the school, and to compare the works of that master and his Tuscan contemporaries with the antiques collected for the instruction of the scholars. Here, too, he could listen to discourses on Platonism, and steep himself in the doctrines of an enthusiastic philosophy which sought to reconcile with Christian faith the lore and the doctrines of the Academy. Michelangelo remained a Christian Platonist to the end of his days; he was also a devoted student of Dante. His powers soon attracted attention, and secured him the favour of his patrons in spite of his rugged exterior and scornful unsociable temper. A notable work of this period is the marble Centauromachia (Casa Buonarroti, Florence), a fine work in full relief: Michelangelo followed the antique in his conception and treatment of the nude but the arrangement is his own.

Michelangelo had been attached to the school and household of the Medici for barely three years when, in 1492, Lorenzo died. Lorenzo's son Piero dei Medici inherited the position but not the qualities of his father; Florence soon chafed under his authority; and towards the autumn of 1494 it became apparent that disaster was impending. Michelangelo was constitutionally subject to dark and sudden presentiments, and without awaiting the popular outbreak, which soon followed, he took horse with two companions and fled to Bologna. There he was received with kindness by a member of the Aldovrandi family, on whose commission he executed two figures of saints and one of an angel for the shrine of St. Dominic in the church of St. Petronius. After about a year, work at Bologna failing, and his name having been included on the list of artists appointed to provide a new hall of assembly for the great council of Florence, Michelangelo returned home.

He found a friend in another Lorenzo, the son of Pierfrancesco dei Medici, for whom he executed a statue of the boy St. John. Having also carved a recumbent Cupid in imitation of the antique, it was suggested to him by the same patron that it should be so tinted and treated as to look like a real antique, and sold accordingly. Michelangelo for amusement lent himself to the counterfeit, and the piece was then actually sold for a large sum, as a genuine work of antiquity, to a Roman collector, Raffaelle Riario, cardinal di San Giorgio; the dealer appropriating the profits. When the cardinal discovered the fraud he caused the dealer to refund; it was represented to Michelangelo that if he went to Rome the amateur who had just involuntarily paid so high a tribute to his skill would certainly befriend him. He arrived at Rome for the first time at the end of June 1496. He received no countenance from the cardinal di San Giorgio; neither did the banished Piero dei Medici, who also was now living at Rome, do anything to help him. But Michelangelo won the favour of a Roman nobleman, Jacopo Galli, and through him of the French cardinal Jean de Villiers de la Grolaie, abbot of St. Denis. From the former he received a commission for a "Cupid" (sometimes identified with the cupid in the Victoria and Albert Museum but this, if by Michelangelo, must belong to a later date) and a "Bacchus," (Bargello, Florence), from the latter for a "Pietà" (St. Peter's, Rome). Equal originality of conception and magnificence of technical execution mark the two contrasted subjects.

Michelangelo's stay in Rome at this time lasted from the summer of 1496 till that of 1501. The interval had been one of extreme political distraction at Florence, which had created an atmosphere most unfavourable to art. Nevertheless Ludovico Buonarroti, who in the troubles of 1494 had lost his permanent appointment in the customs, and had come to regard his son Michelangelo as the mainstay of his house, had been repeatedly urging him to come home. A spirit of family duty and family pride was the ruling principle in all Michelangelo's conduct. During the best years of his life he submitted himself sternly and without a murmur to pinching hardships and almost superhuman labour for the sake of his father and brothers. Having now, after an illness, come home in 1501, Michelangelo was requested by the cardinal Francesco Piccolomini to adorn with a number of sculptured figures a shrine already begun in the cathedral of Siena in honour of Pope Pius II. Four only of these figures were ever executed, and those not apparently, or only in small part, by the master's hand.

A work of greater interest in Florence itself had diverted him from his engagement to his Sienese patrons. This was the execution of the famous colossal statue of David, popularly known as "the Giant." It was carved out of a huge block of marble on which another sculptor, Agostino d'Antonio, had begun unsuccessfully to work forty years before, and which had been lying idle ever since. Michelangelo had here a difficult problem before him. Without much regard to the traditional treatment of the subject or the historical character of his hero, he carved out of the vast but cramped mass of material an adolescent, frowning colossus, tensely watchful and self-balanced in preparation for his great action. The result amazed every beholder by its freedom and science of execution and its victorious energy of expression. The best artists of Florence debated on what site it should be set up, and the terrace of the palace of the Signory was chosen, in preference to the neighbouring Loggia dei Lanzi. Here accordingly the colossal "David" of Michelangelo took, in the month of May 1504, the place which it continued to hold until in 1882 it was removed for the sake of protection to a hall in the Academy of Fine Arts, where it inevitably looks crushed and cabined. Other works of sculpture belong to the same period: among them a second "David," in bronze and on a smaller scale, commissioned by the maréchal Pierre Rohan and left by the young master to be finished by Benedetto da Rovezzano, who despatched it to France in 1508 and which is no longer extant; a great rough-hewn "St. Matthew" (Bargello, Florence), begun but never completed for the cathedral of Florence; a "Madonna and Child" executed on the commission of a merchant of Bruges and still to be seen in the Church of Notre Dame at Bruges; and two unfinished bas-reliefs of the same subject, one at the Diploma Gallery, Royal Academy, London; the other in the Bargello, Florence.

Painting: Early Works.—Neither was Michelangelo idle at the same time as a painter. Leaving disputed works for the moment out of sight, he in these days at any rate painted for his and Raphael's common patron, Angelo Doni, the "Holy Family" now in the Uffizi at Florence. The unfinished painting of "the Virgin and Child with Four Angels" in the National Gallery, London has been confidently claimed for Michelangelo; but it lacks his strength and mastery. In the autumn of 1504, the year of the completion of the "David," he received from the Florentine state a commission for a work of monumental painting on a heroic scale. Leonardo da Vinci had been for some months engaged on his great cartoon of the "Battle of Anghiari," to be painted on the wall of the great hall of the municipal council. The gonfalonier Piero Soderini now procured for Michelangelo the commission to design a companion work. Michelangelo chose an incident at the battle of Cascina during the Pisan war of 1364, when the Florentine soldiery had been surprised by the enemy in the act of bathing. He dashed at the task with his accustomed fiery energy, and had carried a great part of the cartoon to completion when, in the early spring of 1505, he broke off the work in order to obey a call to Rome which reached him from Pope Julius II. In the unfinished cartoon of the "Bathers" the qualities afterwards proverbially associated with Michelangelo—his *furia*, his *terribilità*, the tempest and hurricane of the spirit which accompanied his unequalled technical mastery and knowledge—first found expression.

Second Visit to Rome.—Michelangelo had not been long in Rome before Pope Julius entrusted to him the task of executing a sepulchral monument to be completed during his lifetime. The design being approved, the artist spent the winter of 1505–1506 at the quarries of Carrara, superintending the excavation and shipment of the necessary marbles. In the spring he returned to Rome, and when the marbles arrived fell to with all his energy at the preparations for the work. For a while the pope followed their progress eagerly. But presently his disposition changed. In Michelangelo's absence an artist who was no friend of his, Bramante of Urbino, had been selected by Julius to carry out a new architectural scheme, viz., the rebuilding of St. Peter's church. To the influence and the malice of Bramante, Michelangelo attributed the unwelcome invitation he now received to interrupt the great work of sculpture in order to decorate the Sixtine chapel with frescoes. Soon, however, schemes of war and conquest interposed to divert the thoughts of Julius from artistic enterprises. To add to the artist's discomfiture, when he went to apply for payments due, he was first put off from day to day, and at last actually with scant courtesy dismissed. At this he took horse and left Rome, and before the messengers of the pope could overtake him was safe on Florentine territory. Michelangelo's flight took place in April 1506. Once among his own people, he turned a deaf ear to all overtures made from Rome for his return, and stayed throughout the summer at Florence.

Statue of Pope Julius at Bologna.—During the same summer Julius planned and executed the victorious military campaign which ended with his unopposed entry at the head of his army into Bologna. Thither, under strict safe-conduct and promises of renewed favour, Michelangelo was at last persuaded to betake himself. Julius received the truant artist kindly, as indeed between these two volcanic natures there existed a natural affinity, and ordered of him his own colossal likeness in bronze, to be set up over the principal entrance of the church of St. Petronius. For the next fifteen months Michelangelo devoted his whole strength to this new task. In the technical art of metal casting he was inexperienced, and the work was cast by a Milanese whom Michelangelo had called, and on Feb. 21, 1508, the majestic bronze colossus of the seated pope, robed and mitred, with one hand grasping the keys and the other extended in a gesture of benediction and command, was raised to its station over the church porch. Three years later it was destroyed in a revolution. The people of Bologna rose against the authority of Julius; his delegates and partisans were cast out, and his effigy hurled from its place. The work of Michelangelo, after being trailed in derision through the streets, was broken up and its fragments cast into the furnace.

Sixtine Chapel.—Meanwhile the artist had followed his reconciled master back to Rome. The task that here awaited him, however, was the execution of the series of paintings in the Sixtine chapel. Painting, he always averred, was not his business; he was aware of his enemy's hopes that a great enterprise in fresco-painting would prove beyond his powers; and he entered with misgiving and reluctance upon his new undertaking. Destiny, however, so ruled that the work thus thrust upon him remains his chief title to glory. The only work which in all his life he was able to complete as he had conceived it was this of the decoration of the Sixtine ceiling. The pope had at first desired a scheme including figures of the twelve apostles only. Michelangelo proposed instead a design of many hundred figures embodying the story of Genesis from the Creation to the Flood, with accessory personages of prophets and sibyls dreaming on the new dispensation to come, and, in addition, those of the forefathers of Christ. The whole was to be enclosed and divided by an elaborate framework of painted architecture, with a multitude of nameless human shapes supporting its several members or reposing among them—shapes mediating, as it were, between the features of the inanimate framework and those of the great dramatic and prophetic scenes themselves. The pope bade the artist do as he pleased. By May 1508

the preparations in the chapel had been completed and the work begun. Later in the same year Michelangelo summoned a number of assistant painters from Florence. He soon dismissed them, and carried out the remainder of his colossal task alone, except for purely mechanicai and subordinate help. The physical conditions of prolonged work, face upwards, upon this vast expanse of ceiling were trying in the extreme.

After four and a half years of toil the task was accomplished. Michelangelo had been harassed alike by delays of payment and by hostile intrigue. Absolute need of funds for the furtherance of the undertaking constrained him at one moment to break off work and pursue his inconsiderate patron as far as Bologna. This was between September 1510, by which time the whole of the great series of subjects along the centre of the vault were completed, and January 1511, when the master set to work again and began filling the complicated lateral spaces of his decorative scheme.

The main field of the Sixtine ceiling—in form a depressed barrel vault—is divided in Michelangelo's scheme into four larger, alternating with five smaller fields. The following is the order of the subjects depicted in them: (1) the dividing of the light from the darkness; (2) the creation of sun, moon and stars; (3) the creation of the waters; (4) the creation of man; (5) the creation of woman; (6) the temptation and expulsion; (7) the sacrifice of Noah; (8) the deluge; (9) the drunkenness of Noah. The figures in the last three of these scenes are on a smaller scale than those in the first six. In numbers 1, 3, 5, 7 and 9, the field of the picture is reduced by the encroachments of the architectural framework with its seated pairs of supporters, commonly known as "Slaves" or "Atlases." Flanking these smaller compositions, along the lateral spaces between the crown of the vault and the walls on either side, are seated figures of prophets and sibyls alternately; two other prophets are introduced at each extremity of the series—making seven prophets and five sibyls in all. In the triangles to right and left of the prophets at the two extremities are the death of Goliath, the death of Holofernes, the brazen serpent and the punishment of Haman. In the twelve lunettes above the windows are groups of the ancestors of Christ, their names designated by inscriptions, and in the twelve triangles above them (between the prophets and sibyls) other kindred groups crouched or sitting. These last are all shown in relatively simple human actions and household relations, heightened but not falsified by the artist's genius, and rising into majestic significance from roots deep in daily human nature. The work represents all the powers of Michelangelo at their best. Disdaining all the accessory allurements of the painter's art, he has concentrated himself upon the exclusive delineation of the human form and face at their highest power. His imagination has conceived attitudes and combinations of unmatched variety and grandeur, and countenances of unmatched expressiveness and power. As for the intellectual meanings of his vast design, they are inexhaustible, and can never be perfectly defined. Whatever the soul of this great Florentine, the spiritual heir of Dante, with the Christianity of the middle ages not shaken in his mind, but expanded and transcendentalized, by the knowledge and love of Plato;—whatever the soul of such a man, full of suppressed tenderness and righteous indignation, and of anxious questionings of coming fate could conceive—that Michelangelo has expressed or shadowed forth in this great scheme of paintings. The powers of the artist seeem to have expanded with the progress of his work. He seems to have begun (as the spectator entering the chapel has to begin) with what is chronologically the last subject of the series, and rising in ascending scale of majesty through the successive acts of creation from the last to the first.

Death of Pope Julius.—The Sixtine chapel was no sooner completed than Michelangelo resumed work upon the marbles for the monument of Julius. But four months only had passed when Julius died. His heirs immediately entered (in the summer of 1513) into a new contract with Michelangelo for the execution of the monument on a reduced scale. What the precise nature and extent of the original design had been we do not know, only that the monument was to stand four-square and free—a thing hitherto unknown in Renaissance sepulchral architecture—in one of the chapels of St. Peter's But the new design was to consist of a great three-sided structure, two courses high, projecting from the church wall, and decorated on its three unattached sides with statues. A much injured and not indisputable sketch by the master at Berlin, with a copy of the same by Sacchetti, are supposed to show the design at this stage of its reduction. The entire work was to be completed in nine years' time. During the next three years, it would seem, Michelangelo brought to completion three at least of the promised figures, for which the blocks had reached Rome from Carrara as early as July 1508; and they are among the most famous of all existing works of the sculptor's art—namely, the "Moses," now in the church of S. Pietro in Vincoli at Rome and the two "Slaves" at the Louvre.

The "Moses," originally intended for one of the angles of the upper course, is now placed at the level of the eye in the centre of the reduced monument. The prophet supposed to have just found the Israelites worshipping the golden calf, sits heavily bearded and draped, his head raised and turned to the left, his right arm grasping the tables of the law—an incarnation of majestic indignation and menace. The work, except in one or two places, is of the utmost finish. The "Slaves" at the Louvre are youthful male figures of equally perfect execution, nude but for the band which passes over the breast of one and the right leg of the other. One, with his left hand raised to his head, his eyes almost closed, seems succumbing to the agonies of death; the other, with his arms bound behind his back, looks upward still hopelessly struggling. All three of these figures were finished between 1513 and 1516.

By 1516 Michelangelo's evil star was again in the ascendant. Julius II. had been succeeded on the papal throne by Cardinal Giovanni dei Medici under the title of Leo X. The Medici, too, had about the same time re-established their sway in Florence. The consequence to him of the rise to power of the Medici was a fresh interruption of his cherished work on the tomb of Julius. Leo X. and his kinsmen were full of a new scheme for the adornment of the façade of their own family church of San Lorenzo in Florence. Michelangelo offered his services for the new façade. They were eagerly accepted, although for a moment the idea had been entertained of entrusting the work to Leonardo da Vinci. The heirs of Julius at the request of Leo allowed their three-years'-old contract to be cancelled in favour of another, whereby the scale and sculptured decorations of the Julian monument were again to be reduced. Michelangelo soon produced for the San Lorenzo façade a design of combined sculpture and architecture as splendid and ambitious in its way as had been that for the original monument of Julius. The contract was signed in January 1518, and the artist went to Carrara to superintend the excavation of the marbles.

When all was well in progress there under his own eye, reasons of state induced the Medici and the Florentine magistracy to bid him resort instead to certain new quarries at Pietrasanta, near Serravalle in the territory of Florence. Hither Michelangelo accordingly had to transfer the scene of his labours. Presently he found himself so impeded and enraged by the mechanical difficulties of raising and transporting the marbles, and by the disloyalty and incompetence of those with whom he had to deal, that he was fain to throw up the commission altogether. The contracts for the façade of San Lorenzo were rescinded in March 1518, and the whole magnificent scheme came to nothing. Michelangelo then returned to Florence, where proposals of work poured in on him from many quarters. The king of France desired something from his hand. The authorities of Bologna wanted him to design a façade for their church of St. Petronius; those of Genoa to cast a statue in bronze of their great commander, Andrea Doria. Cardinal Grimani begged hard for any picture or statue he might have to spare. Lastly his friend and partisan Sebastian del Piombo at Rome besought him on Raphael's death to return at once to Rome, and take out of the hands of the dead master's pupils the work of painting still remaining to be done in the Vatican chambers. Michelangelo complied with none of these requests. All that we certainly know of his doing between 1518 and 1522 is the blocking out in the rough of four more of

the "Slaves" for the tomb of Julius, and carrying out a commission, which he had received from three citizens of Rome as early as 1514, for a statue of the risen Christ. The roughed-out "Slaves" now stand in the Academy of Fine Arts, Florence; the Christ, practically finished by the master but with the last touches added by pupils, stands in the church, for which it was destined, of Sta. Maria sopra Minerva at Rome.

Return to Florence and Patronage of the Medici.—The next twelve years of Michelangelo's life (1522–1534) were spent at Florence, and again employed principally in the service of the Medici. The plan of a great group of monuments to deceased members of this family, to be set up in a new sacristy or mortuary chapel in San Lorenzo, was first broached to Michelangelo in 1520 by Cardinal Giulio dei Medici. No practical impulse, however, was given to the work until Giulio had in his turn become pope in 1523 under the title of Clement VII. First Clement proposed to associate another artist, Sansovino, with Michelangelo in his task. This proposal being on Michelangelo's peremptory demand abandoned, Clement next distracted the artist with an order for a new architectural design—that, namely, for the proposed Medicean or "Laurentian" library. When at last the plans for the sepulchral chapel or "Sagrestia nuova" took shape, they did not include, as had been at first intended, memorials to the founders of the house's greatness, Cosimo (*pater patriae*) and Lorenzo the Magnificent, or even to Pope Leo X. himself, but only to two members of the house lately deceased, Giuliano, duke of Nemours, and Lorenzo, duke of Urbino. Michelangelo was still engaged on the execution of this work—his time being partly also taken up by the building-plans for the Medicean library—when political revolutions interposed to divert his industry. In 1527 came to pass the sack of Rome by the army of Charles V., led by the connétable de Bourbon, and the apparently irretrievable ruin of Pope Clement. The Florentines seized the occasion to expel the Medici, and set up a free republican government once more. Naturally no more funds for the works in San Lorenzo were forthcoming, and Michelangelo, on the invitation of the new signory, occupied himself for a while with designs for a group of Hercules and Cacus, and another of Samson and the Philistines—the latter to be wrought out of a block of marble which had been rough-hewn already for another purpose by Baccio Bandinelli. Soon, however, he was called to help in defending the city. Clement and his enemy Charles V. having become reconciled, both alike were now bent on bringing Florence again under the rule of the Medici. Michelangelo was appointed engineer-in-chief of the fortifications. He spent the early summer of 1529 in strengthening the defences of San Miniato; from July to September he was absent on a diplomatic mission to Ferrara and Venice. Returning in the middle of the latter month, he found the cause of Florence hopeless from internal treachery and from the overwhelming strength of her enemies. One of his dark seizures overcame him, and he departed again suddenly for Venice. There for a while he remained, negotiating for a future residence in France. Then, while the siege was still in progress, he returned once more to Florence; but in the final death-struggle of her liberties he bore no part. When in 1530 the city submitted to her conquerors, no mercy was shown to most of those who had taken part in her defence. Michelangelo believed himself in danger with the rest, but on the intervention of Baccio Valori he was presently taken back into favour and employment by Pope Clement. For four years more he continued to work at intervals on the completion of the Medici monuments, with the help from 1532 of Giovanni Montorsoli and other pupils, and on the building of the Laurentian library. In 1531 he suffered a severe illness; in 1532 he made a long stay at Rome, and entered upon yet another contract for the completion of the Julian monument, to be reduced now to a still more shrunken scale and to be placed not in St. Peter's but in the church of San Pietro in Vincoli. In the autumn of 1534 he left Florence for good. What remained to be done in the Medici chapel was done by pupils, and the chapel was not finally opened to view until 1545.

The Medici Monument.—The statues of the Medici monument take rank beside the "Moses" and the "Slaves" as the finest work of Michelangelo in sculpture. They consist of a Madonna and Child and of the two famous monumental groups, each composed of an armed and seated portrait-statue in a niche, with two emblematic figures reclining on each side of a sarcophagus below. The "Madonna and Child" (left unfinished because the marble was short in bulk) combines the divers qualities of realistic motive and natural animation with learned complexity of design and imposing majesty of effect. It was set up finally—not in accordance with the artist's first intention—against a blank wall of the chapel, and flanked by statues of SS. Cosmo and Damian, the work of pupils. The portraits are treated not realistically but typically. In that of Lorenzo seems to be typified the mood of crafty brooding and concentrated inward thought; in that of Giuliano, the type of alert and confident practical survey immediately preceding action. At the feet of the duke Giuliano recline the shapes of "Night" and "Day"—the former a female, the latter a male, personification; the former sunk in an attitude of deep but uneasy slumber, the latter (whose head and face are merely blocked out of the marble) lifting himself in one of wrathful and disturbed awakening. As grand, but far less violent, are those of the two companion figures that recline between sleep and waking on the sarcophagus of the pensive Lorenzo. Of these, the male figure is known as "Evening," the female as "Morning." In Michelangelo's original idea, partly founded on antique precedent in pedimental and sarcophagus groups, figures of "Earth" and "Heaven" were to be associated with those of "Night" and "Day" on the monument of Giuliano, and others—no doubt of a corresponding nature, with those of the Morning and Evening Twilight on that of Lorenzo. These figures afterwards fell out of the scheme and the recesses designed for them remain empty. Michelangelo's obvious and fundamental idea was to exhibit the elements and the powers of earth and heaven lamenting the death of the princes. River-gods were to recline on the broad bases at the foot of the monuments. These too are lacking. They were never finished, but a bronze cast from a small model of one of them, and the torso of a large model, have lately been identified, the former in the National Museum and the latter in the Academy at Florence.

Other Works, 1522–1534.—"Victory" marble (National Museum, Florence). A youthful conqueror standing over a bearded enemy, whose shoulders he crushes down with his left knee. Fine and finished work: whether intended for one of the emblematic Victories of the Julian monument, or having some connection with the "Hercules and Cacus" and "Samson and the Philistine," subjects undertaken for the Signory in 1528, must remain uncertain. For the former of these two subjects a wax model at the Victoria and Albert Museum, for the latter a plaster model at the Casa Buonarroti, are claimed, perhaps rightly, as original. "David" (formerly called "Apollo"), marble, unfinished (National Museum, Florence). Both the authenticity and the approximate date of this fine work are beyond doubt: of its origin and destination we are uninformed. "Crouching boy," marble, unfinished (the Hermitage, St. Petersburg). Another masterly sketch in marble; the seated lad stoops forward between his parted knees, having both hands occupied with his left foot; the figure blocked out of the marble, with the least possible sacrifice of the material; the subject and motive enigmatical. "Cupid," marble (Victoria and Albert Museum); probably, but not quite certainly, authentic; if so, then of 1530 or thereabouts; its identification with the early Cupid done for Jacopo Galli at Rome in 1496 is untenable.

Later Life in Rome.—Michelangelo had fully purposed, as soon as he could get free of his task on the Medici tombs, to devote all his powers to the completion of the Julian monument in accordance with the new contract of 1532. But his intention was again frustrated. Pope Clement insisted that he must complete his decorations of the Sixtine Chapel by painting anew the great end wall above the altar, adorned until then by frescoes of Perugino. The subject chosen was the Last Judgment; and Michelangelo began to prepare sketches. In the autumn of 1534, in his sixtieth year, he settled for the remainder of his life, at Rome. Immediately afterwards Clement died, and was succeeded by a Farnese under the title of Paul III. Even more than his predecessor, Paul insisted on claiming the main services of Michelangelo for himself.

For the first seven years after the artist's return to Rome, his time was principally taken up with the painting of the colossal and multitudinous "Last Judgment." This being completed in 1541, he was next compelled to undertake two more great frescoes—one of the Conversion of Paul and another of the Martyrdom of Peter—in a new chapel which the pope had caused to be built in the Vatican, and named after himself—Capella Paolina.

The fresco of the "Last Judgment" in the Sixtine Chapel is probably the most famous single picture in the world. In it Michelangelo shows more than ever the omnipotence of his artistic science, and the fiery daring of his conceptions. But the work, so far as its deplorably deteriorated condition admits comparison, is hardly comparable in the qualities of colour and decorative effect to the earlier and far more nobly inspired frescoes of the ceiling. It is to these and not to the "Last Judgment" that the student must turn if he would realize what is best and greatest in the art of Michelangelo.

The frescoes of the Pauline Chapel are on their part so injured as to be hardly susceptible of useful study or criticism. In their ruined state they bear evidence of the same tendencies that made the art of Michelangelo in its latest phase so dangerous an example to weaker men—the tendency, that is, to seek for unqualified energy and violence of action, both in place and out, for "terribleness" *quand même,* and to design actions not by help of direct study from nature, but by scientific deduction from the abstract laws of structure and movement. At best these frescoes can never have been happy examples of Michelangelo's art.

Other Works of 1534–1549. SCULPTURE.—During the fifteen years when Michelangelo was mainly engaged on these paintings, he had also at last been enabled to acquit himself, although in a manner that can have been satisfactory to none concerned, of his engagements to the heirs of Julius. Once more the influence of the pope had prevailed on them to accept a compromise altogether to their disadvantage. By a final contract dated 1542, it was agreed that the "Moses" executed thirty years before, seated on a low plinth in a central recess, should be the chief figure of the new scheme; in niches at either side of him were to be standing figures of "Leah" and "Rachel." These Michelangelo himself executed hastily with the help of assistants. To pupils entirely was left the carrying out of the upper cornice, with the recumbent effigy of the pope occupying the centre of a weak and incongruous architectural scheme, a Madonna and Child in a niche above, and a prophet and a sibyl in recesses at either side. Meantime all idea of incorporating any of the "Slaves" in the new design had been abandoned. The master gave the two that had been finished in 1513–1516 to Robert Strozzi, who gave them to Francis I. "Brutus," marble (National Museum, Florence). Probably executed soon after 1539, in memory of the tyrannicide Lorenzino de' Medici. To the end of this period or to a year or two later belongs the infinitely pathetic unfinished sketch in marble of a life-size "*Pietà*" (Palazzo Rondini, Rome)—the mourning mother, standing on an elevation behind her son, holds his body upright in front of her by the shoulders. Still later, after 1550, is the more complicated and more finished group of the "*Pietà*," with the corpse of Christ collapsing in utter relaxation through the arms of those who try to uphold it: this Michelangelo destined for his own sepulchre; it stands now in the cathedral at Florence.

PAINTING.—"The Entombment of Christ" (National Gallery, London). This unfinished painting bears all the marks of Michelangelo's design, and must have been begun from a cartoon by him, probably of about 1535–1540.

For nearly all his great life-works mentioned above, preparatory sketches and studies by the master's hand exist. These, with a large number of other drawings, finished and unfinished, done for their own sakes and not for any ulterior use, are of infinite value and interest to the student. Michelangelo was the most learned and scientific as well as the most inspired and daring of draughtsmen, and from boyhood to extreme old age never ceased to practise with pen, chalk or pencil. There are some 250 genuine sheets scattered amongst various collections, chiefly public; those in England (at the British Museum, the University Galleries, Oxford, and the Royal Library, Windsor), are quite half the whole number; other important examples remain still at what was for centuries the home of his heirs, the Casa Buonarroti at Florence; others at the Uffizi, Florence; the Venice Academy; the Albertina, Vienna; the Louvre; the Condé Museum at Chantilly; the Berlin Museum; and, not least, the Teyler Museum at Haarlem. By means of these drawings and the many published facsimiles we are best able to trace the progress of the master's genius and its secrets. We see him diligently copying in youth from the frescoes of Giotto, Masaccio, and his own master Ghirlandaio. At this date his instrument was the pen only, used in a manner of hatching: sometimes extremely careful and close, at others fiercely bold and free, and in either case all his own. Sketches and studies thus drawn with the pen exist for the "David," the "Bathers Surprised," the accessory figures for the tomb of Julius as first conceived, and the great series of the Sixtine Chapel decorations. By, or even before, the date of the Sixtine Chapel, chalk, red or black, comes into use along with the pen, and many of the finest studies for the "Slaves" or "Atlases" and other decorative figures of the ceiling are in the latter material (many more studies are preserved for these subordinate figures than for the main compositions). After the Sixtine Chapel period the pen gives way to red or black chalk almost entirely. Sketches are rare for the great abortive scheme of the Julius monument; almost non-existent for the equally abortive San Lorenzo façade; fairly abundant for the various stages of the Medici monument scheme in its architectural parts, but not for the great figures. About the time of Michelangelo's final change of domicile from Florence to Rome (1532–1535) he began the practice of making highly finished and fully shaded drawings of classic or symbolic subjects in red or black chalk for presentation to his friends, especially to young Tommaso Cavalieri, the object of his passionate Platonic affection, from about 1532. The "Fall of Phaeton," the "Tityos," the "Ganymede," the "Men shooting at a Mark," are well-known examples; in this class of work the Windsor collection is far the richest. At the same time, or soon afterwards, were produced drawings little less powerful and finished of Christian subjects, especially the "Crucifixion," "Entombment" and "Resurrection." Then comes the great fresco of the "Last Judgment," for which there exist both general sketches and particular studies. In the few extant drawings for the Capella Paolina a faltering both of the imagination and of the hand become discernible. To the same or to still later years belong many beautiful but somewhat tentative drawings done either directly for, or nearly in the spirit of, the famous "Crucifixion" which he is recorded to have painted with so much devotion for Vittoria Colonna.

Poetry.—During his later years the long-pent human elements of fervour and tenderness in Michelangelo's nature had found utterance such as they had never found before. He had occasionally practised poetry in youth, and there are signs of some transient love-passages during his life at Bologna. But it was not until towards his sixtieth year that the springs of feeling were fairly opened in the heart of this solitary, this masterful and stern, life-wearied and labour-hardened man. About 1533–1534 we find him beginning to address impassioned sonnets—of which the sentiment is curiously comparable to that expressed in some of Shakespeare's—to a beautiful and gifted youth, the young Roman noble Tommaso Cavalieri. Soon afterwards he made the acquaintance of the pious, accomplished and high-souled lady, Vittoria Colonna, widow of the Marquess Pescara. For ten years until her death, which happened in 1547, her friendship was the great solace of Michelangelo's life. On her, in all loyalty and reverence, he poured out all the treasures of his mind and all his imprisoned powers of tenderness and devotion. She was the chief inspirer of his poetry—of which, along with her praises, the main themes are the Christian religion, the joys of Platonic love, and the power and mysteries of art. Michelangelo's poetical style is strenuous and concentrated like the man. He wrote with labour and much self-correction; we seem to feel him flinging himself on the material of language with the same overwhelming energy and vehemence with which contemporaries describe him as flinging himself on the material of marble—the same impetuosity of temperament combined with the same fierce desire of per-

fection, but with far less either of innate instinct for the material or of trained mastery over its difficulties.

Last Years: Architecture.—And so the mighty sculptor, painter and poet reached old age. An infirmity which settled on him in 1544, and the death of Vittoria Colonna in 1547, left him broken in health and heart. But his strength held on for many a year longer yet. His father and brothers were dead, and his family sentiment concentrated itself on a nephew, Leonardo, to whom he showed unremitting practical kindness, coupled with his usual suspiciousness and fitfulness of temper. During the last years of his life he was much employed in the fourth art in which he excelled—that of architecture. A succession of popes demanded his services for the embellishment of Rome. Between 1536 and 1546 he was engaged on plans for the rearrangement and reconstruction of the great group of buildings on the Capitol—plans which were only partially and imperfectly carried out during his lifetime and after his death. For Paul III. he finished the palace called after the name of the pope's family the Farnese. On the death of Antonio da San Gallo he succeeded to the onerous and coveted office of chief architect of St. Peter's church, for which he remodelled all the designs, living to see some of the main features, including the supports and lower portion of the great central dome, carried out in spite of all obstacles, according to his plans. The dome as it stands is his most conspicuous and one of his noblest monuments: the body of the church was completed in a manner quite different from his devising. Other great architectural tasks on which he was engaged were the reconstruction of the Porta Pia, and the conversion of a portion of the baths of Diocletian into the church of Sta. Maria degli Angeli; the great cloister with its hundred columns, now used as the Museo delle Terme, is the only part of this reconstruction which remains as he designed it. At length, in the midst of these vast schemes and responsibilities, the heroic old man's last remains of strength gave way. He died on the threshold of his ninetieth year, on Feb. 18, 1564.

AUTHORITIES.—For the bibliography of Michelangelo, which is extensive, *see* E. Steinmann and R. Wittkover, *Michelangelo-Bibliographie* (Leipzig, 1927). The most important works, taken in chronological order, are the following: P. Giovio, supplement to the fragmentary *Dialogus de viris litteris illustribus*, written soon after 1527, first published by Tiraboschi, *Storia della letteratura italiana* (Modena, 1871); G. Vasari, in *Vite degli più eccellenti architettori pittori, e scultori*, etc. (Florence, 1550); A. Condivi, *Vita di Michelangelo Buonarroti* (1553); this account, for which the author, a pupil and friend of the master's, had long been collecting materials, was much fuller than that of Vasari, who made use of it in rewriting his own life of Michelangelo for his second edition, which appeared after the master's death (1568). The best edition of Vasari is that by Milanesi (Florence, 1878–83); of Condivi, that by Antonio Maraini (Florence, 1927); for English readers there is a useful translation by H. Home (Boston, 1904). *See* also C. Holroyd, *Michael Angelo Buonarroti* with translations of the life of the master by Ascanio Condivi and three Dialogues from the Portuguese by Francisco D'Ollanda (1903). The first additions of importance were published by Bottari, *Raccolta di lettere sulla pittura*, etc. (Rome, 1754; 2nd ed. by Ticozzi, Milan, 1822); the next by Gaye, *Carteggio inedito* (1840). Portions of the correspondence preserved in the Buonarroti archives were published by Guasti in his notes to the *Rime di Michelangelo Buonarroti* (1863), and by Daelli in *Carte Michelangelsche inedite* (Milan, 1865). Complete biographies of Michelangelo had been meanwhile attempted by J. Harford (London, 1857), and with more power by Hermann Grimm, *Leben Michelangelos* (Hanover, 5th ed., 1879). A great increment of biographical material was at length obtained by the publication, in the four-hundredth year after Michelangelo's birth, of the whole body of his letters preserved in the Buonarroti archives, *Lettere di Michelangelo Buonarroti*, ed. G. Milanesi (Florence, 1875). This material was first employed in a connected but too trivial narrative by A. Gotti, *Vita di Michelangelo* (Florence, 1875). Next followed C. Heath Wilson, *Life and Works of Michelangelo Buonarroti* (Florence, 1876), the technical remarks in which, especially as concerns the fresco paintings, are still valuable. Other lives of Michelangelo are by J. A. Symonds, *The Life of Michelangelo* (London, 1893), full of valuable matter on the history and spirit of Michelangelo's times, but not trustworthy in the criticism of his works. *Michelangelo*, by Fritz Knapp, in the *Klassiker der Kunst* series (Stuttgart, 1906) is a very useful compendium. For the early works of Michelangelo the standard authority is H. Wölfflin, *Die Jugendwerke Michelangelos* (Munich, 1891, and later editions). The most elaborate study of the Sixtine frescoes, magnificently illustrated, is by E. Steinmann, *Die Sixtinische Kapelle*, vol. ii. (Munich, 1905). Consult also C. Justi, *Michelangelo* (Leipzig, 1903), and with caution H. Thode, *Michelangelo u. das Ende der Renaissance* (1902–03). Of the poems of Michelangelo the first sound edition is that already referred to, G. Guasti, *Rime di Michelangelo Buonarroti* (1863); in earlier editions the text had been recklessly tampered with, and the rugged individuality of the master's style smoothed down. An edition with German translations was published by Hasenclever (Leipzig, 1875); and a thorough critical edition by Karl Frey (Berlin, 1897); for the English student the translations by J. A. Symonds, in *Sonnets of Michelangelo and Campanella* (1878) are invaluable. On the drawings of Michelangelo *see* especially B. Berenson, *The Drawings of Florentine Painters* (1903). A comprehensive work on the same subject, in which the most important examples are reproduced and discussed, unfortunately not arranged chronologically, is Karl Frey, *Die Zeichnungen Michelangelos* (Berlin, 1908 *seq.*). An elaborate life by the same author (Karl Frey, *Michelagniolo Buonarroti, sein Leben und seine Werke*) is more to be prized for documentary fullness and accuracy than for critical insight. *See* also Romain Rolland, *Vie de Michelange* (1917); E. Steinmann, *Die Portraitdarstellungen des Michelangelo* (Leipzig, 1913).
(S. C.; X.)

MICHELET, JULES (1798–1874), French historian, was born at Paris on Aug. 21, 1798, of a family which had Huguenot traditions. His father was a master printer, and Jules was offered a place in the imperial printing office, but his father sent him to the Lycée Charlemagne, where he passed the university examination in 1821. Shortly after appointed he began to teach history in the Collège Rollin. Soon after this, in 1824, he married. Between 1825 and 1827 he produced divers sketches, chronological tables, etc., of modern history. In 1827 he was appointed maître de conférences at the École normale.

Four years later, in 1831, the *Introduction à l'histoire universelle* showed a very different style, displaying the peculiar visionary qualities which made Michelet the most stimulating, but the most untrustworthy (not in facts, which he never consciously falsifies, but in suggestion) of all historians. The events of 1830 had unmuzzled him, and had put him in a better position for study by obtaining for him a place in the Record Office, and a deputy-professorship under Guizot in the literary faculty of the university. Soon afterwards he began his chief and monumental work, the *Histoire de France*. But he accompanied this with numerous other books, chiefly of erudition, such as the *Oeuvres choisies de Vico*, the *Mémoires de Luther écrits par lui-même*, the *Origines du droit français*, and somewhat later the *Procès des templiers*. In 1838 he was appointed to the chair of history at the Collège de France. He published, in 1839, his *Histoire romaine*. The results of his lectures appeared in the volumes *Le Prêtre, la femme, et la famille* and *le peuple*.

The principles of the outbreak of 1848 were in the air, and Michelet was one of those who condensed and propagated them. When the actual revolution broke out Michelet devoted himself even more strenuously to his literary work.

He began and carried out, during the years between the downfall of Louis Philippe and the final establishment of Napoleon III., an enthusiastic *Histoire de la révolution française*. Despite or because of its enthusiasm, this was by no means Michelet's best book.

The *coup d'état* lost Michelet his place in the Record Office, as, though not in any way identified with the republic administratively, he refused to take the oaths to the empire. But the new régime only kindled afresh his republican zeal, and his second marriage (with Mlle. Adèle Malairet) seems to have further stimulated his powers. While the history steadily held its way, a crowd of extraordinary little books accompanied and diversified it. Sometimes they were expanded versions of its episodes, sometimes what may be called commentaries or companion volumes. In some of the best of them natural science, a new subject with Michelet, to which his wife is believed to have introduced him, supplies the text. These are *Les Femmes de la révolution* (1854), *L'Oiseau* (1856), *L'Insecte*, *L'Amour* (1859), *La Femme* (1860), *La Mer* (1861), and *La Sorcière* (1862). Developed out of an episode of the history, *La Sorcière* has all its author's peculiarities in the strongest degree. It is a nightmare and nothing more, but a nightmare of the most extraordinary verisimilitude and poetical power. Later short works are: *La Bible de l'humanité* (1864), an historical sketch of religions; *La Montagne* (1868); *Nos fils* (1869), a tractate on education; and *Le*

Banquet, posthumously published, a vivid picture of the industrious and famishing populations of the Riviera. Two collections of pieces, written and partly published at different times, are *Les Soldats de la révolution* and *Légendes démocratiques du nord.*

The publication of this series of books, and the completion of his history, occupied Michelet during both decades of the empire. He lived partly in France, partly in Italy, and was accustomed to spend the winter on the Riviera, chiefly at Hyères. At last, in 1867, the *Histoire de France* was finished. In the usual edition it fills nineteen volumes. Michelet was perhaps the first historian to devote himself to anything like a picturesque history of the middle ages, and his account is still the most vivid that exists. His inquiry into manuscript and printed authorities was most laborious, but his lively imagination, and his strong religious and political prejudices, made him regard all things from a singularly personal point of view.

Uncompromisingly hostile as Michelet was to the empire, its downfall and the accompanying disasters of the country once more stimulated him to activity. Not only did he write letters and pamphlets during the struggle, but when it was over he set himself to complete the vast task which his two great histories had almost covered by a *Histoire du XIX siècle.* He did not, however, live to carry it farther than Waterloo. The new republic was not altogether a restoration for Michelet, and his professorship at the Collège de France of which he contended that he had never been properly deprived, was not given back to him. He died at Hyères on Feb. 9, 1874.

Monod, *La vie et la pensée de J. Michelet, 1798–1852* (2 vols. 1923); and L. Refort, *L'art de Michelet dans son oeuvre historique* (1923).

MICHELL, JOHN (1724–1793), English natural philosopher and geologist, was born in 1724, and educated at Queens' College, Cambridge. He was a fellow of his college, and was appointed Woodwardian professor of geology in 1762, and in 1767 rector of Thornhill in Yorkshire, where he died on April 29, 1793. He was elected a fellow of the Royal Society in 1760. In 1750 he published at Cambridge a work of some 80 pages entitled *A Treatise of Artificial Magnets, in which is shown an easy and expeditious method of making them superior to the best natural ones.* Besides the description of the method of magnetization which still bears his name, this work contains a lucid exposition of the nature of magnetic induction. He was the founder of seismology. Michell was the original inventor of the torsion balance, which afterwards became so famous in the hands of its second inventor Coulomb. Michell described it in his proposal of a method for obtaining the mean density of the earth. He did not live to put his method into practice; but this was done by Henry Cavendish (*Phil. Trans.*, 1708). His most important geological essay was that entitled *Conjectures concerning the Cause and Observations upon the Phaenomena of Earthquakes* (*Phil. Trans.*, li. 1760).

Michell's other contributions to science are: "Observations on the Comet of January 1760 at Cambridge, *Phil. Trans.* (1760); "A Recommendation of Hadley's Quadrant for Surveying," *ibid.* (1765); "Proposal of a Method for measuring Degrees of Longitude upon Parallels of the Equator," *ibid.* (1766); "An Inquiry into the Probable Parallax and Magnitude of the Fixed Stars," *ibid.* (1767); "On the Twinkling of the Fixed Stars," *ibid.* (1767), "On the Means of Discovering the Distance, Magnitude, etc., of the Fixed Stars," *ibid.* (1784).

See Charles Davidson, *The Founders of Seismology* (1927).

MICHEL OF NORTHGATE, DAN (*fl.* 1340), English writer, the author of the *Ayenbite of Inwyt.* Nothing is known of him except what can be gathered from his work. It is a literal translation in the Kentish dialect of a French treatise entitled *Le Somme des vices et des vertues* (also known as *Le Miroir du monde* or *Le Livre des commandemens*, etc.), written in 1279 by Laurentius Gallus, a Dominican monk and confessor to Philip III. of France. This work was translated into Flemish, Catalonian, Spanish and Italian, and appears in no less than six English translations. Dan Michel's autograph ms. is preserved in Arundel ms. 57, which states that the work was completed in the year 1340 on the eve of the apostles Simon and Jude by Dan Michel of Northgate, a brother of the cloister of St. Austin of Canterbury. The value of the book is chiefly philological as an authenticated and dated example of the southern dialect.

The *Ayenbite of Inwyt* was edited for the Roxburghe club by the Rev. J. Stevenson in 1855, and for the early English Text Soc. by R. Morris in 1876.

MICHELOZZO DI BARTOLOMMEO (1396–1472), Italian architect and sculptor, was a Florentine by birth, the son of a tailor. He was trained as a goldsmith and at the age of 24 entered the workshop of Ghiberti, whom he assisted on both doors of the Florentine Baptistry and with the statue of St. Mather's for Or San Michele. He assisted Donatello in bronze work such as the "St. Louis" for Or San Michele and the "Salome's Dance" in the Sienese Baptistery. In 1428 he signed the contract for the exterior pulpit of the cathedral at Prato of which the sculpture is by Donatello. His first independent work in sculpture was the tomb of Bartol. Aragazzi, parts of which are at Montepulciano, and of which the Victoria and Albert Museum has two fine figures of angels (1437). Michelozzo's great friend and patron was Cosimo de' Medici, whom he accompanied to Venice in 1433 during his short exile. While at Venice, Michelozzo built the library of San Giorgio Maggiore. The magnificent Palazzo Medici-Riccardi at Florence was designed by him for Cosimo (1444); it is one of the noblest specimens of Italian 15th-century architecture. He built the library, convent and cloister of San Marco in Florence (1437–1452). In 1446 he succeeded Brunneleschi as architect of the Duomo. In 1448 he executed the tabernacle at S. Miniato for Piero de' Medici. The beautiful silver statuette of the Baptist now in the Opera del Duomo is dated 1452. He remodelled the interior of the Palazzo Vecchio, especially the main court and the hall of The Two Hundred. At Milan he remodelled the Palace of the Medici, now Vismara, and built the Portinari Chapel at the church of S. Eustorgio. He was called to Ragusa in Dalmatia in 1464 and there designed the arcade of the Palazzo Rettorale. He also superintended the fortification on the island of Chios. He died in Florence in 1472 and is buried in San Marco

MICHELSEN, PETER CHRISTIAN HERSLEB KJERSCHOW (1857–1925), Norwegian statesman, was born at Bergen on March 15, 1857. At the general election of 1903 he was returned to the Storting as a member for the country district outside Bergen. Appointed Prime Minister in the spring of 1905 Michelsen played a leading part in the events which resulted in the dissolution of the union with Sweden and the establishment of the new kingdom of Norway. In 1907 he definitely retired from politics and died near Bergen on June 29, 1925.

MICHELSON, ALBERT ABRAHAM (1852–), American physicist, was born in Strelno, Germany, Dec. 19, 1852. His parents moved to San Francisco, Calif., where he studied in the public schools. He graduated from the U.S. Naval Academy in 1873, and was instructor in physics and chemistry there (1875–79). He was then for a short time in the *Nautical Almanac* office. From 1880 to 1882 he studied in Berlin, Heidelberg and Paris. He resigned from the Navy in 1881. In 1883 he was appointed professor of physics at the Case school of applied science, Cleveland, O., and six years later accepted a similar position at Clark University. In 1892 he was appointed professor and head of the department of physics at the University of Chicago. He early directed his researches to the velocity of light, and while in Cleveland invented his interferometer for measuring distances by means of the length of light-waves. His researches enabled him to revise and improve upon the achievements of Fizeau in respect of the velocity of light. He perfected the methods for experimenting, and determined with great precision the speed at which light travels.

Michelson measured a metre in terms of the wave-length of cadmium light for the Paris Bureau International des Poids et Mesures. The consequence is that the metre bar, hitherto carefully safeguarded in Paris, can easily be replaced, since its length

is known in terms of an absolute unit. In 1892 he was a member of the Bureau International des Poids et Mesures and in 1897 of the International Committee of Weights and Measures. He was president of the American Physical Society in 1901, of the American Society for the Advancement of Science in 1910, and of the National Academy of Science (1923–27). He received medals and prizes from many learned societies, and in 1907 was awarded the Nobel Prize for physics. During the World War he rejoined the naval service and devoted his entire time to new devices for naval use. His range-finder was adopted as part of the U.S. Navy equipment. In 1920 he was able to demonstrate by means of light interference that the diameter of Betelgeuse was 260,000,000 miles. This was the first approximately accurate determination of the size of a star. He published *Velocity of Light* (1902); *Light Waves and Their Uses* (1903); *Studies in Optics* (1927); and numerous papers in scientific journals. He was the first to be appointed "distinguished service professor" at the University of Chicago (1926). (For the "Michelson-Morley experiment" in interference of light, with its bearing on the Einstein theory, *see* RELATIVITY.)

MICHELSON-MORLEY EXPERIMENT. A celebrated experiment carried out by A. A. Michelson and E. W. Morley, to attempt to measure a velocity of the earth through the ether by the effect which such a velocity might be anticipated to have on the velocity of light. Had such a velocity been established, axes fixed in the ether could have been taken as standards of fixed position, to which all velocities could be referred, and in this sense we should have been able to talk of the absolute velocity of a material body, as distinct from the relative velocity of two material bodies. The failure of Michelson and Morley to detect any influence of the earth's motion on the velocity of light really formed the starting point of Einstein's theory of relativity (*see* RELATIVITY), and it is on account of its importance for this theory that the experiment is so fundamental, and has been so often repeated.

In the experiment light is sent along two paths at right angles to one another. If the luminiferous ether were a fixed medium, obeying the laws of such a wave-carrying medium as an elastic solid (or, to be more correct, if less suggestive, of a medium obeying the laws represented by Maxwell's original equations) then the time of the passage of the light should be greater for a to-and-fro path in the direction of the earth's motion through the ether than for a to-and-fro path, of equal length, at right angles to the direction of motion. More precisely, when light goes from a source to a mirror at distance l and back, and both source and mirror are moving with the same velocity v, the time taken is $\frac{l}{c-v}+\frac{l}{c+v}$ when the motion is in the direction of the rays, and is

$$\frac{2l}{c}\Big/\sqrt{\left(1-\frac{v^2}{c^2}\right)}$$

when it is crosswise, c being velocity of light. These expressions are approximately $\frac{2l}{c}\left(1+\frac{v^2}{c^2}\right)$ and $\frac{2l}{c}\left(1+\frac{1}{2}\frac{v^2}{c^2}\right)$ respectively, so that the difference depends on $\left(\frac{v}{c}\right)^2$ which, on account of the smallness of all terrestrial velocities compared to the velocity of light, is very small and requires the greatest refinement of experimental skill for its detection. (*See* RELATIVITY.)

If, therefore, the apparatus can be set so that one path lies in the direction of motion, and can then be turned through a right angle, the two beams of light will interchange their rôles, the one which in the first position travelled the faster travelling the slower in the second position. If, further, a system of interference fringes is formed by the two beams, as is done in the Michelson interferometer (*see* INTERFEROMETER), then it follows at once that this fringe system will shift when the apparatus is slowly rotated, so that it must pass through the two positions just specified twice per revolution. Michelson and Morley looked for, but failed to find, any shift of fringes of the order of magnitude to be expected on the hypothesis of a fixed ether.

Preliminary experiments were carried out by Michelson alone in 1881; the experiment with Morley, of a superior order of accuracy, was performed in 1887. In the experiment of 1887 the interferometer was mounted on a heavy block of stone which was carried by a disc of wood floating in a tank of mercury: this arrangement enabled the apparatus to be rotated smoothly without causing any strains to be set up. To increase the light path, and so the effect to be sought, each of the interfering beams was reflected several times backwards and forwards: four mirrors were used to replace each of the single mirrors in the simple form of interferometer, and their supplementary mirrors. The total length of the path of either beam was about 1,100 cm. With such a path length the difference of times to be expected on the fixed ether hypothesis, though only about 1 in 100,000,000, should give rise to a displacement of ·4 of a fringe. But the actual displacement measured was at most a fortieth of this value. In carrying out the experiment the orbital motion of the earth alone was considered, the sun being considered at rest. (The rotational motion of the earth produces a velocity which is, of course, negligibly small compared to the orbital motion.) Readings were made for sixteen different directions, the stone being kept slowly turning and the observations taken by the experimenter walking round with it. The experiment was carried out at midday, when the velocity relative to the sun is in the plane of the apparatus, and at 6 P.M., when the velocity is normal to the plane of the apparatus. To see if there was a velocity of the solar system as a whole through the ether, which might, by a remote chance, have cancelled out the orbital motion at the particular month of the experiment, it was proposed to repeat the experiment every three months. Recent experiments have put this possible explanation of the negative effect out of court.

The experiment is of such fundamental importance that it has been much repeated, with a view both to increasing the accuracy and to investigating suggested explanations of the negative effect, other than that offered by the theory of relativity. In 1904, that is, a year before Einstein first put forward his theory, Morley and Miller carried out new measurements. It had been suggested that the contraction in the direction of motion demanded by the Fitzgerald-Lorentz hypothesis (*see* RELATIVITY) might be a property of particular materials only, and that it would be desirable to try the effect of replacing the stone on which the interferometer parts were mounted by other substances. Morley and Miller used both a wooden and a steel framework to support the apparatus, which was floated on mercury, as in 1887. The path length was increased to 3,224 cm., which is 55 million wave lengths of yellow (sodium) light, so that the fringe displacement should, on the hypothesis of a stationary ether, be 1·1 fringes in place of the ·4 fringes of 1887. In the cellar at Cleveland where the apparatus was mounted the effect was less than one hundredth of this amount, which is alternatively expressed by saying that these results show that the velocity of the earth with reference to a hypothetical stationary ether is at most 3 kilometers (say 2 miles) a second. (The shift is, of course, proportional to the *square* of the velocity, and the earth's orbital velocity is about 30 kilometres per second.) Morley and Miller took into account the motion of the solar system towards a certain fixed point in the heavens, and compounded this with the velocity of the earth in the solar system when computing the magnitude and direction of the velocity of the apparatus.

In 1905 and 1906 Morley and Miller removed their apparatus from the cellar and installed it in a light shed at a height of 300 feet above Lake Erie, to see if possibly the nature of the immediate surroundings, whether massive or no, affected the "ether wind" which the experiment was designed to detect. A possible effect of about $\frac{1}{10}$ of the calculated value was detected, but it was not clear whether this was a spurious effect of temperature. It would be a result of the first importance, constituting a grave blow to the theory of relativity, if an actual effect, which varied with the height above sea level or with the surroundings, could be definitely established, and therefore in 1921 and again in 1925 D. C. Miller carried out experiments of the Michelson and Morley type at Mount Wilson, about 1,800 metres (6,000 feet) above sea

level. To avoid possible magnetic effects the steel frame used in the earlier experiments was later replaced by a concrete frame. Miller, as a result of several thousand readings, arrived at the conclusion that there was a small positive effect, about 9 kilometers per second, as against the full orbital velocity of 30 kilometers per second, and also considered that the experiments in the cellar at Cleveland showed a still smaller positive result. He attempted to explain his results by a drift of the solar system in a direction nearly normal to the plane of the ecliptic. These experiments of Miller naturally attracted much attention, but it appears almost certain that the positive effect must be due to unrecognised sources of error, possibly to temperature effects. It has, for instance, been pointed out, notably by Thirring, that the measurements of Miller are not consistent among themselves, from the point of view of his explanation.

To check Miller's results R. J. Kennedy repeated the experiment, using an ingenious modification of the interferometer, produced by making a small step, only one-twentieth of a wave length in height, on one of the totally reflecting mirrors. This produces two fringe systems bordering on one another, which enables a very slight displacement of the interference patterns, of the order of 4 thousandths of a fringe, to be detected. Kennedy's apparatus was comparatively small, the light path being only 4 metres, and sealed up in a case containing helium, the refractivity of which is only one-eighth that of air, at atmospheric pressure. The experiments were carried out at times of day when Miller's effect should be greatest, but no positive effect was ever found. although a shift one-quarter as great as that measured by Miller would have been detected. K. K. Illingworth has repeated Kennedy's experiments, likewise finding no positive result (1927). Both Kennedy's and Illingworth's experiments were carried out in a constant temperature basement at Pasadena, California, which gives defenders of the reality of Miller's effect a possible line of criticism, namely that while no positive result can be found in a sheltered spot, where massive surroundings check the "ether wind," this does not prove that a small positive effect does not exist at a height, in a free situation. This last possibility is, however, removed by the experiments of Piccard and Stahel, carried out at intervals from 1926 to 1928. These workers placed the apparatus in a free balloon, the chief measurements being made at a height of 2,500 metres. The apparatus was a small interferometer of Michelson-Morley pattern, with multiple reflections. The fringes were registered photographically, on a moving film, and the balloon was kept in steady rotation by small air screws. No trace of an effect was ever found.

In January, 1929, Michelson published a preliminary account of a repetition of the Michelson-Morley experiment carried out by himself in collaboration with Drs. Pease and Pearson, with new refinements: the results, in contradiction to Miller's, were negative.

We may therefore say that the broad result of a series of experiments of Michelson-Morley type is that no motion of the earth through the ether can be detected by an influence on the velocity of light. For theoretical implications *see* RELATIVITY.

BIBLIOGRAPHY.—Brief accounts of the Michelson-Morley experiment are given in the standard text-books of light, cited under LIGHT, and the experiment is discussed in all books on relativity (*q.v.*). The most important original papers are:—A. A. Michelson and E. W. Morley, *Philosophical Magazine*, 24, 449 (1887); E. W. Morley and D. C. Miller, *Philosophical Magazine*, 9, 680 (1905); D. C. Miller, *Proceedings National Academy of Sciences*, 11, 306 (1925); H. Thirring (criticism of D. C. Miller's results), *Zeitschrift für Physik*, 35, 723 (1926); J. R. Kennedy, *Proceedings National Academy of Sciences*, 12, 621 (1926); K. K. Illingworth, *Physical Review*, 30, 692 (1927); A. Piccard and E. Stahel, *Naturwissenschaften*, 14, 935 (1926); 15, 140 (1927); 16, 25 (1928); A. A. Michelson, *Nature*, 123, 88 (1929). (E. N. DA C. A.)

MICHIGAN (mĭsh'ĭ-gan), known as the "Wolverine State," is one of the north central group of the United States of America. It is situated between latitudes 41° 44′ and 47° 30′ N. and longitudes 82° 25′ and 90° 31′ W., and consists of two peninsulas,—the upper or northern and the lower or southern—separated by a strait. The upper peninsula is bounded north by Lake Superior; east by lakes Superior, Huron and Michigan, and by Whitefish bay and St. Mary's river, which separate it from the Province of Ontario, Canada; south by lakes Huron and Michigan and the straits of Mackinac, which separate it from the lower peninsula; and south-west and west by Wisconsin, and the Menominee, Brule and Montreal rivers, which separate it from Wisconsin. The lower peninsula is bounded north by lakes Michigan and Huron and the straits of Mackinac, east by lakes Huron, St. Clair and Erie and the St. Clair and Detroit rivers, which separate it from Ontario; south by Ohio and Indiana, and west by Lake Michigan. In size Michigan ranks 21st among the States of the Union, its total area being 57,980 sq.m. of which 500 sq.m. exclusive of its Great Lakes jurisdiction, are water surface.

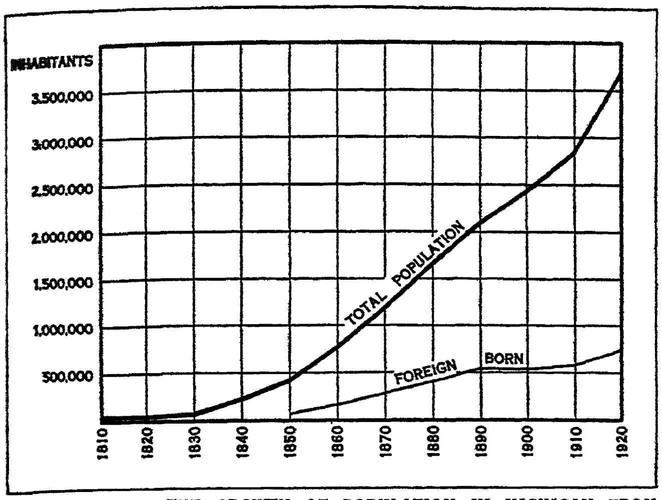
Physical Features.—The northern part of the State is rugged mountainous "old land," not completely worn down by erosion; and the southern part is a portion of the old coastal plain, whose layers contain salt, gypsum and some inferior coal. Lake Huron, on the east, and Lake Michigan on the west of the lower peninsula are each 581½ ft. above sea-level, and Lake Superior on the north of the upper peninsula is 602 ft. above sea-level. For the most part the surface of the State is gently undulating and at a slight elevation above the lakes, but low marsh lands are common to many sections; the north part of the lower peninsula is occupied by a plateau of considerable dimensions, and the north-west part of the upper peninsula is rugged with hills and mountains. Crossing the lower peninsula from Saginaw bay west by south through the valleys of the Saginaw, Maple and Grand rivers, is a depression—the former channel of an old glacial river—in which elevations for a considerable area are less than 100 ft. above the lakes. To the south-east of this depression a water-parting with summits varying from about 400 to 600 ft. above the lakes extends from a point between Saginaw bay and Lake Huron, south by west, to the south border of the State and beyond. The east slope descends quite rapidly to a low flat belt from 5 to 40 m. wide along the east border of the State south from Lake Huron. From Lake Huron to the south-east shore of Saginaw bay a wide sandy beach

MAP SHOWING THE MAIN ROADS IN MICHIGAN

is followed northward by precipitous shores abounding in rocks and bluffs. West of the divide and south of the depression, southwest Michigan is occupied by the valleys of the St. Joseph, Kalamazoo and Grand rivers, by the gently rolling uplands that form the parting divides between them, and by sand dunes, which here and there rise to a height of from 100 to 200 ft. or more along the shore of Lake Michigan, and are formed on this side (but not on the Wisconsin side) of the lake by the prevailing west winds.

The surface of the upper peninsula is more irregular than that of the lower peninsula. A portion extending through the middle

from east to west and south, from west of the centre of Green bay, is either flat and even swampy or only gently undulating. Eastward from Green bay are two ranges of hills; the one lining the south shore and ranging from 100 to 300 ft. in height, the other close to or touching the north shore and reaching in places an elevation of 600 ft. above Lake Superior. The famous Pictured rocks in Alger county on the lake shore, east of Munising, form the



GRAPH SHOWING THE GROWTH OF POPULATION IN MICHIGAN FROM 1810–1920, AND THE PERCENTAGE OF FOREIGN BORN

west portion of this north range; they display a wide diversity of shapes as well as a great variety of tints and hues, especially of grey, blue, green and yellow. The most rugged portion of the State is farther west. South and south-east of Keweenaw bay, in the Marquette iron district, is an irregular area of mountains, hills, swamps and lakes, some of the mountain peaks of the Huron mountains (in Marquette county) rising to an elevation of 1,400 ft. or more above the lake. These and a peak in the Porcupine mountains (2,023 ft. above the sea) in the north-west part of Ontonagon county are the highest in the State. To the south of this is the Menominee iron district, marked somewhat regularly by east and west ridges. Extending in a general north-east and south-west direction through Keweenaw peninsula to the Wisconsin border, and beyond, is the middle of three approximately parallel ranges, separated from each other by flat lands, with here and there an isolated peak (in the Porcupine mountains) having an elevation of from 900 to 1,400 ft. above the lake. The northern portion of these ranges, together with Isle Royale some distance farther north, which is itself traversed by several less elevated parallel ridges, contains the Michigan copper-bearing rocks; while to the south, along the Wisconsin border, is the Gogebic iron district.

The rivers of the entire State consist of numerous small streams of clear water. In the interior of the upper peninsula, along the east border of the lower peninsula south from Lake Huron, and in Saginaw valley, they are rather sluggish; but many of the larger streams of the lower peninsula have sufficient fall to furnish a large amount of water-power, while the small streams that flow into Lake Superior from the central portion of the upper peninsula as well as some of the larger ones farther west, have several falls and rapids; in places also they are lined with steep, high banks. Most of the larger rivers of the State—the Muskegon, Grand, St. Joseph, Manistee and Kalamazoo—are in the west portion of the lower peninsula. Several thousand lakes of clear water, formed by glacial action, dot the surface of the State, and many of them are lined with picturesque woodland shores. Islands in lakes Superior, Michigan and Huron are scarcely less numerous.

Fauna and Flora.—Mammals include black bear, moose, deer, lynx, wolves, coyotes, wildcats, porcupine, fox, squirrels, hares, rabbits, musk rats, minks, weasels, skunks, racoons and woodchucks. The only woodland caribou now known in United States proper are found on Isle Royale. Among the game birds are quail ("Bob White"), grouse, including "partridges" (ruffed grouse), ducks, geese, coots, brant, woodcocks, snipe and plover, as well as the imported Chinese ring-necked pheasants. Of song birds the favourites are the robin, thrush, bobolink, oriole, chickadee, meadow-lark, cat-bird, blue-bird, wrens and warblers. Among fishes, white fish, wall-eyes, lake trout, perch, herring, sun-fish, bass, sturgeon, pike, chubs, suckers, mullets, sheepheads and German carp abound in the lakes. The speckled, brown and rainbow trout thrive in many of the streams. The area now included in Michigan was a forest, except in the south-west, where there were a few small prairies, possibly cleared by the Indians. The remainder of the south part of this area for about 60 m. along the southern boundary was a part of the great hardwood forest of the Ohio basin with woods varying with soil and drainage: on the drier gravel lands were oak forests consisting of red, black and white oak, hickory, ash, cherry, basswood and walnut; in depressions there were maple, elm, ash, beech, sycamore, poplar and willow; and in the south-east there were a few chestnuts and tulip trees. North of this southern hardwood forest there were pine forests on the sandier land, mixed hardwoods and conifers on the loam and clay, and tamaracks and cedar in the swamps. The sandy lands were in part burnt over by Indians, and there was a growth of scrub oak, aspens and huckleberry bushes. The tamarack and cedar swamps now have a growth, especially on their edges, of spruce, birch, balsam, white pine, soft maple, ash and aspens. In 1920 the woodland area, including stump lands, was estimated at nearly two-thirds of the entire State; but of this area not more than 4,000,000 ac. now bear timber worth cutting. The State controls eight forest reserves, whose area is 356,388 ac., which are being re-forested at a rate of about 10,000 ac. a year. White pine, Norway pine and Jack pine are the only species planted. Two national forest units, embracing about a million acres, were established in 1928.

Soil and Climate.—The soil of the south-west and south-east Michigan is for the most part a dark clay loam; in the north central part of the lower peninsula it is a light sandy loam, along the Huron shore it is heavy with blue clay, in the mining districts of the north-west the rocks are usually either barren or very thinly covered; and elsewhere in the State the soil is generally rich in a variety of mineral elements.

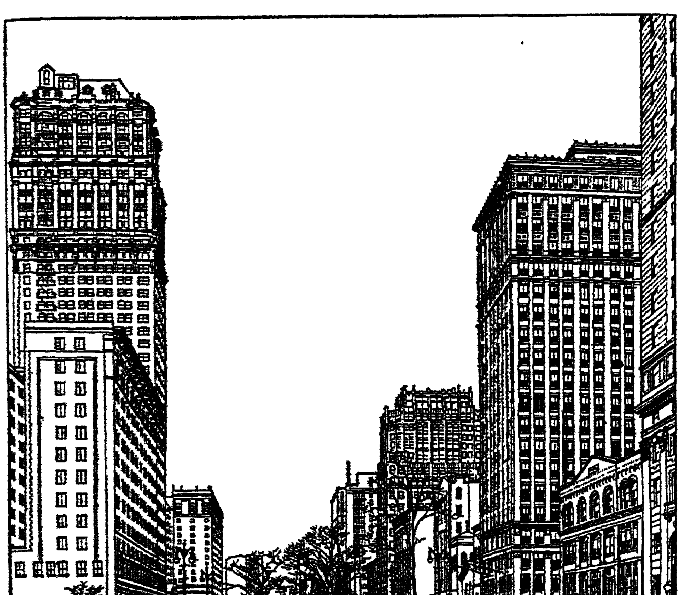
Although the temperature of the entire lower peninsula is considerably influenced by the lakes, yet the prevailing winds being westerly, it is in the west portion of that peninsula that the moderation is greatest, both the summer and winter isotherms being there deflected more than half the length of the peninsula. On the other hand, the prevailing winds of the upper peninsula being north-westerly, the lakes have little effect on the temperature there; and so, while in the south-west the extremes are not great, in the rest of the State they have ranged within two years from 108° to 48° below zero. Throughout the State July is invariably the warmest month, February the coldest; the mean annual temperature is about 45°. The mean annual precipitation is not far from 31 in., a little more than one-half of which falls during the five growing months from May to October; the rain is evenly distributed over all parts of the State, but the snow is exceptionally heavy along the north shore of the upper peninsula.

Government.—The Constitution under which Michigan is now governed was first adopted in 1850, when it was felt that the powers which the first one, that of 1835, conferred upon the executive and the legislature were too wide. In 1908 it was revised.

The Constitution admits of amendment by an affirmative vote of two-thirds of the members of each house of the legislature, followed by an affirmative vote of a majority of the electors voting upon the question; or an amendment may be proposed by an initiative petition signed by 10% of the total number of electors, and such an amendment is submitted to popular vote at the next election and comes into effect only if it receives a favourable majority of the popular vote. Amendments suggested by the legislature have been frequently adopted, and one, adopted in 1862, provided that the question of a general revision of the Constitution shall be submitted to a popular vote once every 16 years and at such other times as might be provided by law. When this question was so submitted for the first time, in 1866, the vote was to revise; but the revision prepared by a convention called for the purpose was rejected at the polls. The revision by the Consti-

tutional Convention of 1907–08 was adopted by popular vote in 1908. The question of revision was again submitted to the electors in 1926 and was rejected by a vote of 285,252 to 119,491. In its present form the Constitution confers suffrage upon every citizen of the United States who is 21 years of age or over and has resided in the State six months and in his township or ward 20 days immediately preceding an election. At the head of the executive department is the governor, who is elected for two years, and who at the time of his election must be at least 30 years of age and must have been for five years a citizen of the United States, and for the two years immediately preceding a resident of the State. A lieutenant governor, for whom the same qualifications are prescribed, is elected at the same time for the same term. Under the first Constitution the secretary of State, treasurer, auditor general, attorney general and superintendent of public instruction were all appointed by the governor, but under the present one they are elected for a term of two years. The State highway commissioner is elected for a term of four years. The governor's salary is fixed by the revised Constitution of 1908 at $5,000 a year. The lieutenant governor succeeds the governor in case of vacancy, and next in order of succession comes the secretary of State. A State administrative board, consisting of all the six elective State officials mentioned, was created in 1921.

Legislature.—The legislature, consisting of a senate of 32 members, and a house of representatives of 100 members (according to the Constitution not less than 64 and not more than 100), meets, in regular session, on the first Wednesday in January in odd-numbered years, at Lansing. Both senators and representatives are elected for a term of two years by single districts, except that a township or city which is entitled by its population to more than one representative elects its representatives on a general ticket. Beginning in 1913 and at each subsequent tenth



BY COURTESY OF THE DETROIT CONVENTION AND THE TOURIST'S BUREAU

WASHINGTON BOULEVARD, IN THE HEART OF THE HOTEL AND SHOPPING DISTRICT OF DETROIT

year, the legislature, under the revised Constitution of 1908, is required to re-arrange the senatorial districts and reapportion the representatives among the counties and districts, using as a basis the returns of the next preceding decennial census; but this obligation has not been strictly followed, the legislature finally in 1925 arranging a compromise calculated to restrict Detroit's representation below that which its population calls for.

No bill can pass either house except by an affirmative vote of a majority of the members elected to that house, and on its third reading the ayes and noes must be taken and recorded; for appropriation bills a two-thirds majority of all members elected to each house is required. All legislation must be by bill, legislation by joint and concurrent resolutions thus being prevented. No bill may be passed at a regular session until it has been printed and in possession of each house for five days; no bill may be passed at a special session on any subject not expressly stated in the governor's proclamation or submitted by special message. The governor has ten days (Sundays not being counted) in which to exercise his veto power (which may be applied to any item or items of any bill making appropriations of money and embracing distinct items), and an affirmative vote in each house of two-thirds of the members elected is required to pass a bill over his veto.

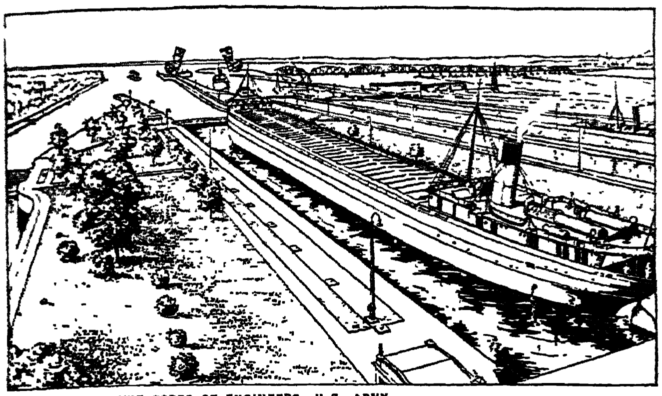
Judiciary.—The administration of justice is entrusted to a supreme court, a continually increasing number of circuit courts, 40 in 1927, one probate court in each county, and not more than four justices of the peace in each township. The supreme court is composed of one chief justice and seven associate justices, all elected for a term of eight years, two retiring every two years; it holds four sessions annually, exercises a general control over the inferior courts, may issue, hear and determine any of the more important writs, and has appellate jurisdiction only in all other important cases. There is only one circuit court judge for a circuit, unless the legislature provides for the election of more; the term of office is six years. Each county elects a judge of probate for a term of four years; he has original concurrent jurisdiction with the circuit court in matters of probate, and has original jurisdiction in all cases of juvenile delinquents and dependents. The legislature may provide for the election of more than one judge of probate in a county with more than 180,000 inhabitants. Justices of the peace are elected by the townships for a term of four years—there are not more than four in each township.

Local Government.—For purposes of local government the State is divided into 83 counties, each of which is in turn divided by north and south and east and west lines into townships. The officers of the township are a supervisor, clerk, treasurer, highway-commissioner, one overseer of highways for each highway district, justices of the peace and not more than four constables, all of whom are elected at the annual township meeting in April. The supervisor, two of the justices of the peace and the clerk constitute the township board, whose duty it is to settle claims against the township, audit accounts, and publish annually an itemized statement of receipts and disbursements. The supervisor is also the township assessor, and the several township supervisors constitute the county board of supervisors who are entrusted with the care and management of the property and business of the county, and may borrow or raise by tax what is necessary to meet the more common expenses of the county. Other county officers are a treasurer, clerk, sheriff, register of deeds, attorney, surveyor and two coroners, each elected for a term of two years, a school commissioner elected for a term of four years, and one or more notaries public appointed by the governor.

City Government.—Under the revised Constitution of 1908 the former classification of cities into four classes and the practice of granting special charters were abolished, and the legislature is required to provide by general laws for the incorporation of cities and villages; "such general laws shall limit their rate of taxation for municipal purposes and restrict their powers of borrowing money and contracting debts." Cities and villages are permitted—upon authorization by the affirmative vote of three-fifths of the electors voting on the question—to own and operate, even outside their corporate limits, public utilities for supplying water, light, heat, power and transportation, and may sell and deliver, outside their corporate limits, water, heat, power and light to an amount not more than one-fourth that furnished by them in each case within their corporate limits; but no city or village of less than 25,000 inhabitants may own or operate transport facilities. Under the revision of 1908, corporate franchises cannot be granted for a longer term than 30 years.

Population.—The first census taken in that portion of the North-west Territory now included in the State of Michigan showed, in 1810, a population of 4,762. The population at other

selected decennial censuses was as follows:—31,639 in 1830; 749,113 in 1860; 1,636,937 in 1880; 2,093,890 in 1890; 2,420,982 in 1900; 2,810,173 in 1910; and 3,668,412 in 1920; an increase of 30·5% within the last decade. The population in 1930 was 4,842,325, an increase of 1,173,913 or 32 per cent. Of the total population in 1920, 1,670,447 were of native parentage; 1,204,545 of foreign or mixed parentage; 726,635 were foreign-born; 60,082 were negroes; and the remaining 6,703 were Indians, Chinese or Japanese. The chief national groups among the foreign-born showed 164,502 natives of Canada (145,867 English; 18,635 French), 103,926 of Poland, 86,047 of Germany, 47,149 of England, 45,313 of Russia, 33,499 of the Netherlands, 30,216 of Italy and 30,096 of Finland. The density of population increased from 63·8 to 84·2 per sq.m. in the decade 1920–30. During the decade 1910–20 the urban population (in places having 2,500 inhabitants or more) increased from 47·2% to 61·1% of the total population. There were 38 cities and 2 villages with 10,000 inhabitants or more in 1930. The population of the following cities in 1930 was: Detroit, 1,568,662; Grand Rapids, 168,592; Flint, 156,492; Saginaw, 80,715; Lansing, 78,397; Pontiac, 64,928; Hamtramck, 56,268 and Jackson, 55,187.



BY COURTESY OF THE CORPS OF ENGINEERS, U. S. ARMY

Finance.—The present Constitution (as revised in 1908) forbids the contraction of a State debt exceeding $250,000 except for repelling an invasion or suppressing an insurrection, and the borrowing power of the minor civil divisions is restricted by a general law. The Constitution of 1850 provided that no general banking law could have effect until it had been submitted to the people and had been approved by a majority of the votes cast on the question. This provision was included in the revised Constitution adopted in 1908, with an additional provision that no amendment shall be made to any banking law unless it shall receive an affirmative two-thirds vote of both branches of the legislature. Every stockholder in a bank is made individually liable for the amount of his stock at its par value in addition to the said stock. All banks are subject to the inspection and supervision of the commissioner of the State banking department.

The assessed value of all property in Michigan in 1928 was $8,201,420,920, on which the State levied $20,500,000 in taxes ($4.46 *per caput*). The remainder of the general revenue was secured, principally, from various specific or indirect taxes, such as the inheritance tax and a tax on corporation franchises. The principal sources of the State road funds are the motor vehicle licence fees ($18,616,326 in 1928) and a tax of three cents per gallon on gasolene ($17,683,913 in 1928). The bonded indebtedness of the State on June 1, 1927 was $83,500,000 or a *per caput* debt of approximately $20.

Educational System.—Michigan was a pioneer State in creating the American educational system; she began the organization of it at the time of her admission into the Union in 1837, and has since been noted for the high standard of her schools. Each township operating under the district act has two school inspectors—one being elected at each town meeting for a term of two years—who with the township clerk constitute the township board of school inspectors, and to this board is given authority to divide the township into school districts and to exercise a general supervision over the several schools within their jurisdiction; a township may be organized as a single district, called a "township unit district." The qualified electors of each district having an ungraded school elect a moderator, a director and a treasurer—one at each annual school meeting—for a term of three years, who constitute the district school board, entrusted with ample power to direct the affairs of the school. Each county has a county school commissioner elected for a term of four years, who exercises a general supervision over the schools within his jurisdiction. Finally, at the head of all the public elementary and secondary schools of the State is the State superintendent of public instruction, elected for a term of two years; he is *ex officio* a member and secretary of the State board of education, and a member, with the right to speak but not to vote, of all other boards having control of public instruction in any State institution.

In 1926 there were 866,945 pupils enrolled in the public schools of the State, and 30,327 teachers were engaged in giving instruction. Of the public school enrolment 720,212 were in the kindergarten and elementary grades and 146,733 were in the secondary schools. Private and parochial schools had an enrolment of 101,137. The net expenditures for public elementary and secondary education, in 1926, were $76,654,656 or a *per caput* based on total enrolment of $88.42. The illiteracy rate was 3% in 1920 as against 3·3% in 1910. In many of the public schools vocational courses were added in recent years. At the institutions of higher education, attendance greatly increased. Some of the colleges with church connection shared in this growth; but the chief enlargement was at the University of Michigan and the Michigan State college of Agriculture and Applied Science.

The higher State institutions of learning consist of a university (*see* MICHIGAN, UNIVERSITY OF), four teachers' colleges and normal schools, an agricultural college and a school of mines. The university (at Ann Arbor) was established in 1837, and is under the control of a board of regents elected by the people for a term of eight years, two every two years; the president of the institution and the superintendent of public instruction are members of the board but without the right to vote. The State teachers' colleges are: the Michigan State Normal college at Ypsilanti (1849); the Central Michigan Normal school at Mount Pleasant (1895); the Northern State Normal school at Marquette (1899); and the Western State Normal school at Kalamazoo (1904). All of these are under the State board of education. The Michigan State college of Agriculture and Applied Science at East Lansing, 3 m. east of Lansing, is the oldest in the United States; it was provided for by the State Constitution of 1850, organized in 1855 and was opened in 1857. The College of Mines, at Houghton, was established in 1885. In 1927 there were 14 other institutions of higher learning within the State, but not maintained by it.

Agriculture.—In 1925 18,035,290 ac. or 49% of the land was in farms. Of this amount 9,671,381 ac. were classified as crop land. All farm property in the above year had an estimated value of $1,523,976,902. The number of farms (192,327) in 1925 showed a decrease of 14,626 as compared with 1910. During the period 1920–25 all farm-land decreased from 19,032,961 ac. to 18,035,290. The percentage of tenantry decreased from 17·7 to 15·1 during the same period. The aggregate value of all farm crops in 1926 was $250,600,000. The table below shows the acreage, product and value of the principal crops in 1926.

Crop	Acreage	Product	Value
Tame hay .	2,869,000	4,097,000 tons	$56,539,000
Indian corn .	1,593,000	54,162,000 bu.	39,538,000
Potatoes . .	249,000	29,880,000 bu.	35,856,000
Wheat . .	984,000	17,998,000 bu.	21,958,000
Oats . . .	1,570,000	51,810,000 bu.	20,723,000
Dry beans .	552,000	6,624,000 bu.	18,547,000

Other crops of considerable economic value were sugar-beets, fruits, barley, rye, peppermint and vegetables. Michigan, in 1926 ranked first among the States of the Union as a producer of dry beans and peppermint, and second only to Colorado as a producer

of beet sugar. The growth of mint on the muck lands in the south-western counties is quite as old as the State. Market gardening is an important industry both in the south-west and south-east counties. All the principal fruits are grown in large quantities in what is known as the fruit belt in the south-west; grapes are grown chiefly in the south-western counties. The area nominally in woodland, including farm wood-lots as well as forests and cut-over lands, comprises nearly two-thirds of the State; but of this area not more than about 4,000,000 ac., nine-tenths of which lie in the upper peninsula, now bear good timber. The barrenness of the sandy soil and the shortness of the growing season have hindered the reduction of land to cultivation, and some 10,000,000 ac. (more than a quarter of the State) are thus a deforested desert.

Minerals.—Michigan, with a mineral product valued at $122,-212,254 in 1925, ranked ninth among the States of the Union. Of the mineral products iron-ore, copper, cement, salt and clay products, respectively, were of chief value. Iron was first discovered in the Marquette district along the shore of Lake Superior early in the 18th century, but active operations for mining it did not begin until 1845; in 1877 mining of the same mineral began farther south in the Menominee district, and seven years later farther west along the Wisconsin border in Gogebic county. From 1890 to 1901 Michigan ranked first in the Union as an iron-producing State, but after 1901 its product was exceeded by that of Minnesota. Since the first discovery of iron-ore up to Jan. 1, 1926, a total of about 1,230,000,000 tons had been shipped from the Lake Superior region of Michigan. Copper mining in the State began about the same time as iron mining. The product in 1845 was 12 long tons; in 1926 the product was 174,779,000 pounds. From 1847 to 1887 the product of Michigan exceeded that of any other State; from 1847 to 1883 its copper product was more than one-half that of all the States, but in 1926 more of that mineral was mined in each of the States of Arizona, Utah and Montana than in Michigan. The chief producing region is in the Keweenaw peninsula and its vicinity.

Fields of bituminous coal extend over an area of over 10,000 sq.m. in the south-east portion of the State; but its quality is inferior. The mining of coal began in Jackson county in 1836, but for many years the production increased slowly. The period of greatest average production was the five years, 1916–20 when 1,301,000 short tons were mined annually. The product in 1926 was 649,000 tons. The principal producing area was in Bay, Saginaw, Tuscola and Calhoun counties. Salt wells are numerous in the middle and south-eastern sections of the lower peninsula; the first successful one was drilled in Saginaw county in 1859 and 1860. For a number of years prior to 1893 Michigan was the leading salt-producing State; then New York became the chief producer for several years. In 1926 the State ranked first among the States with a product of 2,260,320 tons of salt. Gypsum is obtained from deposits along the banks of the Grand river in Kent county and in the vicinity of Alabaster along the shore of Lake Huron in Iosco county. In 1925 649,053 tons valued at $5,447,294 were mined. Marl is found in many parts of the State; limestone most largely in the northern part of the lower peninsula, and in the eastern part of the upper peninsula. The presence of these products has given rise to Michigan's large Portland cement industry; in 1926 the State's output was 12,037,000 barrels. Clay products in 1925 had a value of $7,396,071; about 42% of this total represented the value of the pottery product.

Manufactures.—The manufactured products in 1925 were valued at $4,373,186,136, as compared with $1,086,162,000 in 1914, an increase of over 300%. This advance was mainly due to the extraordinary growth of the automobile industry and its concentration in the State. The value of automobiles manufactured increased from $7,996,534 in 1904 to $1,551,990,000 in 1923. In 1926 the motor vehicles manufactured within the State were valued at $1,820,296,128; motor vehicle bodies and parts had an additional value of $921,901,337. About half the motor vehicles manufactured in the United States in 1925 were made in Michigan. The number of wage-earners engaged in this industry in 1914 was 67,538, constituting 24·9% of the total number of industrial wage-earners in the State; these were increased to 234,492 in 1925, their proportion to the whole being 45·5%. Foundries and machine shops with an average number of 31,291 wage-earners in 1925 had a product valued at $162,545,298. Furniture ranked next, with 21,512 wage-earners and products valued at $99,039,416. Other industries of great value included engines and water-wheels ($95,-932,026); paper and wood pulp ($91,149,648); brass, bronze and copper products ($65,594,415); lumber and timber products ($59,569,472); slaughtering and meat packing ($53,932,676); food preparations ($53,423,945); bread and bakery products ($51,358,975); and butter, cheese and condensed milk ($49,300,-693). Michigan led all other States in 1925 in output of chemicals, drugs, engines and water-wheels, motor vehicles and motor vehicle bodies and parts, and threshing machines. The State ranked third in the manufacture of furniture and food preparations. Detroit with its neighbouring cities Highland Park and Hamtramck, produced more than half the manufactured products of the State. In this district centred the motor vehicle, the foundry and machine shop, the meat-packing, and the brass and bronze industries. Flint, with products valued at $422,644,236, was another important motor vehicle manufacturing point.

Transport.—The building of railways in Michigan began in 1830, but little progress had been made in 1837 when the State began the construction of three railways and two canals across the southern half of the lower peninsula. Some progress was made, but by 1846 the State proved itself incompetent to carry on the work and sold its interest to private companies. The railway mileage continued until 1910 when it was 9,021; since that date there has been a gradual decrease, the mileage in 1925 being 8,349. The principal lines are the Michigan Central, the Pere Marquette, the Lake Shore and Michigan Southern, the Grand Trunk and the Chicago, Milwaukee and St. Paul. The mileage of electric railways was 1,795 in 1925.

Besides railway communication, Michigan has a coastline of about 1,600 m. and several good harbours. The water communications were extended and improved by several canals, among which are the Sault Ste. Marie, which passes the rapids of the St. Mary's river; the St. Clair Flats, at the north end of Lake St. Clair, by which a deeper channel is made through shallow water; and the Portage lake, in the copper district, which connects that lake with Lake Superior. The traffic through the Sault Ste. Marie canal in 1926 according to the annual report of the chief of engineers, U.S. army, was 85,679,000 short tons, and had a value of $1,063,876,000. During 1925 Michigan harbours made shipments aggregating 20,283,000 tons, with receipts totalling 9,277,000 tons.

An excellent system of State trunk roads is maintained by the State highway department. This department, at the close of 1926, controlled 6,756 m. of roads, of which 6,229 m. were surfaced. The total expenditure for rural highways by the State highway department in 1926 was $36,136,000. The total motor vehicle registration for the year 1926 was 1,125,031.

History.—From 1613 until 1760 the territory now within the borders of Michigan formed a part of New France, and the first Europeans to found missions and settlements within those borders were Frenchmen. Two Jesuits, Raymbault and Jogues, visited the site of Sault Ste. Marie as early as 1641 for the conversion of the Chippewas; in 1668 Marquette founded there the first permanent settlement within the State; three years later he had founded a mission among the Hurons at Michilimackinac; La Salle built a fort at the mouth of the St. Joseph in 1679; and in 1701 Cadillac founded Detroit as an important point for the French control of the fur trade. The bitter strife between the missionaries and Cadillac, and the French system of absolutism in government and monopoly in trade were further obstacles to progress. Even Detroit was so expensive to the Government of the mother country that there was occasional talk of abandoning it; and so during the last 59 years that Michigan was a part of New France there were no new settlements, and little if any growth in those already established. During the last war between the English and the French in America, the Michigan settlements passed into the possession of the English, Detroit in 1760 and the others in 1761. The white inhabitants, mostly French, were subjected to an English rule that until the Quebec Act of 1774 was

chiefly military, and as a consequence many of the more thrifty sought homes elsewhere, and the Indians, most of whom had been allies of the French, were so ill-treated, both by the officers and traders, that under Pontiac, chief of the Ottawas, a simultaneous attack on the English ports was planned. Detroit was besieged for five months and both Michilimackinac and St. Joseph were taken. Moreover, the English policy, which first of all was concerned with the profits of trade and manufacture, gave little more encouragement to the settlement of this section of the country than did the French. By the Treaty of Paris, in 1783, which concluded the American Revolution, the title to what is now Michigan passed to the United States, and in 1787 this region became a part of the North-west Territory; but it was not until 1796 that Detroit and Mackinac (Michilimackinac), in accordance with Jay's treaty of 1794, were surrendered by Great Britain. In 1800, on the division of the North-west Territory, the west portion of Michigan became a part of the newly established Indiana Territory, into which the entire area of the present State was embodied in 1802, when Ohio was admitted to the Union; and finally, in 1805, Michigan Territory was organized, its south boundary being then described as a line drawn east from the south extremity of Lake Michigan until it intersected Lake Erie, and its west boundary a line drawn from the same starting point through the middle of Lake Michigan to its north extremity and then due north to the north boundary of the United States. During the War of 1812, General William Hull, the first governor of the Territory, although not greatly outnumbered, surrendered Detroit to the British without a struggle; in the same year also Mackinac was taken and Michigan again passed under British rule. This rule was of short duration, however, for soon after Commodore Oliver H. Perry's victory on Lake Erie, in September of the next year, Detroit and the rest of Michigan except Mackinac, which was not recaptured until July 1815, were again taken into the possession of the United States.

THE MASONIC TEMPLE IN DETROIT, THE LARGEST IN THE WORLD

Development.—Up to this time the Territory had still remained for the most part a wilderness in which the fur trade reaped the largest profits, its few small settlements being confined to the borders; and the inaccurate reports of the surveyors sent out by the United States Government described the interior as a vast swamp with only here and there a little land fit for cultivation. The large number of hostile Indians was also a factor in making the Territory unattractive. But during the efficient administration of Lewis Cass (*q.v.*), governor of the Territory from 1813 to 1831, the interference of the British was checked and many of the Indians were removed to the west of the Mississippi; printing presses, established during the same period at Detroit, Ann Arbor, Monroe and Pontiac, became largely instrumental in making the country better known; the first steamboat, the "Walk-in-the-Water," appeared at Detroit in 1818; the Erie canal was opened in 1825; by 1830 a daily boat line was running between Detroit and Buffalo, and the population of Michigan, which was only 4,762 in 1810 and 8,896 in 1820, increased to 31,639 in 1830 and 212,267 in 1840. In 1819 the Territory had been empowered to send a delegate to Congress. By 1832 the question of admission into the Union had arisen, and in 1835 a convention was called in Detroit, a Constitution was framed in May which was adopted by popular vote in October, State officers were elected, and application for admission was made; but a dispute with Ohio over the boundary between the two caused a delay in the admission of Michigan into the Union as a State until Jan. 26, 1837. Since admission into the Union the more interesting experiences of the State have been connected with internal improvements and with banking, which together resulted in serious distress; in the utilization of its natural resources, which have been a vast source of wealth; and in the development of its educational system, in which the State has exerted a great influence throughout the Union. From the beginning of its Government under its first State Constitution in 1835 until 1855, Michigan had a Democratic administration with the exception of the years 1840–42, when opposition to the financial measures of the Democrats placed the Whigs in power. But it was in Michigan that the Republican Party received its first official recognition, at a State convention held at Jackson on July 6, 1854, and from 1858 to 1928 the administration, with the exception of four gubernatorial terms, was Republican.

Winchell, *Michigan: Being Condensed Popular Sketches of the Topography, Climate and Geology of the State* (1873), is in large measure restricted to the southern half of the State; *see* also the bibliography bulletins of the U.S. Geological Survey for special articles relating to Michigan. (L. A. W.)

MICHIGAN, LAKE, the third largest of the Great Lakes of North America and the only one wholly within the boundaries of the United States. It is about 307 m. in length, averages about 70 m. in width, and has a maximum measured depth of 870 feet. The lake is bounded on the north and east by the State of Michigan, on the south by Indiana and on the west by Illinois and Wisconsin. It has a water surface of 22,400 sq. m. and a drainage basin of some 69,040 sq. miles. Taking the average for the past 68 years, its mean surface is 580·94 ft. above mean sea-level, being the same as Lake Huron and 21·28 ft. below that of Lake Superior. The average or normal elevation of the lake surface varies irregularly from year to year. During the course of each year, the surface is subject to a consistent seasonal rise and fall, the lowest stages prevailing during the winter months and the highest during the summer months. In addition to the annual fluctuation, there are occasional oscillations of irregular amount and duration. Sometimes these are apparently seiches, resulting from variations in barometric pressure, which may produce changes ranging from a few inches to several feet, and return to normal, within a few hours. The dangerous storms of the autumn, winter and early spring are usually westerly. Ice interferes with navigation in the northern part of the lake in winter; the average closing and opening dates for navigation in the Straits of Mackinac are Dec. 15 and April 12, respectively.

Harbours.—The harbours along the shores are generally situ-

ated at the mouths of rivers. Most of these rivers are small and unimportant, the larger streams being the Menominee and the Fox, both of which empty into Green bay, the most important arm of the lake. The early plan of improvement consisted of parallel piers protecting a dredged channel; subsequently, at some harbours, detached breakwaters were built to provide additional protection from prevailing storms. In recent years, the injurious effects of storm waves in inner harbours have been relieved by the formation in the lake of a wave-stilling basin, enclosed by breakwaters or piers which converge to an entrance opening in deep water beyond the inner piers, this basin allowing the waves to expand and lose force instead of being conducted through the confined channel between the parallel piers. Such basins now exist at Holland, Ludington, Manistee, Manistique, Two Rivers, Manitowoc, Sheboygan and Racine. The outer harbours at Milwaukee, Chicago and South Chicago (Calumet), protected by breakwaters, afford commodious and safe anchorage for all classes of vessels. The harbours of Port Washington, Waukegan, Indiana Harbor and Gary are entirely artificial, consisting of dredged channels and basins protected by breakwaters and piers. As a result of the improvements made and maintained by the United States and local interests, the harbours are generally accessible to vessels drawing from 14 to 21 ft. at low stages.

The port of Escanaba on the north shore of the lake is an important shipping point for iron ore. Green Bay and Milwaukee are centres of distribution for coal from Lake Erie ports. Near the south end of the lake the Chicago district is a great industrial centre, consuming large quantities of water-borne raw materials, principally iron ore, coal and limestone, which are handled through the important ports of Calumet (South Chicago), Indiana Harbor, Gary and Buffington. Milwaukee, Chicago and Calumet are grain-shipping ports.

The commerce for the calendar year 1927 of the principal ports on the lake in tons is shown in the following table:—

Water-borne Commerce of Ports on Lake Michigan During 1927

Ports	General cargo		Car ferry	Total
	Foreign	Domestic		
Manistique . .	.	6,194	262,754	268,948
Menominee . .	11,147	325,691	419,523	756,361
Green Bay and De Pere . . .	24,498	1,744,156	..	1,768,654
Kewaunee . .	..	2,075	330,603	332,678

Gary	4,151	5,392,834	..	5,396,985
Buffington . .	..	1,380,688	..	1,380,688

The transfer of loaded freight cars on car ferries on the Great Lakes was inaugurated in 1892 by the Ann Arbor railroad. The present service on Lake Michigan, which is by far the most extensive of its kind in the world, consists of two ferries operated between Grand Haven, Mich., and Milwaukee, Wis., by the Grand Trunk railway; seven between Ludington, Mich., and Milwaukee, Manitowoc, Wis., and Kewaunee, by the Pere Marquette railway; four between Frankfort and Menominee and Manistique, Mich., and between Frankfort, Mich., and Manitowoc and Kewaunee, Wis., by the Ann Arbor railroad.

Engineering.—Lake Michigan is connected at its north-east extremity with Lake Huron by the Straits of Mackinac, 48 m. long, with a minimum width of 6 m.; the water is generally deep and the shoals lying near the usually travelled routes are well marked.

The head of the Illinois river watershed is separated from Lake Michigan by a low divide. In 1848 the Illinois and Michigan canal was constructed from the Chicago river across the divide to the Illinois river at a point just below La Salle, thus permitting through navigation. In 1900 the sanitary district of Chicago completed a drainage canal from the south branch of the Chicago river to the Des Plaines river at Joliet. This, combined with work in the Chicago river, reversed the flow of the latter and permitted the flow of water from Lake Michigan through the canal into the Des Plaines and thence to the Illinois. It also provided a navigable channel 21 ft. deep, with a minimum bottom width of 200 ft., from the lake to a point between Lockport and Joliet, where a power plant was constructed. In 1908 the Illinois waterway was provided for by amendment to the State's Constitution, to be financed by the sale of bonds, to permit navigation from Lockport to Utica, with the intention of connecting the Great Lakes with the Mississippi system. The waterway is designed for 9 ft. depth, and was under construction in 1928. The Federal Government has undertaken the improvement of the Illinois river with a view to securing a navigable channel of the same depth to the mouth, where connection is made with the Mississippi river.

Under authority of Sec. 10 of an act of Congress approved on March 3, 1899, the secretary of war, upon the recommendation of the chief of engineers, issued on March 3, 1925, to the sanitary district of Chicago, a permit to divert from Lake Michigan, through its main drainage canal and auxiliary channels, an amount of water not to exceed an annual average of 8,500 cu.ft. per second, the instantaneous maximum not to exceed 11,000 cu.ft. per second under certain conditions including the requirements that the sewage be artificially treated, that controlling works be constructed to prevent the discharge of the Chicago river into the lake, and that the water service of the city of Chicago be metered. This permit, if not previously revoked or specifically extended, becomes null and void on Dec. 31, 1929. Action has been brought by some of the Lake States to restrain the Chicago drainage district from diverting water from Lake Michigan, and the matter was finally settled by the Supreme Court in favour of the Lake States in January, 1929.

Jean Nicolet is credited with being the first white man to navigate Lake Michigan. Sent west by Champlain on a voyage of exploration, he threaded his way in a birch canoe from Georgian bay through the Straits of Mackinac and thus discovered Lake Michigan in the summer of 1634. Later explorers were Joliet, Marquette and La Salle.

Lake Survey Office (1928); *Document* No. 4, Committee on Rivers and Harbors, 69th Congress, 1st Session; *Annual Report* of the chief of engineers, War Department. (E. JA.)

MICHIGAN, UNIVERSITY OF, situated at Ann Arbor, Mich., is one of the principal educational institutions of the United States. It includes a college of literature, science, and the arts, opened in 1841, a medical school (1850), a law school (1859), a school of dental surgery (1875), a college of pharmacy (1876), a college of engineering, separately organized in 1895, a college of architecture (1913), a school of education (1921), a school of business administration (1924), and a school of forestry and conservation (1927). The graduate school of the university was established as a separate division in 1912. The first summer courses were given in 1894. In 1926–27 there were in all departments 689 instructors and 13,257 students. The university was one of the first in America to admit women, having opened its doors to them in 1870; since 1900 they have constituted nearly one-third of the student body. Up to March 1928 the university had conferred 53,509 degrees. The organic relation of the university to the other schools of the State was well established in 1870 through the establishment of a department of education, the first in any American university, and a provision that graduates from high schools which had been examined and approved by a committee from the university should be admitted without examination.

The libraries of the university comprise a total of 649,912 volumes, of which 441,013 volumes are housed in the General Library Building (1919) occupying the centre of the campus.

The William L. Clements Library of American History, the gift of Regent Clements of Bay City, occupies a separate building (1923) and comprises one of the largest and most valuable collections on Colonial and Revolutionary history in the world.

The university's resources are inventoried at over $35,000,000, of which over $29,000,000 is invested in buildings and lands. The physical property of the university includes 51 larger buildings and many smaller ones. At a little distance from the campus is the great university hospital which with other buildings in the hospital group furnishes bed accommodations for over 1,000 patients and serves as a great hospital centre for the whole State of Michigan. Its administration is entirely in the control of the university.

A noteworthy feature of the university's equipment are the buildings devoted to physical education and sports. In addition to the Waterman Gymnasium for men and the Barbour Gymnasium for women, on the campus, the university possesses a great playground in Ferry Field comprising over 75 acres. Here is the Yost Field House, 345 ft. long by 165 ft. wide, devoted to a year-round programme of intercollegiate sport, while a building equally large for intramural sports was completed in 1928. The football stadium has accommodation for 87,000 spectators.

Recent important developments in the university are: the establishment of the University college (to be open in 1929), including practically all the first and second year students in the university under a united administration; the establishment of a special fund in 1927 for faculty research; the development of special divisions for engineering research and cancer research; the establishment of a series of scholarships for oriental women through the funds left by the late Levi L. Barbour of Detroit; and the inauguration of a programme for the erection of dormitories.

The university is governed by a board of eight regents, two elected biennially by popular suffrage. The internal government rests to a large extent with the president and the members of the faculty of professorial rank organized as the university senate. The principal income of the university comes from the Treasury of the State of Michigan with the annual receipts for the year 1926–27 for all purposes totaling $10,500,000. The university also has a small permanent income of $38,000 derived from the sale of the lands originally set apart by the State for educational purposes under the Ordinance of 1787.

The first incorporation of a university within what is now the State took place in 1817 when the Governor and judges of the Territory established the "Catholepistemiad, or University of Michigania," with a remarkable Greek system of nomenclature for its courses and faculties. Neither this institution, however, nor its successor, which came four years later, the first University of Michigan in Detroit, ever offered courses of a collegiate character. It was not until the admission of Michigan into the Union as a State in 1837 that an Organic Act under the constitution of 1835 made possible the organization of the present university and its establishment at Ann Arbor. The regents first met in June 1837 and plans were begun in 1838. A series of branches were established in neighbouring towns to furnish the necessary students; these were soon discontinued, however, and the whole effort of the newly established Board of Regents centred in the university which opened its doors in 1841. The first division, the department of literature, science, and the arts was much like a New England college. The prospects at first were not promising, but in 1851 a new State constitution provided that the regents should be elected by the people instead of being appointed, as originally provided, by the Governor. They were also directed to choose a president and Henry Philip Tappan (1805–81) was selected. It was under his administration (1852–63) that the present broad and liberal policies of the university were clearly defined. The germ of graduate study was planted and a scientific course was introduced. Gradually the various schools and colleges of the university came into being. In 1871–72 the German seminar method was introduced in graduate work in history, and in 1878 the elective system was established.

MICHIGAN CITY, a city of La Porte county, Indiana, U.S.A., on Lake Michigan, 40 m. E. by S. of Chicago. It is on federal highways 12 and 20, and is served by the Chicago, Indianapolis and Louisville, the Michigan Central, the Nickel Plate, the Pere Marquette and electric railways, motor bus and truck lines and lake steamers. The population was 19,457 in 1920 (18% foreign-born white) and was 26,735 in 1930 by Federal census. It is the seat of the Northern State prison and a United States Life Saving station, and the see of a Protestant Episcopal bishop.

The commerce of its harbour in 1925 was valued at $1,712,750; and its manufactures in 1927 were valued at $24,987,996. Michigan City was founded about 1830, incorporated as a village in 1837, and chartered as a city in 1867. Since 1922 it has had a commission-manager form of government.

MICHMASH, a place in Benjamin about 9 Roman miles north of Jerusalem (Eusebius, *Onom.*), and the scene of Jonathan's daring exploit against the Philistines (1 Sam. xiv.): mod. Mukhmās, pop. 400. It was re-colonised after the exile (Neh. xi. 31); Jonathan made it his administrative centre (1 Macc. ix. 73), and it was a large village in Eusebius' time. The only archaeological interest is a cave with columbaria. There are megalithic monuments in the neighbourhood.

MICHOACÁN, or **MICHOACÁN DE OCAMPO,** a State of Mexico touching on the Pacific. Pop. (1921) 939,849, chiefly Indians and mestizos. Area, 23,198 sq. miles. Its territory is divided into two nearly equal parts by the Sierra Madre Occidental, the northern part belonging to the great central plateau region, and the southern to an extremely broken region formed by the diverging branches of the Sierra Madre, with their wooded terraces and slopes and highly fertile valleys. The general slope of the southern part is southward to the river Balsas, or Mescala, which forms its boundary-line with Guerrero. The narrow coastal zone on the Pacific is only 101 m. long and has no ports or towns of importance, the slopes being precipitous and heavily wooded and the coast-belt sandy, hot and malarial. The Lerma, on the northern frontier, and the Balsas on the southern, are the only rivers of importance in the State, their tributaries within its boundaries being small and swift-flowing. There are several large and beautiful lakes in the State, the best known of which are Pátzcuaro and Cuitzco. Lake Chapala lies on the northern boundary. Michoacán lies within the most active volcanic region of Mexico: Jorullo (4,262 ft.) is near its southern line, and Colima (12,750 ft.) is north-west of it in the State of Jalisco. The climate is for the most part temperate and healthy, but it is hot along the Pacific coast. Michoacán is essentially a mining region, producing gold, silver, lead and cinnabar, and having rich deposits of copper, coal, petroleum and sulphur. The natural products include fine cabinet and construction woods, rubber, fruit, palm oil and fibres. The soil of the valleys is highly fertile, and produces cereals in the higher regions, and sugar-cane, tobacco, coffee and tropical fruits in the lower. Though the plateau region was settled by whites soon after the Spaniards came to Mexico, there are districts on the southern and Pacific slopes that still belong almost exclusively to the Indians. Besides Morelia, the capital and largest city, the principal towns of the State are: La Piedad (pop. in 1921, 12,115), an important commercial town on the Lerma river and on the Mexican Central railway, 112 m. N.N.W. of Morelia; Zamora (in 1921, 13,863), 75 m. W.N.W. of Morelia; and Uruapan (in 1921, 13,689), on the Mexican National, 55 m. S.W. of Morelia in a mountainous district celebrated for the fine quality of its coffee.

MICKIEWICZ (mĭk-ē'ā-vĭts), **ADAM** (1798–1855), Polish poet, born near Nowogrodek, in the Russian government of Minsk, where his father, who belonged to the lesser nobility, had a small property. The poet was educated at the Vilna university; but, becoming involved in political troubles as a member of a secret patriotic student society, he was imprisoned for a time by the Russian Government and afterwards ordered to live in Russia. He had already published two small volumes of miscellaneous

poetry at Vilna, and at St. Petersburg he was a great favourite in society. In 1825 he visited the Crimea, which inspired a collection of sonnets.

In 1828 appeared his *Konrad Wallenrod*, a narrative poem describing the battles of knights of the Teutonic order with the heathen Lithuanians. Here, under a thin veil, Mickiewicz represented the sanguinary passages of arms and burning hatred which had characterized the long feuds of the Russians and Poles. The object of the poem, although evident to many, escaped the Russian censors, and it was suffered to appear. It is a romance in the Byronic vein and contains two beautiful lyrics. After a five years' exile in Russia the poet obtained leave to travel abroad; and he never saw his native country again. Visiting parts of Germany and Italy, he paid his homage to old Goethe at Weimar, and was received very cordially. It was on these wanderings of his that Mickiewicz wrote the greatest scenes of his fantastic drama *Dziady* (Forefathers' Eve), the subject of which is the half-pagan religious commemoration of their ancestors practised among the peasantry of the Slavonic nations. Interwoven with this subject from folk-lore, there is, in the earlier portion of the poem (the so-called "Fourth Part") a dramatic account of an unhappy early love affair of the poet's, and, in the later and more important portion, called the "Third Part," a picture of his own and his Vilna fellow-students' sufferings in the Russian prison, and a powerful poetic statement of the workings of his genius while a mystical religious philosophy was being produced in his mind by the influence of personal and national suffering.

Mickiewicz' acknowledged masterpiece is his epic poem *Pan Tadeusz,* published in 1834. Its scene is laid in Lithuania on the eve of Napoleon's expedition into Russia in 1812, and its subject is a family feud among the country gentry, happily terminated by a wedding. In this epic idyll, Mickiewicz gives us a picture of the homes of the olden-time Polish nobility and gentry, with their somewhat boisterous but very genuine hospitality, their meals and manners and pastimes, and their readiness for patriotic sacrifice in the service of their country. Turning to the land of his childhood with the loving eyes of an exile, he gives us delightful descriptions of Lithuanian skies and forests: through the medium of his poetry, the modest landscape of the Lithuanian country-side has become dear and familiar to every Pole, and to many readers outside Poland.

In 1832 Mickiewicz left Rome for Paris, where most of his later life was spent in poverty and unhappiness. He had married a Polish lady, Celina Szymanowska, who became insane. In 1838–39, he occupied the chair of Latin Literature in the University of Lausanne, Switzerland. In 1840 he became professor of Slavonic languages and literature in the Collège de France. His last lecture was given on May 28, 1844. He had fallen under the influence of a mystic named Towianski. His lectures became a medley of religion and politics, and thus brought him under the censure of the Government. A selection from his lectures contains some good sound criticism; the philological part is necessarily defective, but the poet shows much intuitive insight into the history and mentality of the Slavonic races, especially of Poland and Russia. In his later years, Mickiewicz endeavoured to turn from poetry to active work for the cause of his country's deliverance. In 1848, he attempted to form a Polish volunteer legion in Italy, but the attempt came to nothing. In 1849 he founded a radical French newspaper, *La Tribune des peuples,* but it only existed a year. His last composition was a Latin ode in honour of Napoleon III. On the outbreak of the Crimean War he was sent to Constantinople to assist in raising a regiment of Poles to take service against the Russians. He died suddenly there in 1855, and his body was removed to France. In 1890 his remains were disinterred and buried in the cathedral of Cracow, the Westminster Abbey of Poland.

Mickiewicz is one of the greatest among Slavonic poets. He is one of the best products of the so-called romantic school in Polish literature. While that literature was cribbed and confined by 18th century classicism, the country was full of legends and picturesque stories which only awaited the coming poet to put them into shape. Hence the great popularity among his countrymen of his ballads each of them being connected with some national tradition. Besides *Konrad Wallenrod* and *Pan Tadeusz,* attention may be called to his early poem *Grazyna,* which describes the adventures of a Lithuanian chieftainess against the Teutonic knights. A fine vigorous Oriental piece is *Farys.* Very good, too, are the odes to Youth and to the historian Lelewel; the former did much to stimulate the efforts of the Poles to shake off their Russian conquerors. It is enough to say of Mickiewicz that he has obtained the proud position of the representative poet of his country; her customs, her superstitions, her history, her struggles are reflected in his works. He is the great voice of Poland appealing to the nations in her agony.

Bibliography.—The poet's life has been written, and his correspondence edited, by his son, Ladislas Mickiewicz (4 vols., Poznan, 1890–1895, French *Life* in 1 vol., Paris, 1888). The standard modern Polish work on Mickiewicz is that of Professor J. Kallenbach (*Adam Mickiewicz,* 2 vols., 4th edition, Lwów, Ossolineum, 1925). In English, see *Adam Mickiewicz, the National Poet of Poland,* by Miss Monica M. Gardner (London, Dent, 1912). Translations into English of *Konrad Wallenrod* and *Pan Tadeusz* were made by M. H. Dziewicki and Miss Biggs (1881–85), and more recently, by Professor G. R. Noyes in California and his students (*Pan Tadeusz,* 1917; *Konrad Wallenrod and other Writings,* 1925, University of California Press; *Forefathers' Eve,* prologue and scenes 1–5 of Part Third, 1926, London, Eyre and Spottiswoode). (R. Dy.)

MICKLE, WILLIAM JULIUS (1735–1788), Scottish poet, son of the minister of Langholm, Dumfries-shire, was born on Sept. 28, 1735. He was educated at the Edinburgh high school, and became a brewer. He failed in business, and went to London in 1763. There he published (1765) "a poem in the manner of Spenser" called the *Concubine* (afterwards *Syr Martyn*); was appointed corrector to the Clarendon Press, and translated the *Lusiads* of Camoens into heroic couplets (specimen published 1771, complete work, 1775). Scott read and admired Mickle's poems in his youth, and founded *Kenilworth* on his ballad of *Cumnor Hall,* which appeared in Thomas Evans's *Old Ballads . . . with some of Modern Date* (1784).

MICMAC INDIAN OF NOVA SCOTIA, CANADA

MICMAC. An Algonkin people of Nova Scotia and northern New Brunswick, probably discovered by Cabot in 1497. They formed a confederacy of seven tribes: their name means "allies." They were non-agricultural and made much use of canoes and fish. They were consistently friendly to the French and hostile to the English settlers, whom they fought bitterly after the cession of Acadia to Great Britain. Estimated at 3,000 to 3,500 during the seventeenth and eighteenth centuries, they now number nearly 4,000. Their dialect differs considerably from that of their neighbours, so that they may represent a fairly early offshoot of the Algonkin family. (A. L. K.)

MICON, a Greek painter of the middle of the fifth century B.C. He was closely associated with Polygnotus of Thasos, in conjunction with whom he adorned the Painted Stoa, at Athens, with paintings of the battle of Marathon and of the Greeks and Amazons. He collaborated with the same artist in paintings in the Theseum and the Anaceum, and was esteemed also as a sculptor of athletes.

MICROANALYSIS, CHEMICAL. Chemical analysis (*see* Chemistry, Analytical) becomes chemical microanalysis when the quantities of substances examined or measured are very small. The power to deal successfully with minute quantities of material has been acquired as a consequence, in the first place, of the increased precision of such instruments as the microbalance and the spectroscope, and, in the second, of a general advance in analytical knowledge and technique.

Microchemical methods are of the highest importance because of their ever-increasing application, not only in chemical, biochemical, and pathological research, but also to daily life and industry. Artificial products and the products of animal and

vegetable life are usually obtained as mixtures, more or less complex, which can be separated by physical means (distillation, crystallisation, dialysis, etc.), into component parts consisting each of a more or less pure chemical substance. The identification of these substances and the control of their purity depend ultimately upon chemical analysis. The recognition and estimation of traces of impurities, frequently a matter of great public importance, must generally be carried out by microchemical methods; and it is becoming increasingly appreciated that quantitative microanalysis often affords the most rapid and economical means of examining even bulk products and chemically pure substances. This is particularly true of the products of research, many of which can be isolated only with difficulty and in minute quantities and yet often exercise the most important functions. It is only necessary to mention in this connection the vital rôles played by catalysts and promoters in chemical processes, and those of the vitamins, hormones, and enzymes, in biochemical phenomena.

Microanalysis may be either *qualitative, i.e.,* concerned only with the detection of the kinds of substances present; or it may be *quantitative,* being then concerned also with the proportions in which the substances occur. Thus, it might be required to know whether strychnine were present in a given drug, or whether human blood were present as a given stain; or again, it might be required to decide whether the proportion of arsenic in a given foodstuff (beer or cocoa) exceeded a certain limit. Speaking quite generally, it may be said that the quantity of material required for, or measured in, a given microanalysis is from 1 to 2% of that in the large-scale or macroanalysis. The methods employed in microanalysis are usually essentially similar to those in the corresponding macroanalysis. This is particularly the case in:

Quantitative Microanalysis, in which the classical methods of analysis for elements and radicals (*see* CHEMISTRY: *Analytical*) are preserved in refined forms. These developments have taken place since 1910, and are due principally to Fritz Pregl of Graz. They have been rendered possible by the elaboration, by W. H. Kuhlmann of Hamburg and by others, of a chemical microbalance capable of determining loads (up to 20 grams) to within two or three thousandths of a milligram; of being manipulated with ease and rapidity; and of retaining sensitiveness during many years.

General methods are now in use for the quantitative estimation of the following elements and radicals: Carbon and hydrogen, nitrogen, chlorine, bromine, iodine, sulphur, selenium, tellurium, phosphorus, arsenic, copper; carboxyl-, methoxyl-, ethoxyl-, methylimido-, and acetyl-groups. In addition, metals in salts; ash content; water content; and molecular weight (ebullioscopic method) may be microanalytically determined.

The weight of material required for each determination varies from 0·5 to 15 milligrams (0·0005 to 0·015 gram); it is usually from 3 to 5 milligrams (0·003 to 0·005 gram.). The microanalytical methods are at least as accurate as the large-scale methods, in some cases more so; they are much more rapid than the latter; and they involve economy in respect of power, bench space, and materials. The necessary skill and accuracy to operate the methods is easily acquired by any chemist. There can be little doubt that these methods are rapidly replacing the older and more cumbrous processes, and that their general adoption will greatly accelerate the progress of chemical and biological knowledge.

A brief outline of one of the most important processes is given below:

Determination of Carbon and Hydrogen.—A weighed quantity (3 to 5 milligrams) of the substance, placed in a small platinum boat, is burned in a current of oxygen (dried by passage through the tubes B and D) in the apparatus shown in the diagram. The hard-glass tube, C, is 40 cm. in length, and contains a filling of chemicals (as indicated in the diagram) designed to arrest the escape of nitrogen, sulphur, halogens, and other products which might vitiate the analysis. The remaining gaseous products of the combustion, water and carbon dioxide, are swept over with air, and are retained, respectively, in the tubes A_1 and A_2, which are weighed on the microbalance both before and after the experiment. From the gains in weight of these tubes, the amounts of hydrogen and carbon in the original material are calculated. The gas pressures at different points of the apparatus are carefully regulated, and the temperature of the lead peroxide is maintained at 180° C by means of the external heating device shown at H. Practically all classes of organic substances may be analysed with great accuracy in this apparatus.

Reference may be made also to the semi-micro-analytical methods, requiring 50 milligrams and upwards of material, of H. Ter Meulen, who has employed manganese dioxide in the combustion tube. Especially worthy of notice is his method of determining oxygen in organic compounds by heating in hydrogen in the presence of a nickel catalyst. (H. Ter Meulen and J. Heslinga, *Recueil des Travaux chimiques des Pays-Bas,* 1922 *et seq.*)

Some of the following methods of qualitative micro-analysis, may be applied quantitatively also, *e.g.,* spectroscopic analysis. (*See* A. B. P. Leme, *Comptes rendus,* 1918, *166,* p. 465, and *Zeitschrift für das Gesamtgebiet der Mikrochemie und Mikrophysik,* W. Muller, Vienna; 1923 *et seq.*)

Qualitative Microanalysis.—Since each chemical produces its own characteristic spectrum, an examination, by means of the spectroscope (*q.v.*), of the flame or spark spectrum of a substance reveals the identities of the elements present. The delicacy of the method far transcends that of the most sensitive chemical reactions. Thus, the presence of one hundred-thousandth part of a milligram of lithium may be revealed by means of the spectroscope; or, again, five hundred-thousandths of a milligram of the rare gas, neon, present in the atmosphere, may be detected. In this manner the metallic elements gallium, rubidium, indium, caesium and thallium were discovered. The absorption spectra (*q.v.*) of many inorganic and organic substances are also characteristic, thus enabling the presence of these substances to be recognised. Examples are: copper sulphate; the blood pigments (haemoglobin and oxyhaemoglobin); and the porphyrins.

Far more widely employed, however, are the purely chemical methods which depend upon the production, on the addition of reagents to the sample or to its solution, of colorations or of colour changes; of precipitates having characteristic odour, colour, or crystalline form; or of gases or liquids which can be distilled over and identified. These tests, many of which are very delicate, may be specific for particular compounds, radicals, or elements; or for groups of these. Thus, the presence of 1 part of copper in 100

million parts of water is shown by the blue colour produced on the successive addition of alcoholic hydrogen peroxide and guaiacum resin in pyridine. The presence of 1 part of gold in 20 million parts of solution is revealed by the yellow coloration given with *o*-tolidine. Prussic acid (1 part in 2 millions of air) may be detected by means of the blue colour which it gives upon a test paper moistened with a solution containing *o*-tolidine, acetic acid, and copper acetate. There are many hundreds of such tests, some of which are also quantitative.

Methods of manipulating minute quantities of liquids and precipitates have been worked out, particularly by F. Emich of Graz. Thus two drops of a mixture of two organic liquids may be fractionated and the boiling points of each ascertained with accuracy.

MICRO-ASBESTOS, MIKROASBEST, ASBESTPULVER, BURGENLÄNDISCHE ASBESTINE, trade names for a fibrous asbestos product obtained from crumpled and crushed serpentine rocks which occur near Rechnitz, Austria. It is used as a filler in the rubber trade, in absorbent papers and matrix boards, for insulating, in acid and weather resisting paints, in plastics and synthetic resins, for making certain types of flooring, in asphaltic roof compositions, and for many other uses where an inert acid resisting mineral filler is indicated. (*Cf.* Asbestine.)

MICROBE: *see* Filter-passing Viruses.

MICROCEPHALY: *see* Neuropathology.

MICROCLINE, a triclinic potash felspar (*q.v.*) of the same composition as orthoclase ($KAlSi_3O_8$), which it closely resembles in physical and chemical properties. The triclinic character is established by its crystallographic and optical properties, viz., the cleavage angle 001:010 (89°30′), the twinning and the optical extinction. Twinning on the albite and pericline laws is almost universal and produces a characteristic grating or quadrille structure seen in thin sections of the mineral examined in polarized light. This feature and the extinction angle of 15°–17° on the face 001 distinguish the mineral from orthoclase. Laue X-ray photographs of microcline and orthoclase are identical, but the inner crystal structure of these minerals had not yet been determined. The evidence, however, does not support the contention that orthoclase owes its apparent higher symmetry to a submicroscopic twinning leading to zero optical extinction in 001. Microcline is unknown in surface lavas, but is common in plutonic rocks as granite and syenite and in pegmatites. Rare in contact metamorphic zones, it is widely distributed in the crystalline schists. (C. E. T.)

MICROCOSM, a term often applied in philosophical and in general literature to man regarded as a "little world" (Gr. μικρὸς κόσμος) in opposition to the "macrocosm," great world, in which he lives. From the dawn of speculative thought in Greece the analogy between man and the world has been a common-place, and may be traced from Heraclitus and Empedocles, through Plato, Aristotle, the Stoics, the Schoolmen and the thinkers of the Renaissance down to the present day. Thus Lotze's comprehensive survey of mental and moral science is termed *Microcosmus*. The most systematic expression of the tendency indicated by the term is the monadology of Leibniz, in which the monad is regarded as containing within its own closed sphere an expression of the universe, the typical created monad being the human soul.

MICROCOSMIC SALT, so named by the alchemists because it is contained in the decomposing urine of man (the "microcosm") is ammonium sodium hydrogen orthophosphate, $NH_4NaHPO_4 \cdot 4H_2O$. It is interesting historically as being the raw material from which Brand prepared phosphorus, whence it is called "salt of phosphorus." (*See* Chemistry: *Analytical*.)

MICRODISSECTION: *see* Protoplasm.

MICROMANIPULATION. This term has recently been applied to a specialized technique for operating on microscopic objects under the high magnifications of the compound microscope. The operations are made with microneedles (for microdissection), micropipettes (for microinjection) and microelectrodes, held and moved in different planes by a mechanism styled the micromanipulator.

The delicate, rigid tips of the microneedles and micropipettes are usually of glass or quartz; the microelectrodes of salt-filled pipettes or of metal. The injections are made with a syringe connected to the pipette by a coil of capillary tubing. The movements are so accurately controlled that such delicate operations can be made as to puncture and tear a mammalian blood-corpuscle 8 microns (0·008 mm.) or less in diameter. The pipettes for microinjection have apertures less than one micron across.

With this technique colloidal particles and bacteria have been manipulated and isolated, and histological structures microinjected and dissected for physiological studies. The technique has also made possible investigations on the physical and chemical properties of the protoplasm of living plant and animal cells. There is also a micro-radio-puncture technique developed by Tchakotine. (*See* Protoplasm.)

MICROMETER, a name generally given to any device for measuring small angles or dimensions (from Gr. μικρός, small, μέτρον, a measure). In particular a great variety of appliances used for astronomical measurement are called micrometers.

One of the immediate difficulties of accurate measurement of linear dimensions is to secure coincidence between the measuring appliance and the object measured. For inaccessible (celestial) objects, coincidence is, of course, impossible; for accessible objects, *e.g.*, a photographic plate, the plate and the measuring appliance are likely to get in each other's way. The remedy is that either the measuring scale or the thing measured should be *insubstantial*. Certain devices, such as interferometers, can be regarded as representing the first alternative; but, in general, the simplest solution is to arrange that the thing measured shall be insubstantial, viz., an optical image, accessible and offering no interference with our measuring tools, but forming a faithful reproduction to scale of the object whose dimensions we really wish to know. Both in the telescope and the microscope a real image is formed in the focal plane; here we place the "pointer" of our micrometer—a movable wire, a scale ruled on glass, or some other fiducial mark—and move it about in the midst of the ghost that we are measuring. We view the coincident pointer and image through an eyepiece, which acts as a magnifying glass. Most micrometers make use of the principle of the screw; the pointer is displaced uniformly by turning a screw. If, for example, the step of the screw is 0·5 mm., and the screw-head is read to $\frac{1}{1000}$ of a revolution, we measure to 0·0005 mm. (about equal to the wave-length of light). Needless to say, many precautions are necessary if we would actually attain such high accuracy.

Filar Micrometer.—The first micrometer used with a telescope was made by William Gascoigne, about 1638. It consisted of two pointers with parallel straight edges, which could be brought together or separated by turning a screw. He made measurements of the diameters of the sun, moon and planets, which are still extant, and prove that his invention made a very great advance on earlier measurements. The modern successor of this instrument is the *filar micrometer*, in which the two pointers are replaced by parallel wires or spider-webs, carried on metal frames. Two screws are provided, one of which moves

the pair of wires as a whole, and the other alters the separation of the two wires. In most observations, only the reading of the second screw is required, the first screw being merely an aid in setting. Much work formerly done by visual measurement is now done photographically, and the use of the filar micrometer is now mainly for measurement of the separations and position angles of double stars. (*See* also HELIOMETER.)

Travelling-wire Micrometer.—This is an appliance used in conjunction with the transit circle (*q.v.*) which has proved very successful in avoiding magnitude-equation and other systematic errors, and is now generally adopted in fundamental observation. The older method was to tap off on a chronograph the observed times of passage of a star across a series of fixed wires set in the focal plane of the telescope. In the travelling-wire or "impersonal" micrometer, the observer continually turns a screw so as to keep a fine wire or web continually bisecting the moving star image. (The turning of the screw moves the eye-piece as well as the wire, so that the bisected star remains apparently stationary at the centre of the field of view.) Electrical contacts are made when the moving frame reaches definite positions, and the time when the wire, and therefore the star, reaches a series of positions is thus automatically recorded on the chronograph.

Photographic Measuring Machines.—These are examples of the application of the micrometer to the *microscope*. There is a wide variety of patterns, and nearly every observatory has its own form, designed to embody some special improvement, valuable either for securing accuracy or for saving time in the particular work there pursued. Many lines of work involve a prodigious amount of measurement of photographs, and the time-saving factor is therefore of great importance. We can only summarize here some of the typical requirements. The photographic plate must be carried on slides allowing it to move in two perpendicular directions, so that any point of it can be brought directly under the microscope. The frame should have great rigidity, in order that perfect focus may be preserved. The cross-wires, glass scale or other fiducial marks, are in the focal plane of the microscope objective, and are movable in two directions at right-angles by two micrometer screws. The eye-piece is mainly responsible for the magnification. Magnification by the objective is seldom greater than 3:1; there are, in fact, many advantages in using unit magnification, *i.e.*, the image in the focal plane of the objective is the same size as the photograph itself. It may be recalled that in visual observing we magnify with the eye-lens an image formed in the focal plane of the telescope; by inserting a photographic plate in the focal plane this image is materialized and rendered permanent; the objective of the measuring microscope converts this back into an insubstantial image, preferably of the original size, and we then make our deferred examination of it with an eye-lens.

In accurate (as distinct from time-saving) machines, the modern tendency has been towards simpler construction. The secret of success is to remove the difficulties before reaching the stage of micrometric measurement, instead of elaborating the measuring instrument to solve them. In researches on stellar parallax and proper motion, it is necessary to compare two or more photographs of star fields taken at different epochs. In parallax work the photographs are now often taken on the same plate (which is kept undeveloped in the interval between the epochs), the different images of the same star being arranged close together in a symmetrical way. In proper motion work the photograph at one epoch is taken through the glass of the plate, *i.e.*, with the plate "the wrong way round"; the two plates to be compared are then placed film to film so that corresponding images are very near together. In either case the comparison resolves itself into measuring exceedingly small distances between pairs of images, and there are comparatively few sources of error.

Similar principles apply to machines for measuring spectra (celestial or laboratory). Here the motion and measurement are in one dimension only, and a line is a somewhat easier object to set on, either with single or parallel wires, than a star image. Whenever possible the measurements are made relatively to a comparison spectra, so that only small differences of position are to be measured. (A. S. E.)

MICRONESIA (from Gr. μικρός, small, and νῆσος, island), one of the three great divisions of the oceanic islands in the central and western Pacific. Lying to the north of Melanesia, it embraces the following groups: Mariana, Pelew, Caroline, Marshall and Gilbert. For full details of these various groups of islands, *see* Pacific Islands.

ETHNOLOGY

This area, besides countless small islands, comprises the Mariannes or Ladrones (Japan and U.S.A.), the Carolines, East and West (Japan) and Marshall (Japan), and Gilbert (British) groups. The people are a highly mixed stock, Melanesian to an extent, with a Polynesian influence strong in the eastern portion, whilst over all is a later infusion of Malay blood, particularly in the Western Carolines. Their skin colour extends from brown to nearly yellow, the hair is black with a tendency to curl. Eyes are almost black, the cheek bones being highly placed. The stature of the Micronesians is only medium, nor are they so robust as the Polynesians. Everywhere the Chiefly caste is well established, although such influence is not so much hereditary as personal. In languages great differences are found. The basis, however, contains Polynesian roots. Tattooing is much in vogue for both sexes, particularly on the body, slaves being debarred from this privilege. In the main they are an inoffensive and lazy people, but liable at times to get out of hand. As navigators they formerly excelled, whilst in the Marshall group the regular use of charts was common. These, formed from palm strips, showed the relative position of the various islands, and occasionally were elaborate affairs, several feet long. Although accurate to the extent of showing the prevailing winds and ocean swell, they were only of use from the actual island on which they were made. The Ladrones, from their discovery by Magellan in 1521, were controlled by the Spaniards until 1898. Of the original inhabitants little remains, except numerous stone monuments, rapidly falling into decay. To-day, they form a miscellaneous and somewhat degenerate people, of whom immigrants from the Carolines are an important section, outwardly at least, all converts of the former Catholic priests. In Guam, the largest island, records of the original Chamorro religion and social structure hardly exist, the sole records being the somewhat imperfect account of the Jesuit missionary Le Gobien, whose narrative in French was published in 1700. These people, one reads, were hardy and warlike, and opposed the Spaniards for many years and finally ceased to exist as a race. Of the Gilbert group, comparatively little knowledge of old customs remains. The people are a sturdy race, much tinged with Polynesian blood implanted on a Melanesian stock. The possession of a light coloured skin, therefore, was esteemed as occular proof of the dominant Polynesian element, and a custom was in vogue for marriageable girls to undergo a course of "bleaching," extending over a year or more. The chief held great power, and some, particularly the king of Apamama, as recorded by Robert Louis Stevenson, lived in great style. Polygamy was practised and maintained on harem lines, with specially appointed officials; alternatively, slavery was a regular institution, and their numbers were controlled at their masters' discretion. The ordinary method of burial was interment under the dwelling house, although with very important people the body was allowed to shrivel in the sun, and was kept indefinitely, being produced at festivals. Crania were objects of regard and were preserved in a shrine near the dwelling. This survival of a skull cult indicates that the Melanesian element was formerly strong enough to implant some of their customs on the invaders. The presence of the soul was recognized, for after death it passed away to the West, as among the Polynesian peoples. Local legend definitely states that the invaders came from Samoa, some 700 years ago.

The inhabitants of the Marshall group show less admixture of Polynesian blood than the Gilbertese, whilst their social structure and mode of life is more nearly related to the Caroline peoples, a dolichocephalic race. Both groups are composed of a great number of small islands, wherein individual differences exist; in addition a marked contrast is found between the eastern and western portions. The inhabitants of the last offer peculiar fea-

tures, due to Malay, or even Chinese influence. Two excellent accounts of the Pelew Islands at the western end are accessible. That of the wreck of the "Antelope" in 1783 and the narrative of one Amasa Delano, an American ship's captain, in 1791. The Carolines were known to the Portuguese in 1526, being named in 1686 after Carlos II. of Spain. They remained under nominal Spanish control down to 1899, when the group was purchased by Germany. In the island of Ponapé remain great stone enclosures and remains of artificial islands constructed in the quiet waters of the lagoons, evidence of a numerous and energetic population, since formerly these islands were the stepping stones of the early Polynesian immigrants. The investigations of Hambruch in 1910, following those of Christian, show that formerly a vast area of artificially formed land, reclaimed from the shallow water, was occupied by temples, palaces, and burying places. An elaborate social organization was in force, whilst the king was the embodiment of the gods. To-day, the whole area is congested with ruins and abandoned by the few remaining natives. The people are now divided into numerous clans, each having its chief; next, prior to the nominal conversion to Christianity, came the priests, who exercised considerable power and combined the functions of doctors. The chiefs retain to this day considerable power and have great hold on their followers. Little is known of the former religion, which was of an animistic character, and even now certain recognized natural objects are venerated. The Melanesian system of "club houses" for the males is in full force and afford the most elaborate structures in the villages. On the island of Yap this custom is particularly prevalent, and the stone money discs peculiar to this island are disposed round these "club houses" as evidence of wealth. These discs reach a diameter of 12 feet and represent the communal wealth. This stone currency, being the ownership of the community, is an object of pride to the natives, and the Germans, when in possession, enforced local laws by the simple expedient of painting the German arms on the most valued till such time as the village had carried out the Government requisitions. The institution of these "club houses" forms an important part of the social life of the men, the females being excluded, and it is the custom for the young men to reside therein at an early age.

The occurrence of pottery vessels for domestic purposes affords another peculiarity of the western Carolines, where also the betel nut (*Areca cathecu*) is chewed extensively, whilst the natives of the eastern portion are addicted to the use of kava, a true Polynesian custom.

Weaving with the loom is common to both divisions and sexes indifferently; the material used is either fine fibres from the banana, or the hibiscus; elaborate and effective patterns in colour are produced with pleasing effect.

MICROPEGMATITE, in petrology, a very fine intergrowth of quartz and alkali felspar, occurring often as the last product of consolidation in many igneous rocks which contain high or moderately high percentages of silica. It shows the same structure on a minute scale as certain pegmatites (*q.v.*) or coarse granitic veins do on a large scale (*see* the article, Petrology); the quartz forms angular patches scattered through a matrix of felspar. In polarized light the separate areas of one mineral all extinguish at the same time, and this proves that even though apparently discontinuous they have the same crystalline orientation. The felspar may be considered an irregular crystal of spongy structure, the interstices being filled up by another spongy crystal of quartz. This kind of mineral intergrowth is said to be "graphic," because the coarsely graphic veins have triangular quartz areas dotted over a felspathic background resembling certain primitive inscriptions. Micropegmatite differs from "graphic granite" only in being so much finer grained that its nature can only be detected with the microscope. The felspar of micropegmatite is usually orthoclase, but sometimes albite, oligoclase or microcline. Occasionally it has crystalline form, and then it has been proved that the quartz may be so disposed that the two minerals have a definite relation between their crystallographic axes (parallel growth). The quartz typically occurs as angular patches. Micropegmatite is often so fine grained that even in the thinnest sections and with high powers it cannot be resolved into its components. This fine micropegmatite resembles threads, having a divergent arrangement. In some rocks the whole ground mass consists of spherulitic growths of fibrous micropegmatite (*see* Quartz-Porphyry); in their centres there is often a quartz or felspar crystal; the outer boundaries of the spherulites are not usually circular but irregular owing to the interlocking of adjacent spherulites at their margins.

In rocks where micropegmatite frequently occurs (*e.g.*, granite, porphyry and granophyre, quartz-diorite) it is usually the last product of consolidation, and represents the mother liquor left over after the other minerals had separated out in more or less perfect crystals. Hence it has no definite form of its own, but fills up the irregular interspaces between the earlier crystallizations. For that reason it has been compared to a eutectic, and supposed to be the mixture of quartz and felspar which has the lowest fusion point. Eutectics are common in alloys and often have a very perfect micrographic structure. The eutectic mixture of quartz and orthoclase has been estimated to contain 70–75° of the latter. This theory, however, is not without its difficulties; analyses of micropegmatite prove that its composition is by no means constant (this may perhaps be due to small admixtures of soda and lime felspars). Furthermore micropegmatite is not always the last consolidation product, as a eutectic should be, but may occur as well-shaped phenocrysts lying in a felsitic or glassy matrix which solidified at a still later time. Micrographic structures in the minerals of igneous rocks prove only that these minerals crystallized simultaneously. (J. S. F.)

MICROPHONE or **TELEPHONE TRANSMITTER,** a device for converting mechanical energy of sound waves into electrical energy with similar vibrational characteristics. The first instrument used for this purpose was the telephone receiver invented by Alexander Graham Bell in 1876, the same type of instrument being then used in a telephone circuit for transmitting and receiving. (*See* Telephone.) The term microphone, however, was first used by D. E. Hughes in connection with his discovery in 1878 that a loose contact in a circuit containing a battery and a telephone receiver may give rise to sounds in the telephone corresponding to the vibrations to which the contact is subject.

Hughes constructed his microphone in the form of a horizontal carbon rod resting in grooves in two carbon blocks, the battery and telephone receiver being connected in series with these blocks.

Microphones have in general been developed on two main lines.

First, as instruments (similar to the Hughes type) where the action is that of an amplifying relay, the impact of sound waves on the microphone causing a variation of energy supplied by a local battery. In this case efficiency is the primary object.

Secondly, as instruments where the electrical energy is mainly derived through the microphone from the mechanical energy of the sound waves, the first considerations being the perfection of frequency characteristic and a linear relation between air pressure and consequent electric current.

The former type has been developed for commercial purposes such as telephone communication systems; the latter for scientific work such as sound measurement (*see* Sound) and for purposes where high quality is essential, as, for instance, in broadcasting and gramophone recording installations.

The conversion of pressure vibrations in the air into corresponding electrical vibrations in an electrical circuit is generally carried out in two operations, which take place simultaneously.

First of all the sound wave impinges on a surface in the instrument (usually known as the diaphragm), which is capable of slight movement. The variation of air pressure on this diaphragm causes it to move to and fro in a manner corresponding to the

backwards and forwards movement of the particles in the air—that is corresponding to the original sound.

The second operation is that in which the diaphragm by its movement causes a corresponding change in some property of an electrical circuit. Thus the diaphragm may be one plate of a condenser producing variations in capacity, or it may be part of an inductive electromagnetic system, or it may cause variations of electrical resistance. In each case variation of current takes place by diaphragm movement.

Thus, in studying the performance of microphones, two things must be considered: first, the mechanical movement of the diaphragm; secondly, the nature of the method in which this movement sets up the changes which we desire.

Commercial Types.—The majority of these are of the loose contact type, the resistance of the contact varying with the pressure applied.

The change of resistance with pressure varies greatly with materials used, and it has been found that particles of carbon in light contact with each other produce the greatest change in resistance when subjected to small variations of pressure.

The electrical A.C. energy produced at the contact, since the power is taken from a local battery, may be many times the energy of the accoustic input, and this may be increased by increasing the current from the battery passing through the contact. But there always exists a slight variation of current at the contact even when no sound waves are impinging on it, which is heard as a hiss in a telephone receiver, and if the current through the contact is increased too much, the hiss becomes a loud crackling noise, due to overheating at the contact points.

Another disadvantage is that the contact or contacts may get into a very insensitive state known as "packing," the remedy for which is an occasional shaking.

The connection between input pressure and output current for this type of microphone is only linear (*i.e.*, proportional) for a very small range of pressures.

Speech transmission and reproduction can, however, be considerably distorted before becoming unintelligible to the human ear, and the efficiency of the microphone can be improved by introducing resonances at certain frequencies which are useful for intelligible transmission. Microphones of this type incorporate diaphragms with natural periods round about 800 cycles per second, and although the lowest and highest frequencies are lost with a considerable decrease in naturalness, the result is sufficiently good, even with the non-linear conditions of normal use, to be

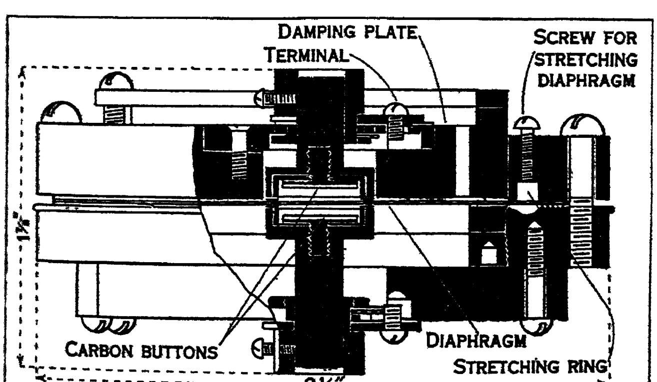

FIG. 1.—WESTERN ELECTRIC DOUBLE-BUTTON CARBON MICROPHONE

intelligible and practicable for transmission over a telephone system.

A familiar type of commercial microphone is one in which the current-varying element or "inset" is a cell consisting of two small carbon electrodes with polished faces, the space between which is filled with carbon granules. One of the electrodes is fixed and the other attached to a circular metal plate, which acts as a diaphragm to receive the sound waves.

This type of microphone, on account of the fact that it deals with only a limited range of frequencies, and also provides non-linear distortion, is quite unsuitable for the transmission of music and natural speech.

High Quality Types.—In recent years a careful study of the response of microphones to sound pressure has been made, with the objects in view of accurate sound measurement and of faithful transmission of speech and music. As a rule, to obtain high quality, efficiency must be sacrificed. Thermionic valve amplifiers must be used to bring the voltages provided by the

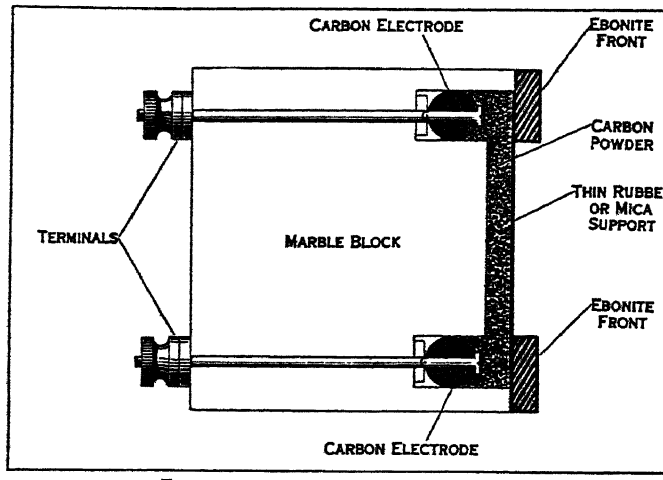

FIG. 2.—REISZ CARBON MICROPHONE

microphone up to the strength required for any particular practical purpose.

This type of microphone must rigidly fulfil certain conditions, while others must be satisfied as far as possible. These conditions are as follows:

(1) The microphone must have a good frequency characteristic. It must be equally responsive throughout the range of frequencies from 25 cycles to 10,000 cycles per second. (2) The condition of linearity must be satisfied for the range of pressures with which it is likely to deal. (3) The microphone must be free from inherent noise or hiss. (4) It must be sensitive so that not too much amplification is necessary to bring the voltage output to a suitable strength. (5) The microphone must be robust so that its essential characteristics in the given conditions of use are retained and it must be easy to install and maintain. (6) It must be sufficiently small to cause no serious disturbance to the sound field.

Usually some sort of compromise must be made, depending on the purpose for which the microphone is to be used.

Two types of carbon microphone come in the "high quality" class. The first, the Western Electric "double-button" carbon microphone (fig. 1) has a diaphragm of duralumin, stretched to a natural period above the useful range of frequencies, and subject to air damping. A capsule of carbon granules is placed on each side of the diaphragm. The second, called the Reisz microphone (fig. 2) has no diaphragm as such, but the sound acts on a layer of very fine carbon granules, placed on a heavy non-conducting block, and held in position by some material such as thin rubber or mica. The flow of current and its variation take place in a direction at right angles to the direction of application of pressure.

Each of these microphones has a fairly good frequency characteristic, and is linear up to moderate sound pressures, but for the largest sound pressure variations met with in practice, the linear relation does not hold and "blasting" or non-linear distortion takes place.

The best known "high quality" microphone is the condenser microphone developed into an instrument of precision by the Western Electric Co., Ltd. (fig. 3).

The diaphragm is of duralumin, and is stretched to a very high natural period and air damped, and held very close to a solid insulated metal plate, the two forming the sides of a condenser.

A stretched diaphragm of this type naturally exihibits very marked resonance characteristics, having a much greater response for its natural frequencies than other frequencies. If damping is increasingly applied all over the diaphragm the resonances tend

to be less marked, and a point will be reached when the frequency characteristic curve becomes almost level corresponding to a fairly equal response for all frequencies under consideration. A further increase in damping will only result in reduction of overall sensitivity. In the first microphones of this type designed by Wente, the diaphragm was stretched to a period of 17,000 cycles per second, thus outside the useful and audible range of

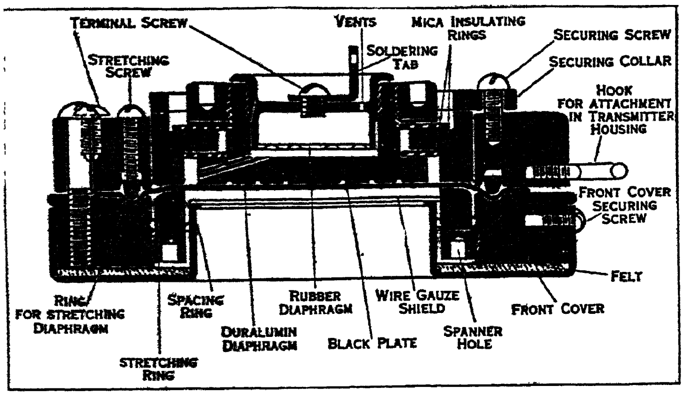

FIG. 3.—WESTERN ELECTRIC CONDENSER MICROPHONE

frequencies, the response inside the range being fairly uniform.

The air damping or cushioning due to the proximity of the fixed plate, which was held at a distance of about three thousandths of an inch from the diaphragm, was adjusted to the correct value by sinking holes in the face of the fixed plate. The type was rather insensitive and large amplification was necessary, but the frequency characteristic could be made practically perfect.

In more recent types which have been developed with a view to obtaining greater sensitivity, the stretching frequency has been reduced so as to bring it into the audible range. The frequency characteristic (*see* fig. 5) is not quite so good, but sufficiently good for most practical purposes.

The advantages of the condenser microphone (*see* fig. 4) besides its good frequency characteristics, are that it is quite linear, and free from background noise. Its chief use is for sound measurement, as it can be calibrated with accuracy, and with careful use retains its calibration for several years. (*See* SOUND.)

Several electrodynamic types of microphone have been pro-

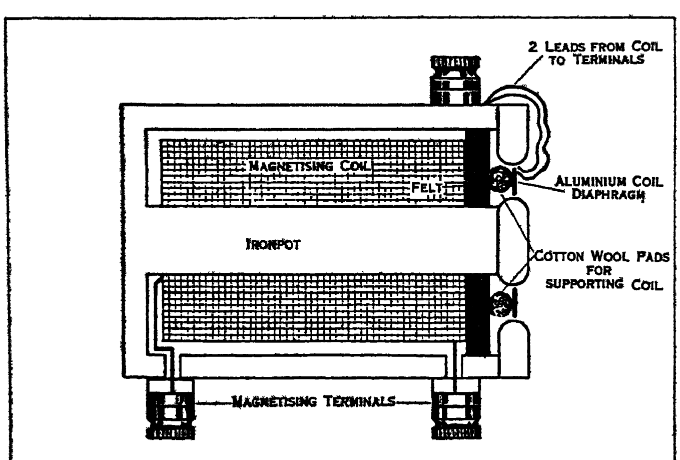

FIG. 4.—SYKES-ROUND ELECTRO-DYNAMIC MICROPHONE

duced. In the Sykes Microphone as perfected by Round (fig. 4) a flat annular ring of aluminium wire is suspended in a magnetic field, and acts as the diaphragm to receive sound waves. In another type developed by Siemens-Halske, the diaphragm consists of a thin strip of aluminium foil suspended in a strong magnetic field.

Although linear these two types have not such perfect frequency characteristics, lacking response to the lowest frequencies.

Various other types of microphones have been evolved for special purposes, but they have not been put to much general use. For instance the hot wire microphone has been developed by Tucker for the detection and location of gunfire and of aeroplanes. The microphone consists of a fine wire grid which is heated by a local battery and connected in a bridge type of circuit. The impact of sound waves cools the grid and the resultant change of resistance is observed. It is insensitive and must be used with resonators to increase the effect. As a consequence it cannot be used for musical purposes.

The glow discharge microphone has been made by the Westinghouse Co., and also in Germany in the form of a capsule consist-

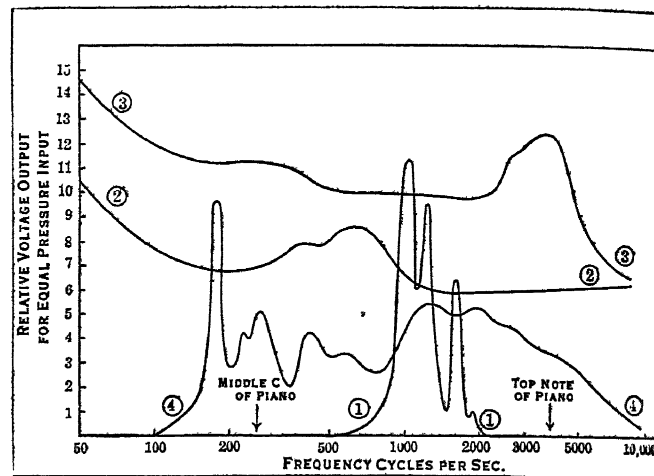

FIG. 5.—FREQUENCY CHARACTERISTICS OF MICROPHONE SHOWING RESPONSE OF DIFFERENT TYPES OF MICROPHONE TO MUSICAL FREQUENCIES (1) Solid back microphone. (2) Reisz microphone. (3) Condenser microphone. (4) Sykes microphone

ing of two electrodes between which an open electric discharge is maintained. The resistance of the discharge varies under the influence of sound waves striking it.

Although sensitive and having a good characteristic, this microphone is not particularly stable, and needs frequent replacement of electrodes.

Crystal microphones, where advantage is taken of piezo-electric effect, have been used for work with high frequencies; and eddy-current microphones where a metal diaphragm in moving in an electromagnetic field sets up currents by induction in a fixed circuit, have been investigated from the point of view of telephone measurement work.

Microphone Amplifiers.—Valve amplifiers for use with microphones have been constructed with practically perfect frequency and linearity characteristics.

Resistance capacity intervalve coupling is used to take care of the former, and the valves are operated on the straight, parts of their characteristics being chosen with sufficient factor of safety in their relative positions, to make sure of the latter.

With carbon and electromagnetic microphones, which are usually of low impedance, a coupling transformer is used to the grid of the first valve of the amplifier. The condenser microphone however has a very high impedance, and it is usual to polarise the microphone by a high voltage battery through a resistance of several megohms, the change in potential across this resistance due to variations in the capacity of the microphone being impressed through appropriate coupling condensers on the grid of the first valve.

Another method of using the condenser microphone is as part of a tuned high frequency circuit of an oscillating valve, variations of capacity causing variations of (high) frequency which can be rectified in a circuit coupled to the original circuit and amplified as required. This method has the advantage that the condenser microphone is not used in a high impedance circuit.

Methods of Measurement.—The measurement of the performance of microphones is difficult on account of the absence of a really fundamental method of sound measurement.

It is however possible to get a fairly good idea of the frequency characteristics of any particular microphone by a method of comparison with a standard. The following four methods have

been evolved, and give results fairly well in agreement although it is very difficult to make proper allowance for the conditions under which measurements by the various methods are carried out:

(1) *Rayleigh Disc.*—A disc of mica about 1 cm. in diameter with a mirror in the centre is suspended by a torsion thread in a sound field. The velocity of the air particles is measured by the angle through which the disc turns, and the value of the sound pressure can be deduced. König and other workers have evolved formulae by which the strength of the sound field can be calculated. The difficulty in this method is that the disc cannot be used in the open air or in a normal sized room on account of its susceptibility to small draughts or gusts of wind. The measurements have to be made in a box lined with sound absorbent material, and it is difficult to estimate exactly the effect of this box on a sound field produced inside it. A given microphone is placed near the disc inside the box and its frequency characteristic determined by a method of comparison.

(2) *Thermophone.*—The Western Electric Co. in developing their condenser microphone have used the thermophone for calibration purposes. It consists of a strip of gold leaf placed in a small enclosed chamber very close to the diaphragm of the condenser microphone. Alternating current of various frequencies is passed through the strip, the thermal action setting up corresponding air pressures at the diaphragm of the microphone. The theory was worked out by Wente, and the microphone can in this way be calibrated.

(3) *Compensation Method.*—This is due to Gerlach who arranged a conducting diaphragm in a strong magnetic field and passed through it a current of the same frequency as that of a nearby sound source, and adjusted the phase and strength of the current so that the diaphragm remained stationary under the two forces due to the sound pressure from the source, and the current passing through itself. The value of the air pressure at the face of the diaphragm can be deduced from the strength of the current. An analogous electrostatic method of measuring sound (field strengths) has also been worked out.

(4) *Electrostatic Method.*—Round has employed a method which can be used in certain cases where the diaphragm is flat and completely open. In front of the diaphragm (which if of non-conducting material is gold plated for the purpose) is brought a solid metal block with a flat face, and pressure is applied to the diaphragm by electrostatic attraction. It is possible thus to obtain the relation between pressure on the diaphragm and voltage output for various frequencies.

Each of the above methods gives either a calibration of a microphone or the measurement of a sound field. In the latter case the calibration of any type of microphone can be obtained by comparison, but it is important, whatever method is used, to know what precautions must be taken and what corrections must be applied to obtain a satisfactory result.

It is believed that the most accurate results are those obtained with a condenser microphone calibrated by means of the thermophone. For this reason the British Broadcasting Corporation, in the method of calibrating microphones for broadcasting purposes which it has developed, uses a calibrated condenser microphone in conjunction with a high quality loud speaker which is capable of producing pure tones at frequencies from 40 to 8,000 cycles per second.

This loud speaker is placed in a room the walls, ceiling and floor of which have been covered with material absorbing over 80% of the sound impinging on them.

The condenser and other microphones are swung on a trapeze at given mean distances in front of the loud speaker, and the resulting voltage from the microphones amplified and measured on a thermo galvanometer. (*See* INSTRUMENTS, ELECTRICAL.) The method of swinging and the existence of lag in the movement of the thermo junction get over the difficulties caused by the standing waves set up between loud speaker and microphone, and by those due to reflection by the walls, and after applying the proper corrections the frequency characteristic of any microphone can be obtained. In the same way the characteristics of any loud speaker can be measured.

The frequency curves of several types of high quality microphone as measured in this manner are shown in fig. 5. The curves are not supposed to indicate the relative sensitivities of the various types.

MICROSCOPE, an optical instrument for examining small objects or the fine detail or structure of objects (Gr. μικρός, small, σκοπεῖν, to view); it acts in such a way that in the eye a clearly focussed image is formed which is larger than the unaided eye could produce. Microscopes are distinguished as *simple* or *compound.* A simple microscope is generally called a *magnifying glass* and consists of a single positive lens, or of a lens combination which acts as a single positive lens. A compound microscope generally consists of two lens systems each of which acts as a single positive lens. The system nearer the object (called the *object-glass* or *objective*) forms a real enlarged image of the object. This image is then viewed through the second system (called the *eyepiece*) as though it were a real object being examined by a magnifying glass.

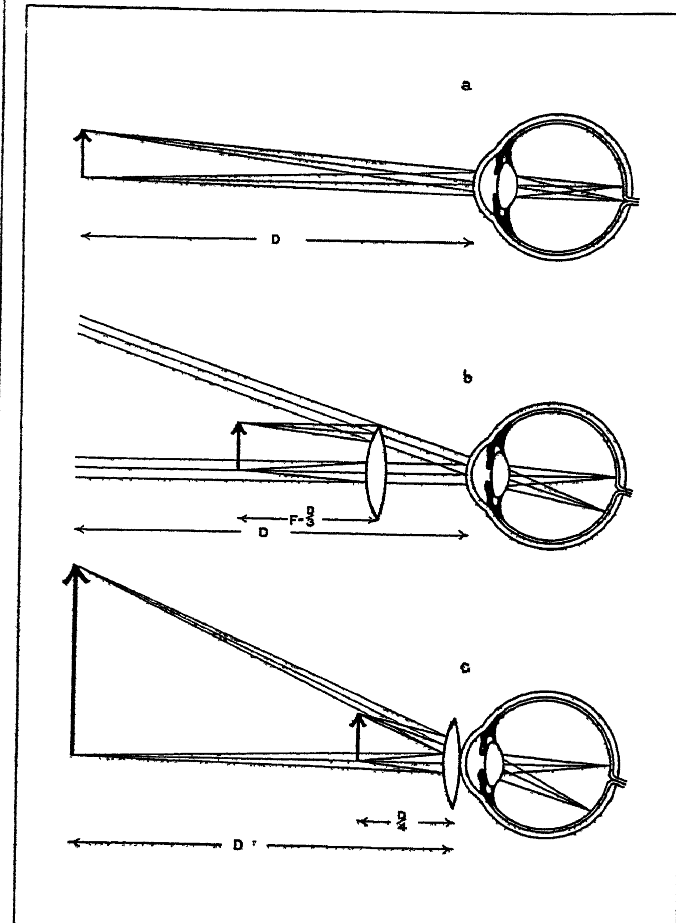

FIG. 1.—MAGNIFYING POWER OF SIMPLE LENS
(a) Object at distance of clearest vision (D), seen with unaided eye. (b) Object at principal focus of a lens having focal length D/3. Image is at infinity. Magnifying power = 3. (c) Object so near to lens that the image is formed at distance D. Magnifying power, if the lens is in contact with the eye, = 4

SIMPLE MICROSCOPE

The distinctness with which the detail of an object can be seen depends on (a) the sharpness of the image produced in the eye and (b) the size of this image. As an object is brought nearer and nearer to the eye, it is seen more and more distinctly, pro-

vided the image is kept sharply focussed on the retina, because the image and image-detail get larger and larger. The upper limit of distinctness is reached when the object is in the nearest position at which its image can be sharply focussed. For the normal eye this distance is taken to be 10 in. or 25 cm., and this is called the *normal distance of clearest vision* (fig. 1.a). By using a simple microscope in front of the eye, it is possible to bring an object nearer than the distance of clearest vision for the unaided eye, and yet to see it clearly (fig. 1.b).

If f is the focal length of the lens and D the observer's distance of clearest vision, the image seen is larger than the largest image that could be seen clearly by the unaided eye in the proportion D/f. This is the *magnifying power* of the lens when used in this way. The assumed standard value for D, is the normal distance of clearest vision, *i.e.*, 10 in. or 25 cm. We thus obtain

$$\text{Magnifying Power} = \frac{10}{f\,(\text{in.})}, \text{ or } \frac{25}{f\,(\text{cm.})}.$$

If the distance between the object and the lens is made somewhat smaller than the focal length of the lens, the rays from the object may be made to enter the eye as though they came from an enlarged object situated at the distance of clearest vision (fig. 1.c). When the lens is held quite close up to the eye and used in this way its magnifying power is given by

$$\text{Magnifying Power} = \frac{10}{f\,(\text{in.})} + 1, \text{ or } \frac{25}{f\,(\text{cm.})} + 1.$$

Magnifying powers of lenses of comparatively long focus are given by the second formula, but the magnifying powers of short-focus lenses are calculated by the first formula. These formulae really give nothing more than standard methods of *rating* a lens in terms of its magnifying properties. Only a person with a distance of distinct vision equal to 10 in. (*i.e.*, only a normal-eyed person) will use a lens so as to obtain its *rated* magnifying power.

When an object is viewed through a fine hole in an opaque screen held close to the eye, the rays from any point in the object enter the eye in such narrow pencils that the image appears sharp, even when the object is well within the distance of clearest vision. A fine hole can thus be used, in a way, instead of a simple microscope.

Regulation of the Rays.—Simple microscopes of moderate or low powers are not usually fitted with diaphragms at all, as the pupil of the observer's eye determines what rays are effective in producing the image seen. The eye is usually placed close up to the simple microscope, so that by moving the eye about in its socket the images of different parts of the object can be brought on to the central portion of the retina, exactly as is done when the eye is examining an object without the aid of a lens.

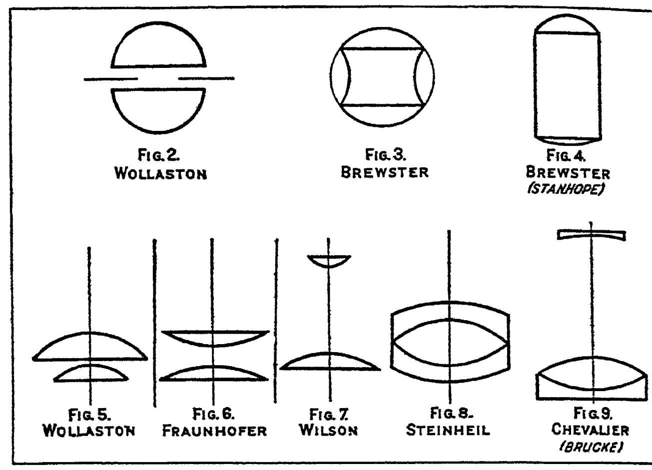
In high-power lenses it is necessary to limit the rays which are allowed to pass through the lens, so as to reduce the effects of the *aberrations* of the lens. This is done by fitting one or more diaphragms, so that only those rays for which the lens is properly corrected can pass through. In order to examine different portions of an object by means of such a lens, it is necessary to move the eye from side to side by moving the whole head, exactly as though the object were being examined through a hole in a screen.

The brightness of an object as seen through a simple microscope remains practically constant as the eye is moved about, unless the rays from the particular portion being observed are partly cut off by the lens mounting, or by a diaphragm in the lens.

With high power lenses the light is often caused to pass through an area smaller than the pupil of the eye. There is then a loss of brightness in the image, and it may be necessary to illuminate the object strongly.

Depth of Focus.—In using a simple microscope to examine a three-dimensional object, different levels in the object can be focussed by making use of the accommodation of the eye, though this range is only very small with lenses of high power. With lenses of low power, or with lenses which have very small apertures, there is also a certain range of depth in the object which appears all to be in focus at once. Actually only the points in one plane are truly focussed at any one time. If circular images on the retina are smaller than about $\frac{1}{5000}$ in., however, they appear sharply defined, hence there is an appreciable depth of focus obtained with lenses of low power or very small aperture, owing to the small angle of the cone of rays entering the eye from any particular point in the object.

Common Forms of the Simple Microscope.—An ordinary convex lens with spherical surfaces does not give a perfect image,



FIGS. 2–9.—VARIOUS FORMS OF SIMPLE MICROSCOPES

owing to the aberrations of the lens. The aberrations with which we are chiefly concerned are (1) chromatic aberration, (2) spherical aberration, (3) astigmatism and (4) flatness of field (*see* OPTICS). To obtain a perfect image it is necessary, therefore, to correct the lens (1) so that it will bring light of all colours to a common focus, (2) so that each zone of the lens will have the same focus as the other zones, (3) so that each oblique pencil of light will come to a point focus after passing through the lens, and (4) so that points lying in one plane in the object will all appear sharply focussed at one time. These corrections can only be carried out by combining together lenses of different powers and made of different glasses, though spherical aberration can be appreciably reduced without using more than one lens.

Among the early lenses which were constructed so as to have reduced spherical aberration is Wollaston's. Wollaston made his lens as two almost hemispherical lenses with a diaphragm mounted centrally between their plane faces. Sir David Brewster improved on this by embedding a diaphragm in a transparent cement used between two hemispheres of glass. He obtained a precisely similar result by grinding a groove round a sphere of glass. Coddington did much towards making this type of lens more widely known and it is generally called the Coddington lens, though Coddington did not invent this nor did he claim to have done so. Brewster also invented a lens in the form of a glass cylinder with its ends ground and polished as spherical surfaces of different curvature. When the more convex end is placed towards the eye, any object held in contact with the less curved end can be seen clearly. This form is usually known as the Stanhope lens.

Among early compound lenses are Wollaston's doublet which consists of two plano-convex lenses the focal lengths of which are in the ratio 3:1, and Fraunhofer's lens consisting of two plano-convex lenses of equal power with their convex sides mounted inwards and separated somewhat from each other. Wollaston's doublet was improved later (1) by introducing a diaphragm between the two lenses, (2) by increasing the separation between the lenses, and (3) by substituting *two* lenses for the smaller lens, thus converting the system into a triplet. The triplet form was used when very high magnifying powers were required.

To correct for chromatic and spherical aberration simultaneously, positive and negative lenses of different powers and made of different types of glass are used in combination as doublet or triplet systems. Combinations of such systems can also be used. Steinheil's *aplanatic* is a typical triplet system of two negative

lenses combined with a single positive. By using suitable combinations of lenses, magnifying glasses having powers $\times$ 40 can be made practically free from aberrations, and satisfactory lenses giving $\times$ 70 and even $\times$ 100 have been produced. A type of lens which, though used as a simple microscope, is designed on the same lines as one form of compound microscope, was suggested by Chevalier and made by Brücke. It consists of a positive achromatic doublet, with a negative lens mounted at some distance behind it.

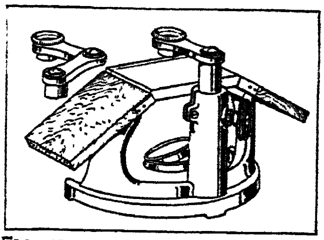


FIG. 10.—DISSECTING MICROSCOPE (BECK)

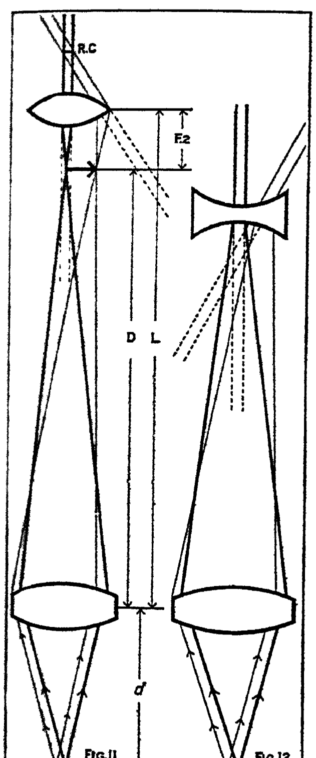
Stands.—For certain purposes, such as dissection work, it is convenient to mount the simple microscope on an arm which is adjustable relative to a stage on which the object is laid. If a high-power simple microscope is being used, provision must be made for accurate focussing and for adequate illumination of the object. Usually, however, only low-power work is done nowadays with a simple microscope, and for this reason the stands are not generally provided with more than a rack and pinion adjustment, with a mirror beneath the stage for illuminating transparent objects, and with a condensing lens for illuminating opaque objects. Detachable arm rests are fitted to the more complete models and the lens holder is adapted to take lenses of different powers, which are interchangeable one with another.

The stage is either made of plate glass, or as a frame covered with a white opal-glass plate.

For dissecting and similar work it is of advantage if the details of the object can be seen as they are actually disposed in space. To meet this requirement stereoscopic devices are used.



FIGS. 11 & 12.—DIAGRAMMATIC REPRESENTATION OF COMPOUND MICROSCOPES

Paths of the rays through a microscope with a positive lens as eyepiece are shown in Fig. 11. The rays pass through R.C., the Ramsden circle or eyepoint, after leaving the eyepiece. In Fig. 12 are shown the paths of the rays when a negative lens is used as the eyepiece

COMPOUND MICROSCOPE

A compound microscope consists of a positive or converging lens, called the *object-glass*, which forms a real, inverted, magnified image of the object. This image is then viewed by means of a second lens, called the *eyepiece*, which is usually another positive lens or lens system (fig. 11). For certain purposes a negative lens is sometimes used as the eyepiece; this cause an "erect" image to be seen (fig. 12).

If we consider the object-glass as a thin lens, with the object at a distance d on one side of it and the image at a larger distance D on the other side, then the image will be larger than the object in the proportion D/d. This proportion D/d is the *magnification*, M_O, produced by the object-glass. The eyepiece may be considered as a simple microscope, of magnifying power M_E, which is used to examine the magnified image formed by the object-glass. The total magnification obtained is thus equal to $M_O \times M_E$. The distance d is approximately equal to f_1, the focal length of the object-glass, while D may be taken as equal to the "tube-length" (L) of the microscope. This gives M_O equal to L/f_1. The value of M_E is taken as $10/f_2$, where f_2 is the focal length of the eyepiece in inches (see *Simple Microscope*). Hence, if all the quantities are expressed in inches, the magnification obtained is given approximately as

$$\text{Magnification} = \frac{L}{f_1} \times \frac{10}{f_2} = \frac{10L}{f_1 f_2}.$$

With an object-glass and an eyepiece, each of one inch focus, therefore, the magnification obtained, if the tube length is 10 in., would be about 100, or, with a tube length of 6 in., about 60.

THE OBJECT-GLASS

The quality of the image seen in the compound microscope depends primarily on the quality of the real image formed by the object-glass. Any imperfections in this image are magnified when the image is viewed through the eyepiece. The image formed by the object-glass should, therefore, be as sharp as possible, and to secure this the aberrations of the object-glass should be reduced to the smallest practicable values. The object-glass should also have a high *resolving power.*

Resolving Power.—Imagine the lens L (fig. 13.a.) to be a perfectly corrected lens with its aperture limited by a diaphragm, the edges of which are at DD. A luminous point is at O, on the axis of the lens, and an image of this point is formed at I by the lens. This image will not be a point but, in consequence of the diffraction of the light at the diaphragm, will take the form of a bright disk surrounded by concentric dark and bright rings (*see* LIGHT). The brightness of the central disk and of the surrounding system of rings is indicated in fig. 13.b, in which the form of the curved line represents the distribution of brightness in the image plane around I. The diameter of the first dark ring, or the full diameter of the central disk, is represented by the distance dd. The brightness of the disk falls off rapidly towards the edge, and a visual estimate of the diameter would usually put it at about $\frac{2}{3}$ of the full diameter dd. The diameter dd depends on the wave-length of the light emitted by the source at O, and on the angles which the extreme rays make with the axis of the lens.

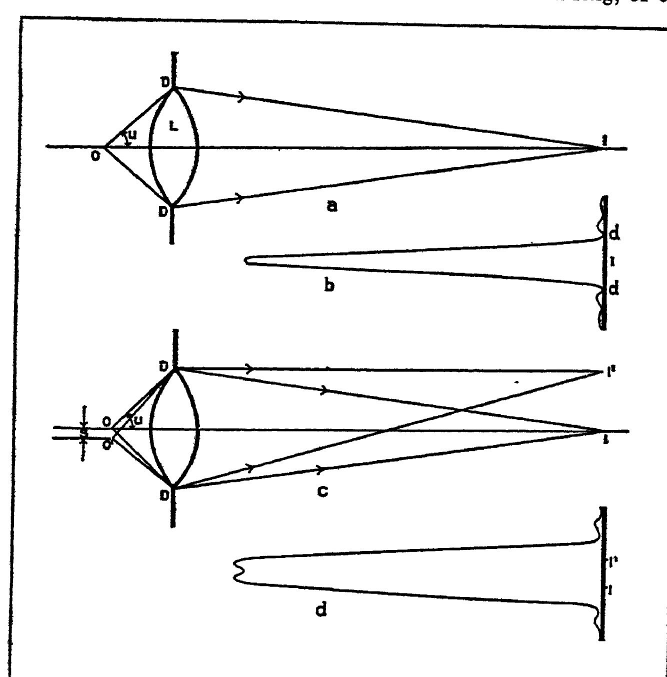


FIG. 13.—RESOLVING POWER OF A LENS

(a) Shows the image-forming rays from a single self-luminous point at O, the "geometrical" image being at I. (b) Distribution of light in the image plane round the geometrical image-point I, is indicated in this figure; the central bright area extends as far as dd. (c) Shows the image-forming rays from two self-luminous points O and O[1], the geometrical images being at I and I[1]. (d) Indicates the distribution of light in the image-plane when O and O[1] are so close together that their images are only just distinguishable

If we have two independent similar point sources at O and O' (fig. 13.c) equidistant from the lens, each of these will produce a disk image with its surrounding system of rings; the centres of the two systems will be at I and I' respectively. If the disks are

completely separated they will be seen clearly, but if they overlap by more than a certain amount they will merge into a single bright area over the centre of which the brightness is almost uniform: the two disks will not then be distinguishable as separate images. In the latter case the *resolving power* of the lens is insufficient to enable O and O' to be resolved as separate point sources. The resolving power of a microscope object-glass is usually stated in terms of the minimum distance which must exist between two details in the object if their images are to be distinguishable as separate images.

Now if the extreme ray OD makes an angle u with the axis of the lens, the two point sources O and O' (fig. 13.c) will give rise to diffraction disks which will be just completely separated if

$$s = \frac{1 \cdot 22\lambda}{\sin u},$$

where λ represents the wave-length of the light emitted by the sources O and O', and s represents the distance between O and O'. The edges of the diffraction disks are, however, only very faint, consequently the images can be plainly distinguished even if the diffraction disks overlap to a quite appreciable extent. The distribution of brightness indicated in fig. 13.d, corresponds to the relation

$$s = \frac{0 \cdot 51\lambda}{\sin u}.$$

Between the two brightest points there is, in this case, a line in which the intensity is 97% of that at the two maxima. This is probably sufficient for the two maxima to be just distinguishable. For a trained observer with eyes of normal acuity, the limit of resolution obtainable may thus be taken as about

$$s = \frac{\frac{1}{2}\lambda}{\sin u}.$$

If the medium has a refractive index n, the wave-length of the light will be shorter than it would be in air, in the proportion $1/n$. We can use λ_a, the wave-length *as measured in air*, in this formula by substituting λ_a/n for λ, when we obtain

$$s = \frac{\frac{1}{2}\lambda_a}{n\sin u}.$$

The quantity $n\sin u$ is a property of the lens, since it depends on u and on the refractive index of the medium in which the lens is intended to be used on the object side; it is called the *numerical aperture* of the lens. For a "dry-front" lens n is unity, and the maximum numerical aperture such a lens can have is 1.

Immersion Lenses.—Many lenses are designed for use with a layer of fluid filling the space between the front of the lens and the object or cover-glass. The maximum numerical aperture such an *immersion lens* can have is determined by the refractive index of the *immersion fluid*, by the refractive index of the cover-glass (if any) over the object, or by the refractive index of the front lens of the object-glass, whichever of these three has the lowest value. The front lens of an immersion object-glass is usually made of crown glass of refractive index 1·508 to 1·525; the cover-glasses most commonly used have a refractive index between 1·515 and 1·525. For most immersion lenses, therefore, a thickened cedar-wood oil, having a refractive index of 1·515 to 1·525, is used as the immersion fluid. For obtaining still higher resolving powers, object-glasses have been made with front-lenses of refractive indices up to 1·66, for use with proper immersion fluids. A *homogeneous immersion* lens is an object-glass designed for use with an immersion fluid having the same refractive index as its front lens.

Aberrations of Object-glasses.—Unless the aberrations of the lens are very small, the actual resolving power will fall short of that corresponding to the numerical aperture, except with certain special methods of illumination which may give a semblance of resolution. In an object-glass, therefore, we require, in addition to a reasonable magnifying power, (a) an appropriately large numerical aperture and (b) the most nearly perfect corrections it is possible to obtain over the whole of this aperture.

Spherical aberration can be corrected by combining together individual lenses, of suitable forms, all made of one kind of glass. A more usual method is to use combinations of lenses of different glasses which may either be cemented or may be mounted at suitable distances from each other and separated by air. This method lends itself to the simultaneous correction of both spherical and chromatic aberrations, and is therefore used for all ordinary microscope object-glasses. In the more powerful object-glasses several individual lenses and lens systems must be used in order to obtain the requisite degree of correction over the whole aperture (fig. 14).

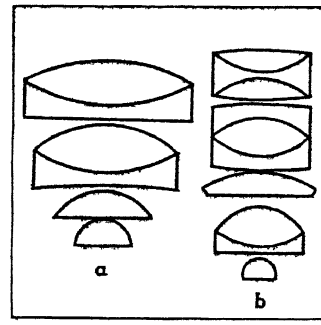

FIG. 14.—EXAMPLES OF LENS SYSTEMS USED IN OBJECT-GLASSES
(a) Achromatic system, (b) apochromatic system

To secure a good image of a small object it is not sufficient merely to correct the spherical aberration for a point on the axis of the object-glass. It is necessary, in addition, that the light in the object plane be brought to focus in the corresponding area in the image plane. Seidel (1856) and Clausius (1864) investigated the conditions which must be fulfilled to obtain this, and showed that there must be a definite relation between the inclinations of the rays on the object side and the inclinations of the corresponding rays on the image side. Helmholtz and Abbe investigated this independently in 1873 with similar results. The condition is, if a ray from a point lying on the axis in the object plane is inclined to the axis at an angle u, the corresponding ray on the image side must be inclined to the axis at an angle u' such that

$$n\sin u = C\sin u',$$

where C has the same value for every ray coming from the point in question. Abbe drew special attention to the importance of this condition being satisfied in designing microscope object-glasses, and gave to it the name of the "sine-condition." If the axial spherical aberration has been corrected but the sine-condition has not been fulfilled, the pencils of rays which come from a point a little off the axis are brought to focus at different distances from the axis on the image side (fig. 15), giving different magnifications according to the zone of the lens through which the pencils pass.

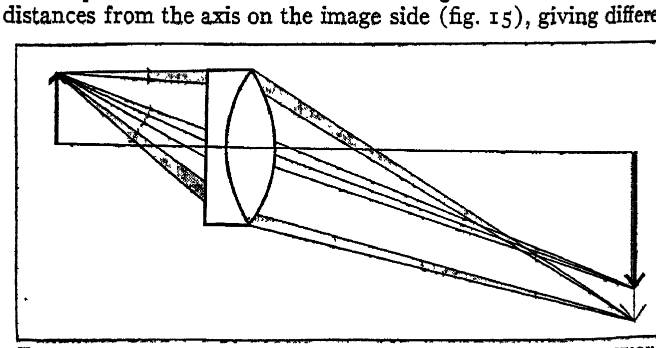

FIG. 15.—EFFECT OF NON-COMPLIANCE WITH THE "SINE-CONDITION"
Rays passing through different zones of the lens produce different degrees of magnification

Chromatic aberrations can be corrected by using lens combinations in which the individual lenses are made of different types of glass. A negative lens of low power, made of flint glass, will produce a dispersion equal and opposite to that produced by a positive lens of considerably higher power made of crown glass. Two such lenses, correctly combined together, will act as a positive lens with a common focus for both the blue and red rays. Such a lens is called an *achromatic lens*.

Although the blue and the red rays of certain selected wave-lengths can be brought to a common focus in this way, rays of other wave-lengths will not come to the same focus as the red and

blue rays, owing to the differences between the relative "partial" dispersions of the two glasses. The lens thus gives an image which is slightly coloured at the edges, and is said to show "secondary colour." In modern *apochromatic* lenses three selected wave-lengths are made to have a common focus; thus only a trace of "tertiary colour" is present and this in some instances is so small as to be unnoticeable. It has not been found possible, as yet, to design apochromatic lenses which give precisely equal *magnification* for light of different colours. This can be corrected by a suitable eyepiece called a "compensating eyepiece" (*see* p. 438). An achromatic lens is usually corrected spherically for *one* colour only, an apochromatic lens should be corrected so as to have no spherical aberration for light of *two* different colours.

Other Aberrations of Object-glasses are:—curvature of field, distortion, astigmatism, and extra-axial coma. These are aberrations of oblique pencils; their effect is to impair the image of any object-details lying off the axis, and to cause the image to lie on a curved surface so that it cannot all be seen in focus at one time. These defects are not of great importance in the ordinary use of the microscope since, if the sine-condition is satisfied, the definition is good over an appreciable area round the centre of the field where the field is flattest. For microphotographic work, however, these aberrations are most objectionable. It is possible to select types of design such that, in correcting the lens for axial, spherical and chromatic aberrations, the aberrations of oblique pencils are kept within small limits over a fairly large angle. Any object-detail to which particular attention is being paid should be brought into the middle of the field of view, *i.e.*, on to the axis of the object-glass.

Monochromatic Object-glasses for Visual Work.—For the purpose of obtaining higher resolving powers than have hitherto been obtainable with achromatic and apochromatic object-glasses, certain *monochromatic* lenses have been made, for use with radiations of one wave-length only. This method makes it possible to obtain full correction for spherical aberration over a numerical aperture larger than that over which combined chromatic and spherical correction has hitherto been satisfactorily accomplished. Modern apochromatic immersion lenses of high quality are made with numerical apertures up to 1·4, while monochromatic lenses, fully corrected up to 1·6, have been designed.

Aberration Produced by a Cover-glass.—A microscopic object-glass is usually designed to be used with an object placed on the axis at a particular distance in front of the lens and covered with a cover-glass of particular thickness and refractive index. The image of such an object will then be formed at a particular distance behind the lens and, if the lens is properly designed and made, this image will be free from spherical aberration. If the cover-glass is not of the proper thickness the image will not be free from spherical aberration and, to correct the aberration thus introduced, the distance between the object and the object-glass must be altered. This will alter the distance between the image and the object-glass, so the length of the microscope tube (the distance between the object-glass and the eye-piece) will have to be altered accordingly.

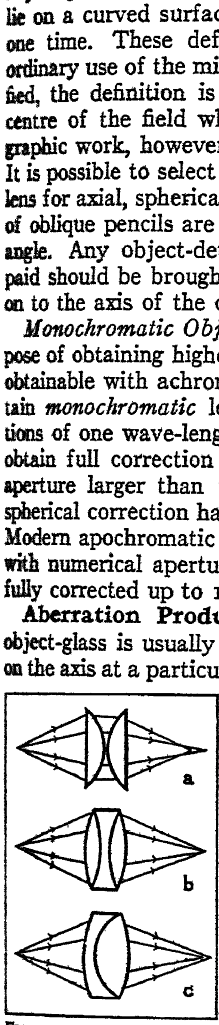

FIG. 16.—CORRECTED AND UNCORRECTED LENS SYSTEMS
(a) Under-corrected, (b) Fully-corrected, and (c) Over-corrected system

The type of aberration introduced is best explained in terms of the aberration of an ordinary uncorrected lens. A system in which the outer rays intersect the axis at a point nearer the lens than the intersection of the central rays is an "under-corrected" system. An "over-corrected" system has a shorter focal length for the central rays than for the outer rays (fig. 16).

The effect of increasing the thickness of the cover-glass is indicated in fig. 17, as is also the way in which a change in the tube-length can be made to correct the aberration thereby introduced. The lens is supposed to be corrected for use with an uncovered object when the image of this object is formed at a distance *L* behind the lens (fig. 17.a). A lens corrected for use with a particular tube-length when used on uncovered objects, can be satisfactorily corrected for covered objects by shortening the tube-length appropriately. Conversely, a lens corrected for covered objects can be used satisfactorily for uncovered objects if the tube-length is appropriately increased.

For use in microscopes with fixed tube-lengths, Amici made separate object-glasses to suit different thicknesses of cover-glass,

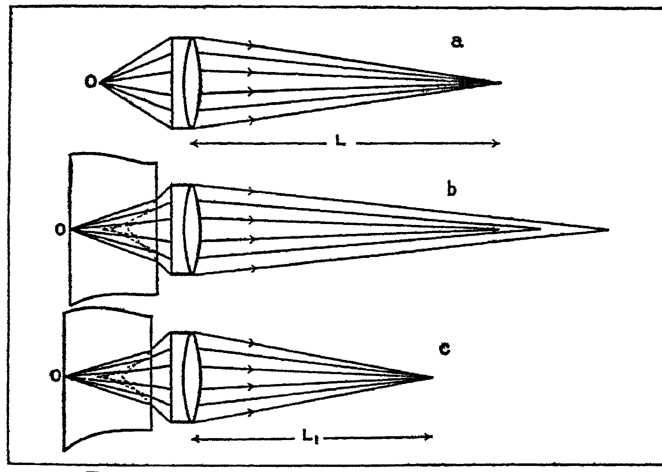

FIG. 17.—ABERRATION INTRODUCED BY A COVER-GLASS
(a) Lens fully-corrected for use with uncovered object when image is formed at distance L. (b) Same lens, with object under cover-glass and focus of central pencils at distance L. Ray system is under-corrected on object side and over-corrected on image side. (c) Same lens, with object as before. By increasing the distance of the lens from the object, the distance of the image is reduced to L_1 and full correction on the image side is obtained

modifying the corrections but preserving the same aperture and power. This was made unnecessary by the introduction in 1837, by Andrew Ross, of object-glasses furnished with a "correction-collar" which enabled the spherical aberration of the object-glass to be adjusted so as to compensate for the aberrations produced by cover-glasses of different thicknesses. The correction-collar was improved later by H. F. Wenham, of the firm of Ross, and still later by Zeiss (fig. 18).

The aberrations produced by refraction at the cover-glass and at the first surface of the front lens of the object-glass can be reduced by filling the space between the object-glass and the object, or the cover-glass, with a medium of higher refractive index than air. Amici introduced the first practical immersion lenses in 1840, using water as the immersion fluid, and improved water-immersion lenses were made by E. Hartnack in 1855. On the suggestion of J. W. Stephenson, Abbe in 1878 investigated the matter and designed the first homogeneous immersion lenses and had these made up by the firm of Zeiss.

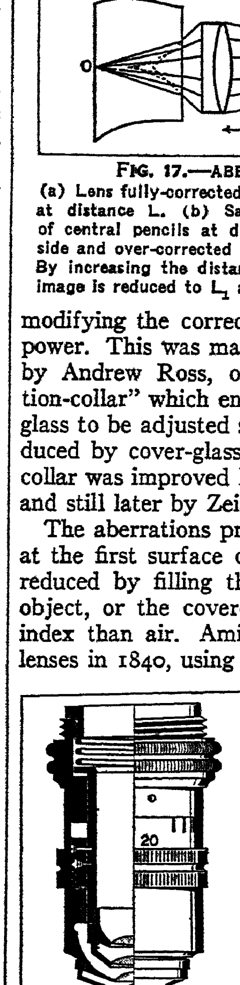

FIG. 18.—OBJECT-GLASS WITH CORRECTION-COLLAR (ZEISS)

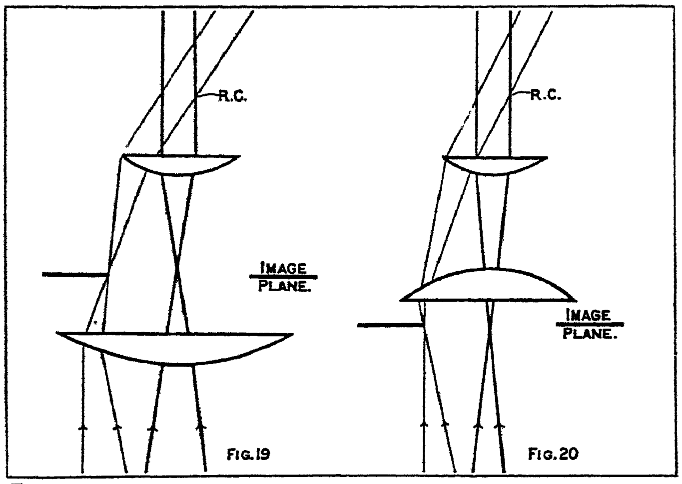
The apochromatic immersion object-glass, in virtue of its large numerical aperture and its almost perfect chromatic and spherical corrections, is the most nearly perfect type of object-glass constructed. Since the first apochromatic object-glasses were designed by Abbe about 1886, slight improvements in the degree of correction have been made, but no such marked improvement as that represented by the difference between achromatic and apochromatic object-glasses.

Object-glasses for Ultra-violet Work.—The number of materials suitable for making lenses to be used with ultra-violet radiations is very limited. Most of the solid materials which are transparent to these radiations are unsuitable owing to their doubly-refracting properties, or else are difficult to obtain in sufficiently large pieces of good optical quality. Object-glasses for use with ultra-violet radiations are nearly all designed as monochromatic lenses (see *Aberrations of Object-glasses*).

An achromatic object-glass made of quartz and fluorite was produced in 1900 by von Rohr for ultra-violet work; this lens

had a focal length of about 4 mm. and a numerical aperture of 0·3. In 1904 the firm of Zeiss introduced a series of lenses, made from fused quartz, for use with monochromatic ultra-violet light, having numerical apertures up to about 1·25. In 1926, an object-glass of novel design for use as a water-immersion lens, and another for use as a homogeneous immersion lens, were designed and computed by the British Scientific Instrument Research Asso-



FIGS. 19 & 20.—PATHS OF RAYS THROUGH HUYGHENS' EYEPIECE (FIG. 19), AND THROUGH RAMSDEN'S EYEPIECE (FIG. 20), R.C. DENOTING THE RAMSDEN CIRCLE IN EACH FIGURE

ciation. Lenses made up to these formulae by the firm of R. and J. Beck have numerical apertures of 1·14 and 1·2 respectively, and are fully corrected for use with the monochromatic ultra-violet radiation for which they were computed. The resolving powers of these objectives are equivalent to those obtained with lenses of aperture 2·28 and 2·4 when they are used with green light.

THE EYEPIECE

The eyepiece serves primarily as a magnifying glass which is used to examine the real image formed by the object-glass. The simpler types of eyepiece are made with a large *field-lens* which bends the ray-pencils from the object-glass towards the axis without greatly altering the convergence or divergence of the rays in the individual pencils. Behind this field-lens, and at some distance from it, is a second and much smaller lens which converts each ray pencil into a parallel or only slightly diverging ray system which is capable of being focussed by the eye. After emerging from the second lens, all these pencils pass through a small circular area called the "eye-point" or the *Ramsden circle*. This area is the image which the eyepiece forms of the object-glass aperture. The eye of the observer should be placed at the Ramsden circle in order to obtain the largest field of view and the maximum brightness over that field.

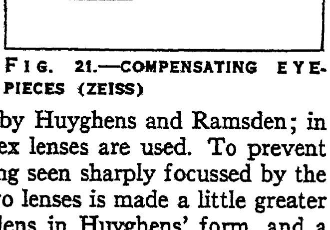


FIG. 21.—COMPENSATING EYEPIECES (ZEISS)

The two types of eyepiece at one time most commonly met with are those originally invented by Huyghens and Ramsden; in both types two simple plano-convex lenses are used. To prevent any dirt on the field-lens from being seen sharply focussed by the eye, the distance separating the two lenses is made a little greater than the focal length of the eye-lens in Huyghens' form, and a little less in Ramsden's form (figs. 19 and 20). The image formed by the object-glass is seen clearly when it lies in a position in front of the field-lens of a Ramsden eyepiece, but with a Huyghens eyepiece the light from the object-glass is intercepted by the field-lens before it has come to focus in the image plane.

The Ramsden eyepiece is convenient to use if the size of the object is to be measured by comparing the size of its image with a scale in the eyepiece fitting. The scale is mounted in front of the field-lens and is made to coincide with the image formed by the object-glass. Any distortion produced by the eyepiece thus affects the image and the scale equally. Except for purposes of this type the Ramsden form of eyepiece is not largely used. In a Huyghens eyepiece the image of the object is formed between the two eyepiece lenses, and hence the comparison scale must be fitted between the lenses. Any distortion produced by the field-lens will, therefore, only affect the image of the object. A comparison of the image with the scale may thus lead to an inaccurate estimate of the size of the object.

These eyepieces, when properly designed, give equal magnification for light of all colours, though the differently coloured images lie in slightly different planes. The eye is much less sensitive to slight "out of focus" effects than to differences of magnification, consequently both types of eyepiece are practically achromatic when properly constructed. The effects of the spherical aberrations of the eyepiece are only small and in practice may be neglected.

The *compensating eyepieces* used to correct the chromatic differences of magnification of apochromatic object-glasses are constructed, in the lower powers, like a Huyghens eyepiece with the second lens replaced by a doublet. This doublet is over-corrected for chromatic aberration. These eyepieces are designed to have a higher magnifying power for red light than for blue so as to correct the chromatic difference of magnification of apochromatic object-glasses; compensating eyepieces can be used with advantage with many high power achromatic object-glasses. In the higher powered compensating eyepieces of certain makers the design is not similar to that of the lower powered compensating eyepieces, a more elaborate system being used (fig. 21). Compensating eyepieces having magnifying powers up to ×100 are obtainable, but it is only with object-glasses of the highest quality that a magnifying power greater than ×25 can be used without making the imperfections of the object-glass image disturbingly apparent. Many other types of eyepieces are made to suit special purposes but it is not possible to describe them in this article.

MODE OF FORMATION OF THE IMAGE IN THE MICROSCOPE

We may take it that the way in which a lens forms the image of a luminous object is understood and generally accepted. The formation of the image of an illuminated non-luminous object requires consideration, however, since the light reaching the lens, whether reflected from, refracted through, or passing round the object, originates from an independent source of illumination, and the object is only "seen" as a result of the way in which it modifies the light which falls upon it. As regards large objects common experience shows that the way in which their images are formed, as in the act of "seeing," can be considered as substantially the same as that in which the images of luminous objects are formed, with the exception that a non-luminous object may, in certain circumstances, be "seen" merely as an opaque mass against a luminous or brightly illuminated background.

At one time it was commonly accepted that an object is seen in the microscope in essentially the same way as larger objects are ordinarily seen, and that the processes involved in forming the microscopic image of a small non-luminous object are the same as those involved in forming the image of a self-luminous body. These were the views put forward by such students as Airy, Arago, Foucault, J. F. W. Herschel, and Helmholtz. When light falls on a very small object, however, diffraction effects, which are not usually observed when the object is large, come into prominence. Abbe made a study of these effects and, as a result of his observations, put forward a new theory of the mode of formation of the image in the microscope. This theory is given in most treatises on the microscope and microscopy and need only be briefly outlined here.

Abbe's Diffraction Theory.—When white light from a distant small source falls perpendicularly on to a diffraction grating, such as could be made by ruling fine lines at regular small intervals through a silver film deposited on glass, much of the light passes straight through the grating in the ordinary way. On

either side of the direct beam, however, beams of coloured light will emerge, the directions of these beams being inclined at various angles to the direct central beam. An object-glass of suitable aperture placed close up to the grating would receive the direct beam and certain of the "diffracted" beams, the number of diffracted beams admitted by the object-glass being dependent on the spacing of the lines in the grating and on the numerical aperture of the object-glass. Each of the beams admitted would give rise to a small image of the source, so that immediately behind the object-glass there would be a central white image of the source with elongated coloured images lying on either side of this. In any particular part of one of these images the light of any one colour vibrates in a manner which bears very precise relationships to the vibrations of light of the same colour in corresponding parts of the other images. As a result, *interference fringes* will be produced in the body tube of the microscope, the distribution of brightness seen in any particular plane being determined by the number and position of the images formed behind the object-glass.

According to Abbe, the "image" seen on looking through the eyepiece is simply the *interference pattern* in the focal plane of the eyepiece. In so far as this pattern is determined by, and therefore characteristic of, the structure of the object, it may be considered to be an "image" of the object, but it cannot be claimed that the form of this "image" bears any true resemblance to the object. Abbe based these views on observations made with gratings illuminated by a parallel or nearly parallel pencil of rays, using object-glasses behind which he could place small diaphragms so that the different diffraction images of the source of light could be cut out or admitted at will. He claimed that the results he obtained in this way are of general applicability, and that the images of non-luminous objects are formed exclusively as the result of interference of the type described, no matter what the structure of the object and irrespective of the way in which the object is illuminated.

To obtain any indication of structure in the object at least two images of the source must be formed behind the object-glass, since two images are required if any interference is to be produced in the body-tube. The smallest numerical aperture that will admit two separate beams of light from the grating (the direct beam and *one* diffracted beam) is given by

$$n \sin u = \frac{\frac{1}{2}\lambda_a}{s}$$

where s is the distance between adjacent similar details in the object, and λ_a is the wave-length of the light used to illuminate the object (as measured in air). In order that a lens of this numerical aperture may admit the two beams, the object must be illuminated obliquely, so that the direct beam is thrown into one side of the object glass aperture and one of the first diffracted beams is just admitted into the other side. The smallest structure-interval that could be resolved by this lens, in the sense that an interference pattern would be produced in the focal plane of the eyepiece, is thus obtained as

$$s = \frac{\frac{1}{2}\lambda_a}{n \sin u}.$$

It will be seen that this result is very nearly the same as that obtained earlier for the resolution of two luminous point sources.

The "Equivalence" Theory.—Many microscopists and physicists did not accept Abbe's theory as being of general applicability, though it was clearly valid under the particular conditions which obtained in Abbe's experiments, *i.e.*, with objects of regular periodic structure illuminated by light from a distant small source. Many experiments were carried out in order to disprove Abbe's theory. Altmann stated in 1880 that the results Abbe had obtained with illuminated gratings, using diaphragms behind the object-glass, could all be reproduced with self-luminous hot-wire gratings when similar diaphragms were used behind the object-glass. Mandelstam carried out these experiments with hot-wire gratings in 1911 and confirmed Altmann's statement. The value of Abbe's experiments as evidence supporting his theory was thus seriously discounted. Evidence based on the experience of microscopists was also put forward as contradicting Abbe's theory, notably by R. Koch in Germany and by Lewis Wright and E. M. Nelson in England. Lewis Wright's views on the mode of formation of the image in the microscope were emphasized by E. M. Nelson's clear demonstrations of the greatly improved images to be obtained by the use of wide axial cones of illumination, as opposed to the narrow axial or oblique pencils more favoured by the adherents to Abbe's theory.

The views held by these people were that, with suitable illumination, any non-luminous body can be considered as "equivalent" to a self-luminous body, and that, under the conditions of illumination commonly used by microscopists, the image is formed in essentially the same way as the image of a luminous body. According to this "equivalence" theory the most perfect resolution should be obtained when the full aperture of the object-glass is being used, *i.e.*, when the cone of illumination is of such an angle that direct rays would, except for such obstruction as the object produces, enter all parts of the object-glass aperture. It usually happens, however, that, as the angle of the cone of illumination is increased from some quite small initial value, resolution is steadily improved at first, but a condition is reached such that further increase of angle of the cone causes contrast in the image to diminish very rapidly, so that resolution, *in the sense of visibility of detail*, is greatly impaired. In the absence of any satisfactory explanation of this phenomenon, it seemed to be in direct conflict with the implications and consequences of the "equivalence" theory, and constituted a formidable stumbling-block to that theory until the causes of the loss of contrast were discovered and were shown to be quite distinct from, and independent of resolution and resolving power proper.

Lord Rayleigh (3rd baron) considered the formation of the microscope image on theoretical grounds, and showed in 1896 that definite interference of the type required by the Abbe theory cannot occur unless the angle of the cone of illumination is small compared with the ratio λ/s, where s is the distance separating adjacent similar details in the object and λ is the wave-length of the light used to illuminate the object (Lord Rayleigh, *Scientific Papers* IV., 1903). This means that, with a wide angle of illumination, the vibrations coming from adjacent points in the object are virtually independent of each other, provided they are separated by a distance which is not small compared with the wave-length of the light used, *i.e.*, each of these points is "equivalent" to a self-luminous point in so far as the light coming from it is concerned.

Theoretical investigations by Mandelstam (1911), Wolfke (1912) and von Laue (1914) confirmed Lord Rayleigh's views. Recently the whole subject has been comprehensively investigated by Berek, and in a series of papers published in 1926 he gives a full discussion of the applicability and limitations of both the theories. The conclusions he arrives at are that, under the conditions of illumination ordinarily used, the image in the microscope is formed, in the main, in the same way as is the image of a self-luminous object. The image thus obtained is a "true" image in the sense that it bears a close resemblance to the object, and has a true "focus-plane." Under the conditions which Abbe used in his diffraction experiments, *i.e.*, with an object of regular periodic structure illuminated by a narrow pencil of almost parallel rays, the only "image" obtained is of the nature of an interference pattern. This "image" has no true focus-plane, the appearance seen in the eyepiece shows very little variation if the eyepiece is moved through quite large distances along the axis of the microscope, and this appearance does not necessarily possess any true resemblance to the object.

The theory that under the conditions of illumination commonly used, the mode of formation of the image in the microscope is, in the main, the same as the mode of formation of the image of a self-luminous object, can thus be taken as well founded. The experimental evidence supporting the theory has accumulated rapidly since the conditions for obtaining contrast have been properly understood. Even before these conditions had been thoroughly investigated, however, important evidence in support of the "equivalence" theory was available from observations made with so-called "dark-ground" illumination (*see* p. 440). According to

the Abbe theory, the resolving power of a lens when used with this form of illumination must necessarily be less than it would be if the object were illuminated with transmitted light. Moreover, no "dry" lens, when used with dark ground illumination provided by a "dry" condenser, could have a greater resolving power than that corresponding to a numerical aperture 0·5. According to the "equivalence" theory the resolving power of a lens should be the same for any method of illumination which ensures that the full aperture of the lens is used. Actual experiment shows that resolving power is not in any way reduced when dark-ground illumination is employed. In fact, the resolution obtainable with this method of illumination often *appears* to be better than that obtainable with ordinary illumination by transmitted light, since dark-ground illumination secures a high degree of contrast in the image obtained. Because of this marked gain in contrast resolution is therefore easily recognizable.

ILLUMINATING APPARATUS AND METHODS OF ILLUMINATION

The methods of illumination commonly used are very varied; each method requires the proper apparatus for its convenient application. The principles involved in some of the most important of these, together with the apparatus needed, are here discussed.

Illumination by Transmitted Light.—To examine an object in this way, light from a suitable source is passed through the

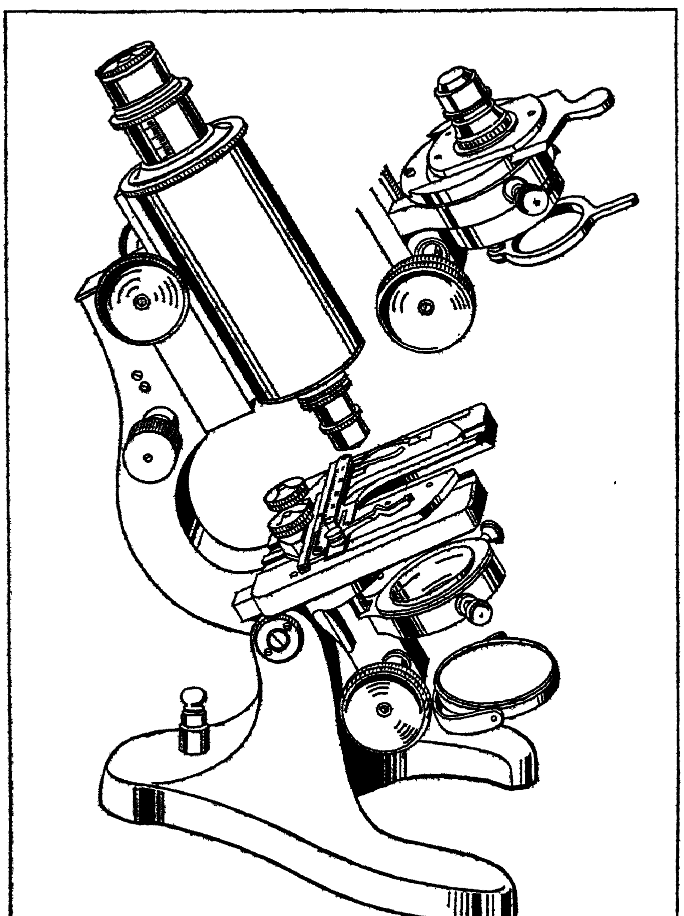

FIG. 22.—MICROSCOPE FOR GENERAL USE (BECK), SHOWING SUB-STAGE ARRANGEMENTS SEPARATELY IN THE SMALLER FIGURE

object and so into the object-glass. Usually the light from the source is reflected from a mirror mounted below the object, the mirror being generally mounted so as to allow of a considerable range of movement both of translation and also of rotation. The mirror may be either plane or concave; usually both types are provided, mounted back to back in a single mount. With a small source of light the plane mirror gives an illuminating beam composed of practically parallel rays. With an extended source the rays reflected from the plane mirror reach the object along directions which give illumination over an appreciable angle. The concave mirror can provide a convergent cone of illumination from quite a small source.

For obtaining an illuminating cone of larger angle than the concave mirror can give, a condenser is interposed between the (plane) mirror and the object. The condenser is a system of lenses capable of concentrating the rays reflected from the plane mirror so that they converge on to the object as a cone of wide angle (*see* fig. 22). A diaphragm, usually of the "iris" type, is fitted below the condenser, in order that the angle of the cone of illumination may be varied conveniently at will. By focussing the condenser so as to form an image of the source, or of a bull's eye lens in front of the source, on to the object, intense illumination of the object is obtained.

Provision should be made for "centering" the condenser in order that the illuminating beam may be truly axial. Dry condensers capable of filling an object-glass having a numerical aperture of 0·95 are obtainable, well corrected for chromatic and spherical aberrations. Immersion condensers are made with numerical apertures as high as 1·4, similarly corrected for chromatic and spherical aberrations and capable of being used with microscope slides of thicknesses up to about 1·5 mm. Immersion condensers are brought up close to the underside of the microscope slide and are put into "immersion contact" with this by filling the space between the underside of the slide and the top surface of the condenser with cedar-wood oil. Immersion condensers are used when it is desired to fill the aperture of an immersion object-glass.

Dark-ground Illumination.—If the condenser aperture is opened wide and a central circular stop is fitted below the condenser, the rays reaching the object form a hollow cone. A similar effect can be obtained by special methods of construction. By choosing an opaque central stop of suitable size, all the *direct* rays from the condenser can be made to pass outside the object-glass, and no light will be received into the object-glass except that which is reflected, refracted, or scattered by the object so as to pass into the object-glass. If the object contains particles, veins, or other structure capable of diverting the rays into the object-glass by any or all of these three processes, such inclusions or structure will be rendered visible in the microscope, and will be seen bright against the dark ground corresponding to the clear homogeneous portions of the object and mounting medium.

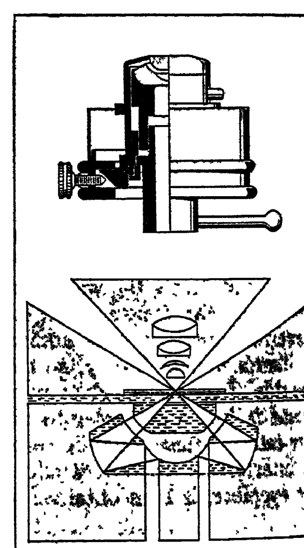

FIG. 23.—IMMERSION DARK-GROUND ILLUMINATOR (BECK)
The paths of the light rays are shown in the lower figure. The upper figure shows a focussing device permitting an image to be focussed when glass slides of different thicknesses are used

Ordinary dry and immersion condensers can be used to give dark-ground illumination if provided with central opaque stops. For work with object-glasses of apertures above 0·65, immersion condensers fitted with central opaque stops can be used, but more satisfactory results are obtained with special immersion dark-ground illuminators. The reflecting systems used in these illuminators give less stray light and at the same time produce a blacker ground.

Most immersion dark-ground illuminators are made for a fixed working distance and are suitable for use with microscope slides of only one particular thickness. The illuminator can be made usable with a thinner slide by packing cover-glasses between the top lens of the illuminator and the underside of the slide, each cover-glass being covered on both sides with immersion oil to provide immersion contact between the top of the illuminator and the

slide. If the slide is too thick there is no remedy. To avoid the inconvenience of a fixed working distance, the firm of R. and J. Beck has introduced an adjustable immersion dark-ground illuminator which, by moving the constituent optical elements relative to each other, can be made to work with microscope slides of any thickness between 0·5 mm. and 1·5 mm.

A dark-ground illuminator computed by E. M. Nelson has the special feature that it will give dark-ground illumination with an object-glass having a numerical aperture as high as 1·4. The working distance of this illuminator is sufficiently large to permit of its being used with slides 0·8–1·4 mm. thick.

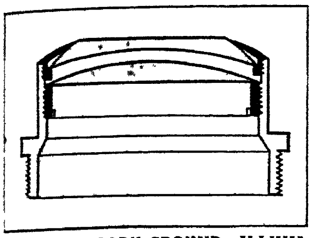

FIG. 24.—DARK-GROUND ILLUMINATOR (WATSON)

Transmitted Polarized Light.—By placing a Nicol's prism, or other polarizing apparatus, between the mirror and the condenser, the object can be illuminated by a cone of light in which the vibrations are all parallel to one direction. If the object has any properties which cause it to modify the state of polarization of the light coming through the *polarizer* and condenser, these modifications can be observed, provided a second polarizing prism (the *analyser*) is used in conjunction with the eyepiece.

If the analyser is set with its polarizing axis at right-angles to that of the polarizer, no light should be seen in the eyepiece,

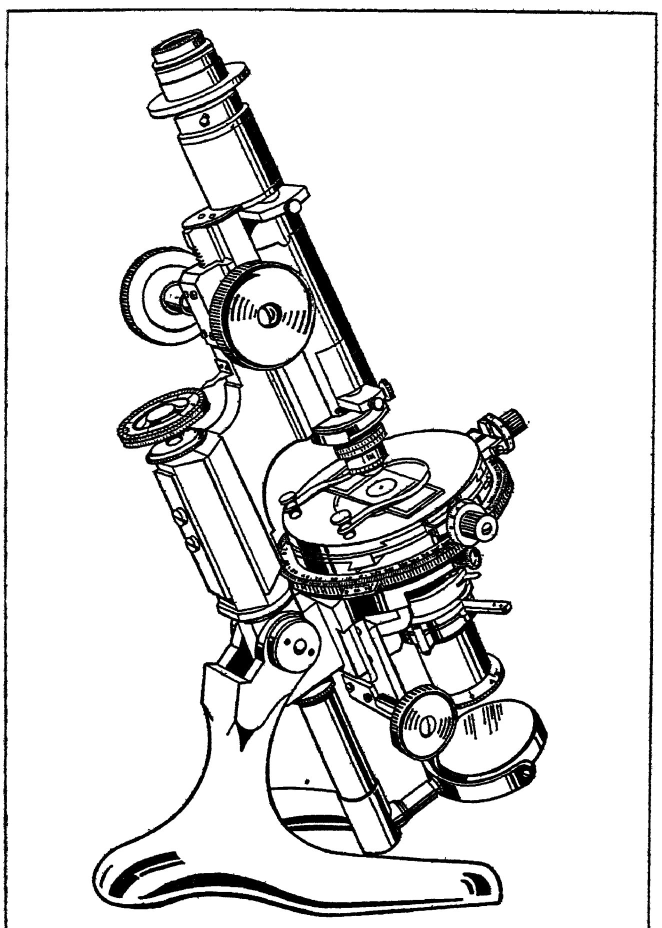

FIG. 25.—PETROLOGICAL MICROSCOPE (SWIFT), AN INSTRUMENT FITTED WITH THE OPTICAL EQUIPMENT REQUIRED TO COVER A WIDE RANGE OF PETROLOGICAL WORK

unless portions of the object have the power of modifying the state of polarization of the illuminating beam. For the complete examination of an object by polarized light, it is necessary to be able to rotate the polarizer and analyser together while keeping the object at rest, or else to rotate the object between the stationary prisms. It is also necessary to be able to rotate one of the prisms relatively to the other. Accessory apparatus of various types is convenient for the special examination of many kinds of objects which show polarization effects, such as fibres and crystals. Microscopes specially equipped with polarizing prisms and accessory apparatus for the examination of objects by polarized light are generally described as petrological microscopes (*see* fig. 25).

Vertical Illuminator.—For examining opaque objects it is necessary to send light down on to the object from above. One

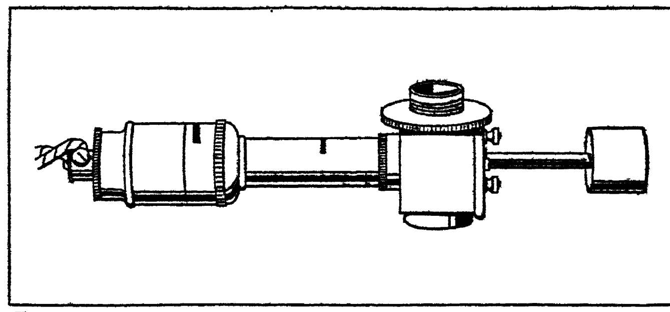

FIG. 26.—VERTICAL ILLUMINATOR (WATSON), A SELF-CONTAINED FORM WITH LAMP, CONDENSER, SLOTS FOR STOPS, REFLECTOR, AND BALANCED WEIGHT; AFTER CONRADY

method of doing this is to mount a cover-glass in a fitting above the object-glass, the plane of the cover-glass being inclined at 45° to the axis of the microscope. Light, admitted through a hole at the side of the fitting, is reflected by the cover-glass down into the object-glass and is brought to focus on the object by the object-glass. The light returning into the object-glass from the object is transmitted with but little loss through the inclined cover-glass, and proceeds to form an image in the usual way. Any inequalities in the cover-glass will tend to impair the resulting image, and in any case this image will be slightly astigmatic owing to the refraction of the light through the inclined cover-glass. To render these effects as small as possible a thin uniform cover-glass should be selected for this purpose.

Prisms, semi-circular mirrors and other types of reflectors are used sometimes instead of the inclined cover-glass just described. Most of these give illumination through only one half of the object-glass aperture, and permit of only the other half being used to form the image of the object. Illumination in this way is apt to cause shadows on the object, while the use of only half the lens aperture causes the resolution to be reduced to one-half, in so far as detail lying parallel to the short dimension of the used aperture is concerned. Furthermore, the portion of the lens used to form the image has a semi-circular aperture which causes the diffraction rings seen round any image detail to depart from their usual circular form. All of these effects may give rise to misleading appearances in the image and may lead to the drawing of false deductions as to the form of the object structure. To avoid these effects, some firms make small annular reflectors for vertical illuminator work. These reflectors send the light down through the outer zone of the object-glass and permit of the rest of the object-glass being used to form the image of the object. Such reflectors do not give rise to misleading effects of the type described above, they merely cut down the available numerical aperture of the object-glass by a small amount. The vertical illuminator is largely used for metallographic work and for examining large opaque objects.

Many object-glasses are unsuitable for use with a vertical illuminator owing to "vertical illuminator glare," *i.e.*, the production of "flare images" which are brought into focus, or nearly into focus, by the eyepiece. These images, which are due to reflections at the various lens surfaces, are superposed on the image of the object, and may render it impossible to see this image properly. Object-glasses for use with a vertical illuminator should be selected for their freedom from this flare effect.

The Ring Illuminator.—An illuminator, which provides "top" illumination without using the object-glass as part of the illuminating system, has been introduced by the firm of R. and J. Beck. This illuminator is an annular lens-mirror reflector. In principle this "ring" illuminator acts in the same way as the

old-fashioned "Lieberkühn" but it is differently constructed, provides much more intense illumination, and is much more convenient.

The object to be examined is mounted on a microscope slide, and on the underside of the slide a small patch stop is gummed if necessary; alternatively an opaque central stop of suitable size can be mounted below the microscope stage. A parallel beam of light is sent up through the stage, and reaches the lens-mirror as a hollow cylinder of light. Any light the object sends back into the object-glass has been either diffusely reflected or scattered by the object. What is seen represents the most natural appearance the object could present if it were enlarged to a degree corresponding to the magnification given by the microscope.

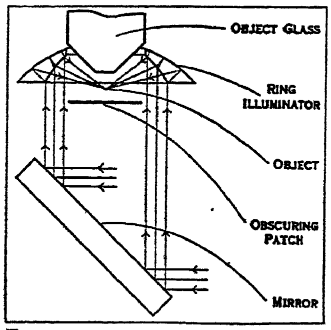

FIG. 27.—APLANATIC RING ILLUMINATOR (BECK), SHOWING HOW LIGHT IS BROUGHT TO FOCUS ON TOP SURFACE OF OBJECT

By building a hollow condenser system round the object-glass, the firm of Chapman and Alldridge has produced a type of vertical illuminator which gives the same kind of illumination as that given by the ring illuminator. A plane mirror is mounted above the condenser with its surface inclined at 45° to the axis of the combined system, an elliptical hole being cut in the mirror to allow of its being fitted round the object-glass. Through a hole in the side of the mount light is admitted. This light is reflected down through the condenser system, and so is brought down to the surface of the object. By adjusting the position of the light source, an image of this source can be brought to focus on the surface of the object at the same time as the microscope is in focus for the object. The appearance of the object resembles that obtained when a ring illuminator is used and, since all the illuminating apparatus is above the object, this type of illuminator is of value in metallographic work, or for use in the examination of any large opaque object. Like the ring illuminator, this illuminator enables "top" illumination to be obtained without incurring any of the difficulties associated with vertical illuminator glare.

Side Illumination.—It is sometimes necessary or useful to illuminate the surface of the object by light projected on to the object from one side and inclined to the surface at almost grazing incidence. This can be done by using a powerful beam, consisting of almost parallel rays, directed slightly downwards on the object. A more convenient way, if great intensity of illumination is required, is to mount a half-lens of high power on the stage of the microscope, so that the principal focus of the half-lens lies in the surface of the object and in the centre of the field of view of the object-glass. An alternative method avoids the production of a coloured image of the source, by a paraboloid reflector.

This method of illumination produces pronounced shadow effects on the surface of the object and shows any surface irregularities in sharp relief. The method is of value in studying the surface contours of objects if due care be taken in translating the appearances seen in the image.

THE MECHANICAL PARTS OF THE MICROSCOPE

While the optical system by which the image is obtained is the most important part of a microscope, the fullest use of this system cannot be made unless the microscope stand is accurately constructed and arranged for the convenient manipulation of the optical parts, the object, and the illuminating system.

The Body Tube and Its Mounting.—The object-glass and the eyepiece are mounted in a body tube, the length of which can be varied so as to allow of the tube-length being adjusted to suit the corrections of the object-glass. The object-glasses are screwed into the bottom end of the body tube and are interchangeable one with another; the eyepieces are made to slide into the upper end of the tube. The body tube is mounted on slides carried by the main limb of the microscope frame, movement of the tube relative to the limb being provided by the coarse and fine adjustments. The coarse adjustment is operated by a rack and pinion mechanism which moves the coarse adjustment slide up and down in machined guides. This type of design is almost universally employed. The fine adjustment slide also works in machined guides, but is operated by a mechanism which is capable of adjusting the position of the body tube by very small amounts. The design of the fine adjustment has attracted the attention of microscope makers for very many years, and the number of designs invented is so great that to describe them here is out of the question.

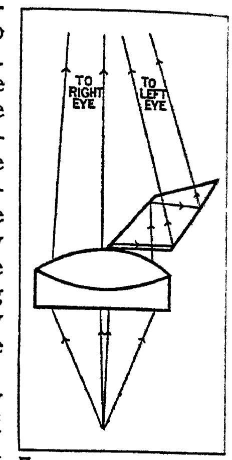

FIG. 28.—WENHAM'S BINOCULAR PRISM
Diagram showing paths of the two rays up to the two eyes

In some instruments the slide of the fine adjustment block fits in guides in the limb, the coarse adjustment slide being carried by guides machined in front of the fine adjustment block. In other instruments this arrangement is reversed. At one time designs were developed in which only the object-glass fitting was carried by the fine adjustment, the object-glass fitting being made to move up or down relatively to the body tube. These designs have practically disappeared.

The fine adjustment should move easily and smoothly, be free from "backlash" and from tendency to stick, and should hold the microscope steady. In microscopes of good make, the body tube can be set by means of the fine adjustment to within $\frac{1}{25,000}$ in. or, in some cases, to within $\frac{1}{50,000}$ in., and can be brought back to its original setting to within similar limits if the fine adjustment is re-set to its original reading after having been altered. In a special instrument made by one English firm, for ultra-violet work, the fine adjustment can be set by means of its indicator so as to bring the body tube to within $\frac{1}{100,000}$ in. of any desired position.

Binocular bodies to allow of the simultaneous use of both eyes are commonly met with. Some instruments are provided with binocular bodies which are interchangeable with the ordinary single-tube (monocular) body. In the binocular bodies prismatic systems are arranged close behind the object-glass, so that light from the object-glass is brought up as two beams of approximately equal intensity, one beam into each eyepiece. Matched pairs of eyepieces are used.

If both eyes receive light from the *whole* of the object-glass aperture, stereoscopic relief is not obtained. To obtain stereoscopic relief, the light coming from the *right* half of the object-glass must be brought up to the *left* eye, and *vice versa*, unless the prism system completely inverts both of the ray systems from the object-glass so as to produce erect images of the object. The binocular prism invented by Wenham in 1861 is the simplest yet devised (1928) for easily giving proper stereoscopic appearances, and this form of prism is commonly used in modern binocular instruments. Wenham's prism brings the rays from the right side of the object-glass up to the left eye, the rays from the left side being allowed to pass on undeviated so as to enter the right eye (fig. 28). The images formed are inverted images in the object, and show proper stereoscopic relief. Many of the early systems did not invert the ray systems so as to produce erect images of the object and gave rise to pseudoscopic effects.

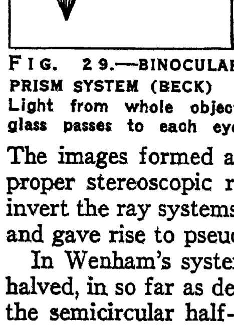

FIG. 29.—BINOCULAR PRISM SYSTEM (BECK)
Light from whole object glass passes to each eye

In Wenham's system the resolving power of the object-glass is halved, in so far as detail lying parallel to the short dimensions of the semicircular half-apertures is concerned. To avoid this, systems are made in which light from the whole object-glass aperture is used in forming each of the images (fig. 29). Stereo-

scopic effects can be obtained with these systems by adjusting the eyepieces so that they produce Ramsden circles separated by a distance slightly less than the distance between the eyes of the observer. When the observer's eyes are placed at the Ramsden circles, the light entering the *right* eye comes mainly from the *left* side of the object-glass and *vice versa.* With a little experience the adjustment required to give stereoscopic relief can be made without difficulty. This may be done more easily perhaps if capped eyepieces are used in which stops with semicircular apertures are fitted, as in Abbe's stereoscopic eyepiece system. The stops are placed in or just below the Ramsden circles, and are used with the curved sides of the apertures outwards. Without these stops it is easy to produce pseudoscopic appearances by making the distance between the Ramsden circles larger than the inter-ocular distance, so that the light entering each eye comes mainly from the wrong half of the object-glass. In the Greenhough binocular two separate microscopes are used, with separate object-glasses (fig. 30). These microscopes are fitted with prismatic erecting systems just below the eyepieces, to produce stereoscopic and not pseudoscopic effects.

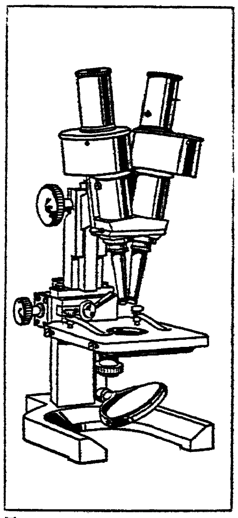

FIG. 30.—GREENHOUGH BINOCULAR (WATSON)
Two separate microscope systems are shown with an "Erecting" prism in each microscope

The Stage.—The stage for carrying the object is usually fixed rigidly to the microscope limb, though in some microscopes it is mounted on slides on the limb and is movable by means of a rack and pinion mechanism. The stage may be a simple plane table on which the object is moved about by hand when different portions are to be examined, or it may be made with slides permitting of movement in two directions at right-angles, and with a bearing to allow of rotation about the axis of the microscope. Centering screws are sometimes fitted so that the axis of rotation may be brought into coincidence with the axis of the object-glass. The stage should be rigidly supported, and should bear the weight of comparatively heavy specimens without serious deflection. The mechanical slides, and the rotation bearings if fitted, should operate smoothly but without tendency to slip under the weight of the movable parts, or under the weight of any specimen likely to be examined. The mechanical slides of the stage should be accurately at right-angles to the axis of the microscope, as should also be the plane in which the stage moves when it is rotated. Except in some metallographic microscopes, the centre of the stage is cut away, to admit light through to the specimen when illumination with transmitted light is required.

The Sub-Stage.—Provision is made below the stage for mounting the illuminating apparatus required for examining an object with transmitted light. The minimum equipment necessary is a mirror which can be moved into various positions, so as to reflect light up through the hole cut in the stage. In the more completely equipped microscopes special sub-stage attachments are fitted. These are adapted to carry a condenser, polarizing apparatus, various stops, a disk of ground glass and colour filters, with an iris diaphragm to permit of varying the cone of illumination provided by the condenser. Geared cells, to permit of rotating various accessories used in the examination of objects under polarized light, such as selenite plates, are often included in the more elaborate sub-stage equipment. The cells used for carrying the stops should be fitted as close as possible to the underside of the condenser, as should also the iris diaphragm.

The sub-stage is usually, but not invariably, carried on a block which slides on the limb of the microscope, and which can be moved up or down by a rack and pinion; the mirror is then mounted on an extension of the limb below the sub-stage slides. The sub-stage condenser fitting should have centring adjustments to allow of the axis of the condenser being brought into line with the axis of the object-glass. The various attachments are generally fitted so that they can be conveniently swung out of position when not required. In most instruments the whole sub-stage can either be swung bodily out of the axis or removed entirely. The sub-stage is often mounted on a pillar attached to the underside of the stage, and is movable up or down on a spiral cut on this pillar. In some instruments there is no proper sub-stage at all, any condenser or other illuminating apparatus being made to slip into a tube fixed under the stage.

The importance of the sub-stage equipment should be strongly urged since, for the systematic study of an object under the microscope, it is necessary to be able to use several different conditions of illumination. A well-equipped sub-stage is essential if this is to be carried out conveniently and, in selecting the equipment for a microscope which is to be used in serious investigations, the sub-stage apparatus should receive as much attention as any other part of the instrument.

Accessory Fittings.—For the greater convenience of the microscopist, fittings of many varieties have been introduced by different makers. Many of these are devised to enable one object-glass to be quickly changed for another, and to minimize the work involved in readjusting the instrument when this is done. The necessity for readjustment arises mainly from minor errors in the mounting of the lenses constituting the object-glass system, or in the mounting of the whole object-glass in the object-glass cell. If critical observation is desired, these errors may necessitate re-centring the condenser, or the object-glass, each time one object-glass is substituted for another.

Rotating nosepieces which carry two or more object-glasses are among the simplest of these accessory fittings. They are not usually provided with centring adjustments for each object-glass, and only permit of the quick changing of one object-glass for another. Interchangeable object-glass carriers, which slide into or clip on to a nosepiece carried by the body tube, are also used. Each object-glass is fitted permanently into its own slide or clip-piece, and is accurately centred once for all. Each object-glass will then be in correct adjustment, so far as centring is concerned, as soon as its carrier is pushed or clipped into position. Similar carriers are made for holding sub-stage condensers. Such accessories, though very convenient in use, are not essential parts of the microscope. For fuller descriptions of them the reader must be referred to the catalogues issued by the various microscope makers.

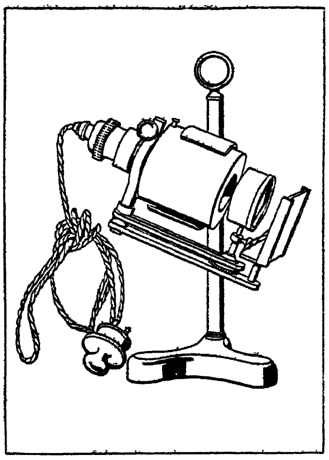
MICROSCOPY, the art of using the microscope. There is little need for stressing the importance of the microscope in the investigation of many widely different problems. In medical, biological, geological, metallurgical and many other kinds of work, the value of the microscope is well understood, and the instrument is used constantly in routine work and in research. In other applications the value of the microscope is being increasingly realized, but its value might be appreciated even more widely if all users of the instrument should make a study of its principles, sufficient to enable them to realize the full implications of their observations. Such study would also prevent erroneous deductions from appearances seen in the image, appearances which might be due to faulty adjustment either of the instrument itself or of the illuminating apparatus. (*See* MICROSCOPE.)

Methods of Illumination Commonly Used.—The most commonly used method of illumination is that in which the object is illuminated by transmitted light. This method is peculiarly liable to give images in which the contrast is seriously impaired due to "glare" effects if the cone of illumination is made sufficiently large for the aperture of the object-glass to be fully utilized. The importance of this method of illumination is not to be belittled, however. It gives information of much value and is convenient to employ; it must, also, be the chief method of examining such objects as thin stained sections of animal and vegetable tissues. The information obtainable with any single type of illumination is necessarily incomplete, however, and should be supplemented where possible by examining the object under other conditions.

Among other methods of illumination ordinary darkground illumination, vertical illumination and side illumination are probably the most commonly used. The ways in which the microscope and illuminating apparatus are adjusted to provide these various forms of illumination are fully dealt with in many treatises and textbooks on the microscope and microscopy (*see* also MICROSCOPE). We must confine ourselves here to emphasizing the necessity of mastering the methods of making these adjustments. The reader is referred to these textbooks, also, for information regarding the appearances obtained in examining objects by these methods and by such other methods as are commonly used in medical, biological, geological and other types of work in which the technique has become almost standardised. We shall restrict ourselves to supplementing that information by giving (*a*) a few examples to illustrate the interpretation of some of the less well-understood appearances obtained by the more usual methods of illumination, and (*b*) descriptions of some of the results obtainable by the use of novel or less commonly used technique, which serve to illustrate the possibilities of extended use of the microscope for obtaining information as to the nature of the object being examined.

The Illuminant.—A powerful lamp with a small radiant will serve as the source of light for every kind of work to be done with the microscope. The use of a small radiant minimises the amount of light reflected down on to the top of the object from the surfaces of the individual lenses in the object-glass, or from the cover-glass, when transmitted illumination is used, and so reduces the loss of contrast due to *lens flare* and *cover-glass glare*. If it is desired to use a larger area of illumination than that obtained by focussing an image of the radiant on to the object, this can be done by placing a bull's eye lens or a piece of ground glass, or both, in front of the lamp, and producing a focussed image of either of these on the object. A small radiant is not essential, however, and much useful work can be done with a simple paraffin lamp or with ordinary gas or electric lamps.

Recognition of Structure.—Although there is a limit to the resolving power of any object-glass, this does not mean that an object-glass cannot give *indications* of structure in objects having structures appreciably finer than the lens could possibly show resolved. Small particles have the power of *scattering* light which falls upon them. The intensity of the scattered light is greatest in directions at right-angles to the illuminating rays, and the percentage of incident light scattered is greater for blue light than for light of longer wave-lengths. The light directly transmitted by an object which contains discrete minute particles is thus deficient in blue and appears as of a yellow or brown colour, while the light seen by looking sideways at the object appears blue. If the particles are regularly arranged in the object there is, in addition to the scattered light, a certain amount of light which leaves the object along definite directions inclined at definite angles to the main beam. This light is *diffracted* light. The diffracted beams obtained from white light are seen as coloured bands, because the vibrations corresponding to the different colours which make up "white" are diffracted along different directions. If the whole of the light in any one diffracted beam is recombined, the resulting "colour" is white. If, however, only part of the light in a diffracted beam is recombined, the colour obtained depends on the colours present in the used part of the diffracted beam.



MICROSCOPE LAMP WITH BULL'S EYE AND SCREEN HOLDER

Many opal glasses, when examined by means of an object-glass of too low a numerical aperture to show the "opal" material as discrete particles, appear of a yellow or brown colour when illuminated with transmitted light. The depth of the colour seen depends on the density of the opal; it is deeper, also, with a narrow cone of illumination than with a cone of wide angle. With darkground illumination giving a hollow cone much wider than that corresponding to the numerical aperture of the object-glass, the opal glass will appear of a marked blue colour. Such appearances of colour can be taken as definite evidence of the existence of particles in the object, even though the particles cannot be seen as separate discrete particles with the particular object-glass used.

Similar effects are obtained with fossil diatoms but the appearances may be complicated by diffraction due to the regular structure of the diatom. The colours seen, whether by transmitted light or dark-ground illumination, then depend on the fineness of the structure in relation to the numerical aperture of the lens. If the structure is much too fine to be resolved by the lens used, the diatom shows as a yellow or brown object with well-marked outlines when examined with transmitted light, and as a blue or whitish-blue object with dark-ground illumination. If, however, the structure is almost resolvable by the object-glass used, areas showing blues and greens or pinks may appear on the diatom when a transmitted cone of suitable angle is used, the colours seen with wide-angle dark-ground illumination being usually approximately complementary to those seen with transmitted light. These colours are due to the admission of portions of the first order spectra into the object-glass, and are indications of a regular structure which is almost resolvable by the object-glass. The intensity of the colours depends on the medium in which the diatom is mounted. Strong colours are shown if the diatom is mounted dry (in air) or in realgar, owing to the large difference of refractive index between the material of the diatom and air (lower) or realgar (higher). A weak colour is shown if the diatom is mounted in Canada balsam or styrax, both of which have refractive indices not greatly different from that of the diatom itself.

Small objects having rounded contours with smooth faces may give rise to a pearly appearance under suitable conditions of either transmitted or dark-ground illumination. This is not necessarily an indication of structure, since the distribution of the pearly light can be shown in some instances to be due to the irregular refractions occurring at the surfaces of the objects. *Tous les mois* starch grains mounted in water show these lenticular refractions very clearly, though there is, in addition, a slight brownish colour discernible on portions of the grains when examined with a narrow cone of transmitted light. This brownish colour is indicative of structure which, in this object, is the result of the growth of one layer over another. The brown colour is very

slight compared with that seen on a diatom such as the *Pleurosigma angulatum*, even when this is mounted in Canada balsam. This indicates that the differences of refractive index in the starch grain structure are only very slight.

Growth structures frequently give double refractive effects, and many instances of animal and vegetable tissues and fibres are known in which evidence of structure can be revealed by examination with polarized light. The use of polarized light in the study of natural and artificial fibres used in the textile and other industries is common, and this method of examination is employed for distinguishing between different types of fibres as well as for controlling various industrial processes connected with the treatment and manufacture of fibres. This method of illumination has considerable diagnostic value in the study of animal and vegetable tissues.

Recognition of Colour.—The colours of stained specimens can be seen quite clearly by transmitted light, but many naturally coloured objects are either so opaque that they appear black by transmitted light or else, with any method of illumination, there is so much general light mixed with the light coming from the coloured object or detail that its precise hue cannot readily be identified. With ordinary dark-ground illumination, surface colours are liable to be masked by light coming through from the lower parts of the object, and the true colours of the surface are not readily perceived. With the *vertical illuminator*, the difficulties arising from this cause are avoided, but the surface colours are much diluted by light regularly reflected from the surface of the object. The *ring illuminator* gives a hollow cone of illumination of wide angle, similar to that used in ordinary dark-ground illumination, the only essential difference being that the ring illuminator reflects the light down on to the surface of the object. As a result of this, illumination by means of the ring illuminator gives a better idea of the true surface colours than that obtained with dark-ground illumination, since the amount of light coming from the surface is bright compared with that coming from lower portions of the object. The ring illuminator also shows up surface colours better than the Vertical Illuminator since, with the former, direct, regular reflections from the surface are largely cut out and the colours seen are diluted with comparatively little of the regularly reflected light. For the study of insect colouring and for much analogous work the Lieberkühn was at one time extensively used as the best method of illumination; the ring illuminator gives essentially the same type of illumination as the Lieberkühn.

If the object under examination has a flaky surface, or is covered with a surface film, it may show iridescent colours such as are seen in a soap bubble. These colours are produced by interference between the light reflected by the upper and lower surfaces of the surface film or surface flake. With light falling almost perpendicularly on the surfaces, the reflected light is of feeble intensity unless the refractive index of the film or flake is high. The interference colours are easily masked, therefore, when a vertical illuminator is used, if the flake or film has a comparatively low refractive index, a little stray light being sufficient to prevent the interference colours from being seen. A film of high refractive index, however, such as a film of oxide or sulphide on copper, gives quite strong interference colours when illuminated with a vertical illuminator.

With the ring illuminator the light strikes the surfaces much more obliquely, and is more strongly reflected because of this. Any of this light which gets into the object-glass should show stronger interference colours than are seen with the vertical illuminator, and this actually occurs if the film or flake is of low refractive index. With a film or flake of high refractive index, however, the amount of light reflected at the first surface is so large that comparatively little light penetrates into the film or flake, and the amount which can be reflected at the lower surface is small. Moreover, the light which penetrates and is reflected at the lower surface is often much weakened by absorption in the film or flake, and the emerging light is of feeble intensity compared with the light reflected at the upper surface. As a result, the interference colours are not in general easily seen when an object covered with a surface film of high refractive index is examined under a ring illuminator.

It may be mentioned, in passing, that these differences can be used to identify the cause of the iridescent colours seen on much antique glass and porcelain. If the interference colours show well under the vertical illuminator and are not seen so well, if at all, when the ring illuminator is used, this is strong evidence that the iridescence is due to a film which has a high refractive index, such as a film of tarnish on a thin metal foil burnt on or just into the glass or glaze, *e.g.*, in "lustre" ware. If, on the other hand, the iridescent colours are shown best with the ring illuminator, they are probably produced by surface flakes of comparatively low refractive index such as result from disintegration of the glass or glaze. Evidence as to the refractive index of the iridescent material can also be obtained if any idea of the thickness of this material can be formed by endeavouring to focus to the levels of its top and bottom surfaces down one edge (not *through* it). If the refractive index is very high, the layer will be too thin for its thickness to be measured, but if the refractive index is comparatively low it should be possible to distinguish a difference of focus between the levels of the top and bottom surfaces when examined with a high power.

These interference colours, whether due to films or flakes, prevent the true colour of the object from being recognised. They can, however, be got rid of by a method now to be described, in which illumination with polarized light is used. This method of illumination also causes much of the regularly reflected light and stray light to be cut out. It is commonly assumed that only doubly-refracting materials will be visible when examined with polarized light when the axis of the *analyser* is at right angles to the axis of the *polarizer* (crossed nicols). This is not so. Reflection at a surface can cause a sufficient change in the state of polarization of the light from the polarizer for an appreciable proportion of the reflected light to be transmitted through the analyser. Moreover, if the surface at which the reflection takes place is coloured, this colour will show up strongly in the light which passes through the analyser.

In order that examination by polarized light may be used satisfactorily for the recognition of surface colour, it is necessary that the refractive index of the reflecting material should differ as much as possible from that of the material which surrounds it. The increased reflection resulting from this is of no advantage, of itself, but this increased reflection is associated with a comparatively large change in the state of polarization produced by the reflection. The visibility of a non-doubly-refracting particle when viewed between crossed nicols is thus dependent in a very large measure on the difference between its refractive index and that of the material in which it is embedded. As a result, particles of high refractive index, such as metals or the more highly-coloured metallic oxides, show up quite strongly when surrounded by almost any transparent medium; whereas particles having a refractive index not greatly different from that of the medium surrounding them, *e.g.*, white "opal" particles in an opal glass, show comparatively feebly, giving but little light compared with that seen on the particles when examined with non-polarized light. To illustrate the ways in which the examination with polarized light can be applied to the identification of surface colours, a few typical examples may be given, though many other applications will occur to the microscopist of experience.

A few flakes of an opal glaze which showed pinkish veins when examined visually, could only be seen as of a brownish-yellow colour with ordinary transmitted light, and as bluish-white by ordinary dark-ground illumination or with the ring illuminator. Transmitted polarized light, even when the nicols were crossed, gave a good deal of general white light owing to the intensity of the opal, and the pinkish colour was completely masked. With the ring illuminator used to reflect polarized light on to the specimen (the polarizer being below the stage as usual), large numbers of coloured particles could be seen when the nicols were crossed, and these particles were of the unmistakable colour of copper. With the nicols parallel, a few of these were distinguishable owing to their having been previously located when the nicols were crossed, but the colours were so much paler that it would have

been impossible to identify the nature of the particles by their colours. Under similar conditions crystals of ferric oxide in a glaze were easily recognized by their deeper red or brownish-red colour.

In a green-gray porcelain "body" of presumably Chinese origin, a few pale-green particles could be detected by careful observation of the porcelain, using ordinary light and a ring illuminator. With polarized light and the ring illuminator a very large number of such particles could be seen, amply sufficient to account for the depth of colour seen when the porcelain was examined visually. Moreover, the colour of the particles was so clearly recognizable that it gave strong presumptive evidence that the particles were a compound of chromium. Subsequent spectroscopic examination identified chromium.

Examination of a tarnished piece of copper by the vertical illuminator showed a flush of colours such as are produced by thin films. With the ring illuminator the whole surface appeared granular except for a few scratches, most of the granules appearing like burnished copper, though a few were blackish. The interference colours were not seen. Examination under the ring illuminator using polarized light, and with the nicols crossed, showed that most of the granules were more crimson in colour than the surface of copper seen in the scratches, and these granules were recognizable as particles of cuprous oxide. The blackish particles showed an intensified darkness of colour; these were particles of cupric oxide.

Diatoms mounted in Canada balsam or styrax are hardly visible when viewed by transmitted light between crossed nicols, but if mounted dry or in realgar they show up brightly unless the main lines in the structure lie parallel to the axis of one or other of the polarizing prisms. As the diatom is rotated, extinction positions highly reminiscent of those obtained with doubly refracting crystals occur, extinction, in the sense of greatly diminished brightness, occurring every 90° of rotation. Reflection surfaces give similar extinctions, and it is very easy to mistake a reflecting surface of any material, whether doubly-refracting or not, for a fragment of a doubly-refracting crystal.

This method of illumination is of very great value in critical microscopy, as can be gathered from the few examples which have been quoted. It is also useful when an object is to be examined with a cone of transmitted light large enough to fill the object-glass aperture, as it enables this to be done without incurring such loss of contrast as results from light reflected by the surface of the cover-glass (cover-glass glare) or by the surfaces of the individual lenses in the object-glass (lens flare). This reflected light is almost entirely stopped by the analyser and, as a result, the full resolving power of the object-glass can be obtained by full use of the object-glass aperture, without any marked loss of contrast such as is usually observed with ordinary transmitted light and a similarly wide-angled cone of illumination. The general appearance of the image when the object is examined between crossed nicols with transmitted light resembles that obtained with dark-ground illumination.

Visibility of Minute Particles or Fibres.—If a particle or fibre is to be visible when examined with transmitted light, using an object-glass of numerical aperture $n\sin u$, the diameter of the particle or the diameter of the fibre must be not less than $\frac{1}{2}\lambda/n\sin u$. Smaller particles or thinner fibres will not obstruct the light sufficiently for the object-glass to resolve the two sets of rays travelling past opposite sides of the obstruction. With dark-ground illumination all the light entering the object-glass is light which has been reflected from or scattered by the object. If, therefore, a particle is large enough, or a fibre thick enough, to send sufficient light up into the object-glass, the particle will be seen as a bright disk, or the fibre as a bright line of light extending much beyond its apparent end as shown by transmitted light.

The visibility of particles and fibres when illuminated by means of a ring illuminator, is similar to that obtained with dark-ground illumination, except in one respect. With dark-ground illumination the light passes up through the lower layers of the specimen and, except when the specimen is very thin, much light may be sent up into the object-glass from these layers. As a result of this, the visibility of any particles or fibres, or of structure generally, may be impaired since, to some extent, the upper layers of the specimen will be illuminated by transmitted light sent up through them from the underlying portions of the object. With the ring illuminator, much of this diffuse transmitted light is avoided and the visibility of particles or fibres is often better than that obtained with ordinary dark-ground illumination.

Minute particles are often much better revealed when intensely illuminated by ordinary dark-ground methods, or by means of a ring illuminator, than when viewed by transmitted light, just as dust particles in a beam of light are visible to an eye looking sideways into the beam but cannot be seen by looking along the beam towards the source of light. Thin objects, such as bacteria or other minute living organisms, in water, are often seen better by means of a lens of moderate numerical aperture, when ordinary dark-ground illumination is used, than by an immersion lens of much higher aperture used with transmitted light. It is worth while emphasising how much work lies within the scope of *dry-front* lenses of numerical apertures of 0·35 to 0·85 if advantage is taken of the high visibility of small particles when intensely illuminated, either by ordinary dark-ground methods or by means of the ring illuminator.

For dark-ground work with object-glasses of numerical apertures between 0·85 and 1·0, immersion object-glasses give more satisfactory visibility of faint objects than do dry object-glasses of corresponding apertures, as stray light from the cover-glass and front surface of the object-glass is largely avoided. For the purpose of rendering very minute particles visible, specially intense dark-ground illumination is used in conjunction with an ordinary microscope. This method of studying minute particles is called *ultra-microscopy*.

The Ultra-microscope.—There is, in theory, no limit to the smallness of a material particle which can be made visible, provided sufficient light can be made to fall on the particle. Bodies of small size have the power of scattering light which falls on them, the intensity of the scattered light being greatest in directions at right-angles to the path of the illuminating beam. Advantage is taken of this in the ultra-microscope, in which the particles to be rendered visible are illuminated by an intense beam of light which is directed through or across the object, in a direction at right-angles to the axis of an ordinary microscope. Each particle scatters some of this light, and the scattered light which enters the object-glass from any one particle is brought to focus as a diffraction disk in the image plane. If the dimensions of the particle are smaller than half the wave-length of the light used, no deductions as to the form of the particle can be made from the appearance of the diffraction disk seen in the image plane. Some estimate of the relative sizes of the different particles can be made from the relative brightnesses of the corresponding diffraction disks, but the diffraction disks will all be of substantially the same size. The size of the diffraction disks becomes smaller and smaller as the numerical aperture of the object-glass used for viewing the particles is increased. Each diffraction disk represents a particle; the number and positions of the particles can thus be determined provided no two particles are so close together that their diffraction disks are practically coincident in the image plane.

The illumination used is of such intensity that an appreciable amount of light is sent into the microscope from a plain slide of glass, either due to lack of homogeneity in the glass, to imperfections of its surface polish, or to fluorescence of the glass. For this reason any specimens which require mounting are usually mounted on slides of polished quartz when they are to be examined by the ultra-microscope. For the examination of fluids the Siedentopf-Zgismondy ultra-microscope is largely used, the fluid being contained in a small chamber fitted with quartz windows, through which a very intense beam of light is passed. The larger the particle and the higher its refractive index relative to that of the surrounding medium, the more readily is the particle seen. With modern methods of illumination, particles of colloidal gold having diameters as small as 1·7 $\mu\mu$ (17 Ångström units, or about $\frac{1}{250}$ of the wave-length of blue light) have been seen.

The ultra-microscope has been used for many purposes, such

as obtaining estimates of the number of smoke particles in the air of different localities, for estimating the amounts of foreign matter in water or in glues, gelatines, etc., as well as for many purposes in connection with the study of colloids. The instrument is also used in investigating the structure of natural and artificial fibres, for the examination of artificial fibres for inclusions, etc. Although the ultra-microscope fails to reveal particles which are separated by distances smaller than the limit of resolution of the object-glass used, the brightness of the haze of light obtained affords a measure of the size and concentration of the particles. Increase of brightness indicates either increase in the number of particles per unit volume or increase in the size of the individual particles. This effect can be made use of in certain work on very minute living organisms and in the study of the growth of minute crystals separating out from solutions. The microscope when used for this kind of work is being employed as a Nephelometer.

Ultra-violet Microscopy.—For the microscopic examination of objects having structures too fine to be resolved by any object-glass when ordinary visible light is used, recourse must be had to methods involving the use of ultra-violet radiations and of lenses made of fused quartz computed for use with ultra-violet light of appropriate wave-length. Glass lenses are opaque to these radiations. In 1904, Dr. Köhler of Jena experimented with ultra-violet light with a view to obtaining resolution of structures previously irresolvable. He used monochromatic radiation of wave-length 275 $\mu\mu$ given by an electric arc between cadmium poles, and projected the image on to a fluorescent screen for visual examination or for focussing in readiness for photographic recording.

In England J. E. Barnard has developed a technique for ultra-violet work which is much simpler than that used by Köhler. In his more recent work described in 1925, he used a combined illuminator made by the firm of R. & J. Beck consisting of an outer system of glass, which acts as an immersion dark-ground illuminator, and an inner immersion system of quartz which enables a transmitted beam to be passed through the object. Both condensers have the same focus, the one for visible light and the other for the ultra-violet radiation used. Either condenser can be stopped out at will, the quartz one by means of a central stop and the glass one by means of an annular diaphragm. The condenser is put in immersion contact with the quartz slide on which the object is mounted, and the object is illuminated with visible light by means of the dark-ground illuminator. The microscope is then focussed so that the object is clearly seen by visible light. The dark-ground illuminator is then closed, the central stop is removed so as to uncover the quartz condenser, and a beam of ultra-violet light is passed into this condenser and focussed by it, without further adjustment, on to the object. The object-glass has not the same focus for ultra-violet light as for visible light, however, so it is necessary to readjust the focus before any photograph can be taken with the ultra-violet light. Arrangements are provided so that by moving the fine adjustment through a known small distance, the requisite readjustment of focus can be made with certainty. If desired, a number of photographs of one object can be taken in succession, so as to show the structure of the object in successive parallel planes separated by distances of the order of $\frac{1}{100,000}$ inch.

The technique developed by Barnard has brought ultra-violet microscopy into an important position in bacteriological research. Bacteria are nearly uniformly transparent to visible light but are not so to certain regions of the ultra-violet spectrum. To photograph bacteria it has hitherto been necessary to stain them with dyes in order to make their outlines or structure visible with transmitted light. In the process of staining, the bacteria are killed, consequently any deductions drawn as to the form and structure of living bacteria are liable to be fallacious if based solely on the microscopic examination of stained specimens. With ultra-violet illumination staining is no longer necessary. Thus, not only is it possible with this new technique to examine the structure of bacteria which have never previously been resolved, but also it is possible to avoid staining the bacteria, so that the structure of living bacteria, whether large or small, can be photographed.

The technique worked out by Barnard offers great promise in other directions, notably in metallurgical research, for determining the detail-structure of metals and alloys. Experimental work to explore the further possibilities of ultra-violet microscopy is in progress, investigations have also been suggested with a view to discovering whether the very short ultra-violet radiations, of wave-lengths about 40 to 60 $\mu\mu$ can be used in microscopy. These Schumann rays are absorbed to a considerable extent by all forms of matter, a layer of air one or two centimetres thick being sufficient to absorb them almost completely, consequently any apparatus in which such rays are employed must be used in a vacuum and must be of the reflecting type.

The Microscope in Metallurgy, Engineering and Spectroscopy.—In metallurgical work an inverted type of microscope is now usually employed, though an ordinary microscope fitted with apparatus for giving illumination from above can also be used. In the more commonly used form, the stage, the microscope proper, the illuminating apparatus and all the other equipment are mounted on pillars carried by slides which can be moved independently along a machined bar, thus forming a type of optical bench. The specimen is illuminated from beneath, vertical or side illumination being provided by various types of apparatus. The illuminated underface of the specimen can be examined visually or can be photographed. The camera is an integral part of the apparatus and is mounted separately from the tube which carries the eye-piece used for visual examination. The same object-glass is used both for visual and photographic work, the change-over being made easily and quickly. Focussing adjustments are fitted to the object-carrier and also to the object-glass support. The fine adjustment can be fitted to either, but is usually on the object-glass support in order that the load it has to carry shall be as small as possible.

The lenses used for metallurgical work should be selected with special regard to the absence of flare when used with a vertical illuminator. Special lenses of high numerical aperture (1·6) for use with (blue) monochromatic light have recently been designed specially for metallurgical purposes, to be as free from flare as possible, to be well-corrected for spherical aberrations and to have as high a resolving power as appears to be feasible with a lens computed for both visual and photographic use.

The mechanical properties of metals and alloys, such as hardness, ductility and tenacity can largely be correlated with their structure as revealed by the microscope. The information provided by the microscope amplifies and extends that obtained from chemical analyses and in other ways, and enables the behaviour of the individual constituents to be more completely followed out when the metal or alloy is subjected to various heat-treatments or to mechanical processes such as forging, hot- or cold-rolling, drawing, pressing, etc.

Microscopes have valuable applications in the workshops as precision measuring devices. The type of microscope for use in the workshop is usually a simple robust instrument having a magnification not greater than about $\times$ 20, with a low-power object-glass and an eye-piece in which a scale or graticule is mounted. The type of graticule or scale used depends on the kind of work in connection with which the microscope is being used, as does also the method of mounting the microscope. For use on flat surfaces the microscope may be rigidly mounted on a plane base, while for other uses, such as in precision screw-cutting, tool- and jig-making, etc., other types of support are used. The microscope is provided with sliding-tube focussing, or with an ordinary rack-and-pinion coarse adjustment. Simple electrical illuminating devices are frequently incorporated with or permanently fitted to these instruments. For examining and measuring screw threads, wires, etc., specially designed microscopes, some of which are of the "projection" type, are used.

It is only possible briefly to point out the properties desirable in the type of attachment which enables the microscope to be used for micro-spectroscopy. It should be so constructed that the object can be brought into the centre of the field and isolated by means of suitable adjustable diaphragms, and arrangements should be made for the spectroscope and slit to be swung in easily when

the object and illumination have been properly adjusted. Provision should also be made for comparing the absorption spectra seen in the microscope with a wave-length scale in the eye-piece and with spectra obtained from known substances. The microspectroscope has many useful applications in the study of colouring matters of vegetable, animal and mineral origin, and can play an important part in micro-chemical work and in the identification of small quantities of fluids or solids having selective absorption for light.

The manifold applications mentioned or indicated in this article show that the microscope can be used for studying by means of light, anything which, as regards size and condition, can be presented to the instrument. It has been said earlier that there is no need to stress the importance of the microscope in medical, biological, geological, metallurgical and many other applications, but it is well to call attention again to its importance in general scientific and industrial work and research. An hour or two at the microscope may not only assist in shaping the problem to be investigated, but it may in many instances enable much laborious work to be avoided, either by solving the problem completely or by indicating those methods of attack most likely to bring a speedy solution. If care be taken to become familiar with the general principles and methods of microscopy, a comparatively small additional experience in any one particular line of work will make the microscope practically indispensable for such work. The many valuable applications of the microscope in science, industry and general education have rightly over-shadowed its use as a means of recreation alone; but it is well to recall the interest, pleasure, enlightenment and inspiration which the microscope can arouse, when used for recreation, as a revealer of unsuspected beauties and of things otherwise unknowable.

For bibliography *see* MICROSCOPE. (H. JA.; H. MO.)

MICROTOMY is the technique of cutting animals or plants or their parts into minute slices. For many years both botanists and zoologists depended on free hand sections made by the razor, and this method is still universally used by botanists except for the finest work. Skilled botanists can cut very thin sections of plant tissues merely by means of a pith mount and a sharp razor, but this method is inapplicable to animal tissues the cells of which are unsupported by stiff cellulose walls, as are those of plants. Consequently the animal histologist, the embryologist or morphologist, who studies the structure of minute animals, and the cytologist, who investigates the structure of individual cells, use special micrological techniques for the preparation of the thin slices of parts of animals with which they are dealing.

Modern microtomy owes its efficiency to two things—first the development of methods of infiltrating tissues and animals with supporting media like gelatine, paraffin wax and celloidin, and second, the development of cutting instruments of precision. The infiltration of tissues with special hardening media is called *embedding;* the special instruments for cutting the tissues into thin slices are called *microtomes.*

MIDAS, a very old royal, possibly also divine, name among the Phrygians and the Briges (a people living north of Greece). In Greek mythology, the following *märchen,* all of a fairly well-known type, are told of "King Midas." (1) By mixing wine with the water of a spring he made Silenus (*q.v.*) drunk, caught him, and induced him to teach him some of his wisdom. (2) He restored Silenus to Dionysus, who, by way of reward, gave him a wish. Midas wished that all he touched might turn to gold; as this included food and drink he was nearly starved to death, and asked that the gift might be taken away again. The god bade him bathe in the river Pactolus, which has had gold in its sands ever since. (3) He preferred the music of Pan (*q.v.*) or Marsyas (*q.v.*) to that of Apollo; Apollo in wrath gave him ass's ears. He concealed this deformity from all but his barber, who, bursting to tell the secret, dug a hole in the ground and whispered it into that, afterwards filling in the hole. Reeds grew from it, which, whenever the wind blew through them, whispered "King Midas has ass's ears."

See Roscher's *Lexikon, s.v.;* H. J. Rose, *Handbook of Greek Mythology* (1928).

MIDDELBURG, the ancient capital of the province of Zeeland, Holland, in the middle of the island of Walcheren, 4 m. by rail N. by E. of Flushing, with which it is also connected by steam tramway and by ship canal (1873), which continues to Veere on the N.E. coast, with a branch eastward to Arnemuiden. Pop. (1926) 19,020. Middelburg contains many old houses. The town-hall, built about 1512, with a square tower 180 ft. high and a façade adorned with statues contains the city archives and antiquarian and historical collections. The old abbey of St. Nicholas, founded in 1150, and now occupied by the provincial council, has old tapestry of the end of the 16th century.

MIDDELBURG, a town of South Africa, 25° 44′ S. 30° 1′ E.; altitude 4,971 feet. Population 2,705 whites in 1921, falling to 2,600 in 1926: natives (1921) 2,066, Asiatics 158, coloured 114. It is situated 98 m. by rail E. of Pretoria on one of the richest coalfields in South Africa. About 20 collieries are at work and the coal is of very good quality.

Middelburg is also the name of a town in the Cape Province, 250 m. by rail N. by W. from Port Elizabeth. Its population in 1921 included 2,093 Europeans, and 2,278 non-Europeans.

MIDDLE AGES, THE. The term is of course a modern term, coined consciously to define the contrast which its authors felt between the centuries which succeeded the downfall of the ancient world and their own time. To them the world of old Greece and Rome was in some ways nearer to them, more intelligible than the Europe held together by a common religious system. It would seem unnecessary to observe that the men and women who lived during the thousand years or so preceding the Reformation were not conscious of living in the middle ages; and yet, so strong are the associations and implications of the phrase, we often unthinkingly speak of the mediaeval world as though it was a world consciously mediaeval, inhabited by beings who thought of themselves as mediaeval. This absurdity has been accentuated by obeisance to specialism. Conveniently enough, scholars are described as mediaevalists and modernists, or they are said to profess modern or mediaeval history.

Conventional Sense of Term.—A more far reaching reason for using the term "the middle ages," in a more conventional sense is that, as time goes on, it will necessarily become more and more meaningless. The persons who first used it were making a gesture of their sense of freedom, and yet at the same time they were implicitly accepting the mediaeval conception of history as a series of well defined ages within a limited framework of time. They did not speak of the six ages or believe in the chronology o Joachimite prophesy, but none the less they inherited a scheme of history which began with the Garden of Eden and would end with the Second Coming of Christ. In such a scheme the thousan years from the fifth to the 15th centuries after Christ might wel be regarded as a distinct, respectable period of history, whic would stand out clearly in the providential pattern. Nowaday we have discarded the Eusebian chronology; we look back to a almost infinite past and forward to an almost infinite future. I the eyes of a scientist a period of a thousand years is neither her nor there. Moreover, the content of history, both before th middle ages and contemporary with them, has been immensel enlarged. The significance of many aspects of mediaeval life ha been changed by our knowledge of previous civilizations—of th civilizations with which mediaeval Europe was in contact.

Downfall of Rome.—If we set our preconceptions on o side, the middle ages are the period in the history of Europea people, and especially of the western peoples, since the downfa of the Roman empire. The breach between ancient and later hi tory was not so clearly defined as we are wont to say—some di tinguished scholars, for example, led by Pirenne, would deny th there was any real breach until the Mohammedans occupied t Mediterranean,—but the settlement on a large scale of the Ge manic peoples within the borders of the Roman empire and t failure of the central imperial government to maintain itself, we developments so striking as to justify the use of the terms "a

cient" and "mediaeval" to describe the state of society before and after them. It is impossible to fix any date, for tastes differ, and the date 250 or 410 or 476 has only a dogmatic significance in the minds of various historians. It is a convenience like the limits of legal memory or the legal doctrine that the House of Lords and its personnel dates from the year 1295.

The Renaissance.—It is still more impossible to fix any date as marking the end of the middle ages. The view that the fate of Constantinople in 1453 was a catastrophic event, unexpected and devastating, which had violent effects upon the whole temper of western society, is quite discredited. The view that the breach between the papacy and various European countries—an event which we describe as the Reformation—diverted the stream of history or introduced new life into history, has more truth in it, but is grossly exaggerated. If we give a sufficiently wide interpretation to the movement known as the Renaissance, and remember that, although it was most consciously intense during the 15th and 16th centuries, it had no obvious beginning and has had no end, we may define the end of the middle ages as the point, reached in different ways and at different times, at which the spirit of the Renaissance was victorious in political, social and artistic life. There has never been anywhere a complete breach with mediaeval institutions or modes of thoughts.

Development of National States.—The settlement of peoples and the gradual development of national states under the joint influence of native habit and the living traditions of the ancient world were not matters of a day. They required more than a thousand years. Everywhere natural forces and conscious contrivance can be traced together, although the element of contrivance varied very considerably in extent. Two great kingdoms, Germany and Italy, began to lose their political unity almost as soon as they had acquired it; they had to wait until the 19th century before they found it again. Switzerland and the Low Countries (the modern Holland and Belgium) were strongly welded into political units in a process in which it is difficult to disentangle the elements of nature, accident and artifice; but the unity, once acquired, has on the whole been permanent. Only a long and complicated process of events could decide that Portugal was to be separated from Castile, and Castile united to Aragon, that Catalonia was to be part of the kingdom of Aragon and not linked up with the Mediterranean littoral north of the Pyrenees, that Hungary was to be attached to the German marchland of Austria and that the River Tweed was to separate a kingdom of Scotland from England.

In these political developments the effect of Roman imperialism, working through geography and tradition, was not very marked. It might be an obstacle to be overcome, as in Italy and the Rhine valley, or an incentive to unity, as in France. But within the structure of society the element of contrivance was largely proportionate to the strength of classical influence, whether this were continuous or consciously revived. The extent and force of this influence have been the theme of endless discussion. How far the land settlement of the Franks was a continuation of the Roman system in Gaul, whether city life in North Italy and on the Rhine was completely interrupted, or, to take examples of a different kind, the extent to which the folk lore and legendary literature of mediaeval peoples was drawn from native sources or derived from the treasure house of the East and the fancies of sophisticated brains, and whether mediaeval art is mainly popular or "learned" in origin—these are some of the problems which still arouse controversy. On the whole the tendency is to emphasize the extent of the artificial and learned element in later centuries and to minimize the importance of continuous classical survivals in the early middle ages. The continuous and ever present influence of the ecclesiastical system is, it is hardly necessary to say, undisputed and is regarded as exceptional even by those who deprecate the view that it was the really formative factor in mediaeval life.

Mediaeval and Modern Culture.—Whatever the final issue of these discussions may be, it is no longer possible to draw a sharp distinction between culture or intelligence in mediaeval and modern times. Compulsory education and the impact upon our everyday life of scientific inventions are recent developments which separate us in external and possibly in more far reaching ways, from the middle ages, though their civilizing effects are still uncertain. The isolation in which so many people lived in earlier days, and the immense differences in wealth, social importance and external trappings between class and class have largely disappeared; the sum of human happiness and comfort is probably greater than in mediaeval times; but the contrast, once so fashionable, between the ages of darkness and the ages of light has no more truth in it than have the idealistic fancies which underlie attempts at mediaeval revivalism. The fascinating perplexity felt by students of mediaeval life is due precisely to the fact that our forefathers were not barbarians struggling forward, unaided, to a state of civilization; but were vigorous, intelligent, semi-civilized people who fell at every turn under highly sophisticated influences. Even before they settled down in the fifth century they had, more or less consciously, entered upon what is termed the "heroic age," in which an exotic element, derived perhaps from the east by way of the Black sea and the great trade routes of central Europe, gave direction to their barbaric qualities. Some of them, like the Visigoths, fell at once under the influence of Roman jurisprudence.

All in due course were affected by the Church and were introduced to forms of organization, thought, art and conduct which they appropriated as best they could. Three or four centuries later their men of learning came under the steadily increasing influence of Greek thought, as transmitted by the Greek speaking scholars of the Eastern empire, by Arabs and Jews; an influence which reached its height in the 13th century. By this time social contact with the East, never entirely lost, had been deepened by the establishment of western states in the Levant, the result of the crusades. Hence the process of sophistication, if the term may be used, was intensified by new periodic injections. However indigenous the expressions of political, social, literary and artistic life were, they flourished in an atmosphere of self-consciousness. They were not all spontaneous, and were rarely "artless." The results were naturally very varied, some bizarre and grotesque, with the seeds of decadence in them, some simple and effortless, some extraordinarily beautiful; some foolish, others profound; some pagan, others Christian.

Distinction of Values.—These facts help to explain the strange inconsistencies of the mediaeval world. To return to our starting point they also make the usual distinction between the values, moral and intellectual, of mediaeval and later times very misleading. If we search in history for examples of sheer goodness, or of forms of delicate perception, or of intellectual greatness, of legal acumen or of constructive ability, we can find them as readily in the middle ages as elsewhere, just as we find, as nowhere else, depths of religious experience. All that was fresh and vigorous in the European peoples could be drawn out and directed in the service of religion and art, learning, and even of statesmanship. Similarly, it could be perverted into an intensity of persecution or cruelty, into decadent orgies of sophisticated superstition, just as it could respond to eccentric and heretical influences, or find its own vent in ways which seem to us to be startlingly modern. A sedentary society, throwing off a continuous stream of wanderers; a conventional society, ruled by custom, yet indulging all sorts of adventures of the spirit; a pagan society responsive at every turn to the teaching of the Christian religion—such was mediaeval society.

Belief in Custom.—Mankind has not yet found the way to health without belief in its past. It steps back with relief into the old tried paths from the highest, the best thought-out experiments in constructive revolution. Societies, during the thousand years after the fifth century, found health in the vigorous persistence of custom, and the veneration for custom. The essential thing to remember is that mediaeval belief in custom was not a dead weight, but a conscious discipline in a changing world. Lawyers and church have idealized it in the light of their belief in a universe bound together by law. Moreover men instinctively clung to their trust in custom, for the conception of the universe with which they were presented did not permit of that constant discovery of the inner relations of things which we

call science. However speculative or transitory modern science is, it has secured popular allegiance by using the mysteries of nature—heat, electricity and so on—in the everyday service of man, so that conservatism nowadays shares its old power with a belief in science. Yet, as has been well said, modern science was both made possible by the earlier, mediaeval, belief in the reasonableness of the world, and was also an adventurous reaction against the rationalism of mediaeval thought. It was a revolt against the rigidity of law, but the belief in law was at the root of the new investigation into facts. The conception of sovereignty illustrates the same tendency in the political world; it was a recognition of the fact that certain social entities were directing their energies in their own self-regarding way, and a repudiation of the belief (due to a mingling of Christian and Roman ideas) in the unity of mankind under a universal law of nature; yet a long discipline had been required, under the régime of custom, in order to make the conception of sovereignty safe or tolerable. Its value is on the wane, and the trust in law in the mediaeval sense seems to be returning.

Influence of the Church.—The Christian Church shaped the European peoples in two ways. It gave direction to the energy of the robust European peoples, and it offered a higher interpretation of the meaning of life. Suicidal strife, with the succeeding stagnation, was checked. The Romans had impressed on the barbarians a system of law and order which they had neither the ability nor the desire to maintain. The Church maintained this system in its own way and, while accepting the traditional social arrangements of the barbarians, enabled them to develop. The response was very extraordinary. Indeed the danger of absorption was so great that the Church in self defense strengthened its organization and emphasized its unity in the Papacy. Hence we have the interplay of political and ecclesiastical forces which runs through the history of feudal and afterwards of national or urban societies, and profoundly modified the structure of the Church itself. Throughout the middle ages the Church maintained the conception of unity and its claim to interpret the moral law. But its other great function, though sometimes lost in the development of organization, was never forgotten. There again the peoples responded. Their craving for certainties or for adventure was met by the development of dogma, the various monastic experiments, the Crusades. They produced an endless series of saints. They tried to comprehend in their schools and universities the learning of the ancient world and to harmonize it with the teaching of the theologian. They built thousands of buildings, bringing all their energy to expression in the name, if not in the service, of a Church and the saints. Our political systems, our scientific thought, and our art are developed from those of the middle ages, and the conscious reactions against the fundamental ideas of the mediaeval church are a tribute to its strength.

(F. M. P.)

MIDDLEBOROUGH, a town of Plymouth county, Massachusetts, U.S.A., 30 m. S. of Boston, on the Taunton river and served by the New York, New Haven and Hartford railroad. The population was 8,453 in 1920; 8,608 in 1930. It has an area of 70 sq.m. and embraces several villages. There are many shoe factories and various other manufacturing industries. The public library and many of the town's improvements owe their existence to gifts from Thomas Sprout Peirce (1823–1901), a local merchant, and to a trust fund created by his will. The town of Middleborough was established in 1669, from common lands called Namassakett.

MIDDLEBURY, a village of western Vermont, U.S.A., the county-seat of Addison county; on Otter creek, Federal highway 7 and the Rutland railroad, midway between Rutland and Burlington. The population in 1930 was 2,003. It has a beautiful location in the Champlain valley, near the Green Mts., and is the seat of Middlebury college (chartered 1800), which has a campus of 244 ac., a forest preserve of 30,000 ac., an endowment of about $3,000,000 and an enrollment in 1927–28 of 1,145. A settlement was made here in 1773. It was deserted at the opening of the Revolution, almost destroyed by British troops, re-established at the close of that war, and incorporated as a borough in 1813 and as a village in 1832.

MIDDLESBOROUGH, a city of Bell county, Kentucky, U.S.A., in the south-east corner of the State, at an altitude of 1,100 ft., among ranges rising to 3,100 ft.; on Federal highway 25E and served by the Louisville and Nashville and the Southern railways. Pop., 8,041 in 1920 (15% negroes); 10,350 in 1930 by Federal census. The city lies in a valley of the Cumberland mountains, 5 m. N.W. of the Cumberland gap, through which Daniel Boone in 1775 marked the Wilderness road, the thoroughfare of the Kentucky pioneers. It is a summer resort, surrounded by beautiful scenery. It was founded in 1889 and incorporated in 1892.

MIDDLESBROUGH, a municipal, county and parliamentary borough in the North Riding of Yorkshire, England, 238½ m. N. by W. from London on the L.N.E. railway. Population (1931) 138,489. It stands on the south bank of the Tees estuary, 5 m. from its mouth in the North Sea, and is the centre of one of the most important iron-working districts in the world. Where Middlesbrough now stands there were at one time a small chapel and priory founded by Robert de Brus of Skelton Castle. These were dedicated to St. Hilda, and were given, together with some lands by de Brus to the abbey of St. Hilda at Whitby in 1130. The priory fell into ruins at the time of the Reformation and very little trace now remains. In 1801 there were, upon the site of Middlesbrough, only a few farm houses with a population of 25. In 1829 a company styling itself the Middlesbrough Owners bought 50c acres of land and began building. When, in 1830, the Stocktor and Darlington railway was extended to Middlesbrough, it becam a new Tees port; four years later the town was lighted with ga and in 1840 a public market was established. In 1841 the popula tion was 5,709. In 1842, the opening of the docks gave it additiona importance; by 1851 blast furnaces were erected and soon th whole district became a thriving iron centre.

Iron stone was mined in the neighbouring Cleveland Hills; lime stone and coal were at hand, transport was made easy by th presence of the young railway and the navigable river way, whicl meant cheap facilities for export. The town grew so rapidly that i 1853, Middlesbrough was given a charter as a municipal borough it was created a county borough in 1888. Iron and steel workin is the most important industry.

The entrance to the River Tees is protected by two break waters, the South Gare, which was begun in 1863 and took 2 years to build is more than 2½ miles in length; and the North Gar which has been completed for a length of 3,330 feet. Extensiv dredging operations have been carried on in the river; since 185 about 45,477,463 cu.yd. of material have been removed from it bed. In 1863 the depth of water on the Bar was 3½ ft. at lo water of ordinary Spring tides; it is now 20 ft. at low water an 37 ft. at high water. Vessels of heavy tonnage which regularl frequent the river require increased depth of water, and to mee this demand powerful ladder-dredgers are used. The scheme sanc tioned by parliament for the widening of the river from Middle brough to the sea will ultimately result in an additional width i the channel, averaging 350 to 400 feet, to the Middlesbrough Doc entrance. This dock is the property of the L.N.E. railway, an was considerably enlarged in 1926. Its area is 26 acres; the ne entrance is 80 ft. wide and total length of quayage is 6,843 ft 3,350 acres of land have been reclaimed from the foreshore of th Tees, much of it by the deposit of slag from the iron works. A the reclaimed land on the south side has been sold for the co struction of iron and steel works, shipbuilding yards, dry doc and deep water quays. The chemical industry, which owes i creation to the presence of salt and to the by-products of th coking ovens, is becoming increasingly important.

Middlesbrough, being the main port of the river Tees, deals wi the bulk of the trade of the region. Its chief exports are coal ar coke, pig iron, brass, plates and rails, galvanised sheets, chemica and bridge work and girders. Its imports are chiefly ores—irc and manganese—coal and wheat.

See Sir J. Bell, *The Iron and Steel Industry in Cleveland; Report the Tees Conservancy Commission;* Bulmer, *Middlesbrough and Shipping Facilities, South Tees-Side Regional Planning Scheme.*

MIDDLESEX, LIONEL CRANFIELD, 1ST EARL OF (1575–1645), was a successful London merchant, who was introduced to James I. by Henry Howard, earl of Northampton, and entered the royal service in 1605. In 1613 he was knighted and was appointed surveyor-general of customs; in 1616 he became one of the masters of requests, and in 1619 master of the court of wards and liveries and chief commissioner of the navy. He was returned to parliament for Hythe in 1614 and for Arundel in 1621. He took part in the attack on Bacon in 1621, and in the same year was created Baron Cranfield and became lord high treasurer. Impeached by the House of Commons for corruption, he was found guilty by the House of Lords in May 1624, but was pardoned in the following year, and restored to the House of Lords in 1640. He died on Aug. 6, 1645.

MIDDLESEX, a county of England, bounded north by Hertfordshire, east by Essex, south-east by the county of London, south by Surrey, and west by Buckinghamshire. Excepting Rutland, the county is the smallest in England. It lies entirely within the Thames basin and within the geological region known as the London basin. The general slope and dip of the strata is to the south-east. South of an irregular line from Uxbridge, north of Hayes, by Hanwell and Ealing to Hyde park and east of a line from the park to Tottenham, the ground is covered by gravels deposited by the Thames. From this river in the south and from the Lea, forming the eastern boundary with Essex, the gravels rise in a series of terraces. Underneath the alluvial gravels and emerging north of the boundary line, indicated above, lies the London clay. It forms the undulating country around Harrow, Chipping Barnet and Elstree. The highest ground is found along the northern boundary, and near Stanmore the hills are 503 ft. high. These hills send two projections southward, one towards Harrow and the other towards Hampstead. On these ridges are the remains of the sandy and pebbly Bagshot beds which formerly covered the London clay area. Glacial deposits are also present in the county, *e.g.*, the pebbly gravels of Stanmore heath, the clay and sand of Finchley, and chalky boulder clay of Southgate. The Reading beds emerge only in the north-west, near Harefield. The western part is watered by the rivers Colne, Crane and Brent.

History and Early Settlement.—Palaeolithic implements have been found in the river drifts at various points, and Neolithic finds are numerous. Beaker pottery and bronze implements have also been found. In spite of this it is probable that the county never had a large population in prehistoric times, because the lower lands were often marshy and subject to floods, while the higher clay lands were forested. Thus, the majority of the artefacts found probably only indicate lines of movement across the county. In Roman times the eastern border from Tottenham to Waltham Cross was traversed by Ermine street; Watling street ran across the county from Cricklewood towards Elstree, and the Roman road from London to Silchester crossed the county from Turnham Green to Staines, where the Romans had a station.

Middlesex was colonized in the 6th century by an offshoot of the East Saxon tribe, and derived its name from its position between the kingdoms of the East and West Saxons. In a charter dated 704 Middlesex is mentioned as a dependency of Essex, but soon after it acknowledged the supremacy of Mercia, and the Mercian council was held at Brentford from 780 onwards. In the 9th century Middlesex formed part of the Danelagh. The only reference to Middlesex in the Saxon Chronicle occurs in 1011, when it was overrun by the Danes. The Conqueror's march upon London was preceded by a general devastation of the surrounding country. At the time of the Domesday survey, the district north of London had a population of 2,302, and formed the forest of Middlesex.

As a shire, Middlesex probably originated about the time of the frith of 886. During the Saxon period the manors held by the church of Canterbury, the bishop of London and his canons of St. Paul's, and the Abbey of Westminster were held as independent franchises. By charter of Henry I. (confirmed by Stephen and Henry II.) the citizens of London held Middlesex at farm for £300, with power to elect a sheriff from among their number, and by charter from John the shrievalty of both London and Middlesex was granted to the mayor and citizens in fee. By charter of 1242 the common pleas for the county of Middlesex were ordered to be held at the stone cross in the Strand. Under a charter of 1447 the lord mayor was authorized to nominate one of the city aldermen as justice of the peace for Middlesex. The six modern hundreds of Edmonton, Elthorne, Gore, Isleworth, Ossulston, and Spelthorne have been scarcely changed since the Domesday survey, except that Isleworth was then Honeslaw (Hounslow), while in the 12th century hidage a hundred of "Mimes" is mentioned, corresponding with the Domesday hundred of Edmonton. Middlesex has always been included in the diocese of London excepting a small portion which is in that of Oxford. The archdeaconry of Middlesex, which includes part of Essex, is mentioned in 1151.

In 1215 Middlesex was ravaged by King John's army. In the Civil War Middlesex supported parliament. Sir Denzil Hollis was defeated by the Royalists at Brentford in 1642, and in 1645 a fruitless treaty between Charles I. and the parliament was concluded at Uxbridge.

The woollen and leather industries flourished in Middlesex in Norman times; hides were tanned at Enfield, bricks were manufactured, and Heston was noted for its wheat. Paper was manufactured in the 17th century.

Agriculture and Industry.—The soil is not particularly suitable for agriculture and the acreage cultivated, as well as the number of livestock, has decreased rapidly as London has expanded, incorporating villages and covering the land with buildings. The most important cultivation is that of market gardens on the rich alluvium in the Thames valley. The county possesses a number of varied industries which depend for their prosperity on their proximity to the metropolis and on the railway lines, the spread of industries along which is a very marked feature of industrial change for the period after 1918.

Communications.—The county is closely intersected with railways, the following companies affording communications: L.N.E.R., L.M.S.R., S.R., G.W.R., Metropolitan and District. Moreover, in some parts the tramway system has been extended over a wide area from London. The principal canals are the Grand Junction, running west from Brentford to the Colne valley, and thence northward; with a branch (the Paddington canal) connecting it with the Regent's canal in London; and, in the east, the Lea navigation.

Administration.—The part of the ancient county transferred to the county of London under the Local Government Act of 1888 was 31,484 ac. in extent, and 771 were then transferred to Hertfordshire; while under the London Government Act of 1899 the southern part of Hornsey was transferred to London. Area of administrative county 148,691 ac., pop. (1931) 1,638,521. The municipal boroughs are Acton, Ealing, Hornsey, Twickenham. The county is within the Metropolitan Police district and within the jurisdiction of the Central Criminal Court. There is one court of quarter sessions held at the Middlesex Guildhall, Westminster, but no county town. The extra-Metropolitan parliamentary divisions, each returning one member, are Acton, Brentford and Chiswick, Enfield, Finchley, Harrow, Hendon, Spelthorne, Twickenham, Uxbridge and Wood Green. The parl. boroughs are Ealing, Edmonton, Hornsey, Tottenham and Willesden; the first three return one member, the last two, two members to parliament.

See John Norden, *Speculum Britanniae: the firste parte, an historicall and chorographicall description of Middlesex* (London 1593: reprinted 1637 and 1723); Daniel Lysons, *The Environs of London* (1792–96); *Victoria County History, Middlesex.*

MIDDLETON, EARLS OF. JOHN MIDDLETON, 1ST EARL OF MIDDLETON (*c.* 1619–1674), belonged to a Kincardineshire family which had held lands at Middleton since the 12th century. In early life he served as a soldier in France; later he fought against Charles I., being especially prominent at the battle of Philiphaugh. He held a high command in the Scottish army. In 1656 the king made him an earl, four years later commander-in-chief of the troops in Scotland and lord high commissioner to the Scottish parliament. Owing to serious dissensions with the earl

of Lauderdale he was deprived of his offices in 1663. He was afterwards (1667) governor of Tangier, where he died in June 1674.

His eldest son CHARLES, 2ND EARL OF MIDDLETON (*c.* 1640–1719), held several offices under Charles II. and James II., being envoy extraordinary at Vienna, joint secretary for Scotland, and from 1684 English secretary of state. In 1693 he joined the exiled king at St. Germain, where he became his secretary of state.

See A. C. Biscoe, *The Earls of Middleton* (1876).

One of Middleton's kinsmen was SIR CHARLES MIDDLETON, Bart. (1726–1813), comptroller of the navy from 1778 to 1790. In 1805, at a most critical time, although 80 years old, he was appointed first lord of the admiralty by Pitt and was created Lord Barham. It was his experience, industry and energy which made possible the great campaign which ended at Trafalgar. He resigned office in Jan. 1806 and died on Jan. 17, 1813. His barony passed through his daughter Diana (1762–1823) to the Noels, earls of Gainsborough, by whom it is still held.

See *The Barham Papers*, Sir J. K. Laughton, ed. (3 vols., 1907–11) and J. S. Corbett, *The Campaign of Trafalgar* (1910).

MIDDLETON, ARTHUR (1742–1787), American politician and signer of the Declaration of Independence, was born at Middleton Place, S.C., on June 26, 1742. His family was one of the most prominent in the colony. The grandfather, Arthur Middleton (1681–1737), was president of the council in 1721–30 and as such was acting governor in 1725–30, and the father, Henry Middleton (1717–84), was speaker of the assembly in 1745–47 and again in 1754–55, a delegate to the continental congress in 1774–76, and its president 1774–75. Like most wealthy South Carolinians of the 18th century, Arthur Middleton was educated in England—at Hackney, at Westminster school and at St. John's college, Cambridge. In 1773 he returned to South Carolina, and in the controversies between the colonists and the home government became a leader of the Whigs. He was a member of the provincial council of safety in 1775–76, and a delegate to the continental congress in 1776–77. He was captured by the British at Charleston in May, 1780, was exchanged in July, 1781, was again a delegate to Congress in 1781–83, and later served in the State legislature. He died on Jan. 1, 1787, near Charleston.

See Benson J. Lossing, *Biographical Sketches of Signers of American Declaration of Independence* (1854); and Charles F. Jenkins, *The Completed Sets of the Signers of the Declaration of Independence* (1925).

MIDDLETON, CONYERS (1683–1750), English divine, was born at Richmond, Yorks., on Dec. 27, 1683. He graduated from Trinity College, Cambridge, took orders, and in 1706 obtained a fellowship, which he soon resigned. In 1717 a dispute with Richard Bentley, who had demanded a large fee on Middleton's being created D.D., involved him in an acrimonious controversy. He wrote "Remarks" and "Further Remarks" on Bentley's *Proposals for a New Edition of the Greek Testament.* In 1723 he was involved in a lawsuit by personalities against Bentley, which had found their way into his otherwise judicious tract on library administration, *The Present State of Trinity College* (1719), written on the occasion of his appointment as university librarian. Observations made during a visit to Italy on the pagan origin of church ceremonies and beliefs were embodied in his *Letter from Rome, showing an exact Conformity between Popery and Paganism* (1729). This tract probably contributed to the storm which broke out on his next publication (1731). In his remonstrance with Daniel Waterland on occasion of the latter's reply to Mathew Tindal's *Christianity as Old as the Creation,* Middleton laid himself open to the charge of latitudinarianism. He was hotly assailed from many quarters, and retreated with some difficulty under cover of a sheaf of apologetic pamphlets and a more regular attendance at church. His next important work, a *Life of Cicero* (1741), enhanced his reputation at the time, but was in fact largely borrowed from William Bellenden's, *De tribus luminibus Romanorum.* His chief writings are the *Introductory Discourse* (1747) and the *Free Inquiry* (1748) "concerning the miraculous powers which are supposed to have subsisted in the church from the earliest ages." Middleton showed that ecclesiastical miracles must be accepted or rejected in the mass; and he distinguished between the authority due to the early fathers' testimony to the beliefs and practices of their times, and their very slender credibility as witnesses to matters of fact. On July 28, 1750, he died at Hildersham, near Cambridge.

The character of Middleton's intellect was captious and iconoclastic, but redeemed from mere negation by a passion for abstract truth. His diction is generally masculine and harmonious. Pope thought him and Nathaniel Hooke the younger, the only prose writers of the day who deserved to be cited as authorities on the language.

See Sir Leslie Stephen's *English Thought in the Eighteenth Century* (1876). His works, containing several posthumous tracts, but not including the *Life of Cicero,* appeared in 4 vols. in 1752 (5 vols. 1755).

MIDDLETON, THOMAS (*c.* 1570–1627), English dramatist, son of William Middleton, was born about 1570, probably in London. He may probably be identified with one of the Thomas Middletons entered at Gray's Inn in 1593 and 1596 respectively. His earliest work was *The Wisdom of Solomon paraphrased* (1597). He began to write for the stage with *The Old Law,* in the original draft of which, if it dates from 1599 as is generally supposed, he was certainly not associated with William Rowley and Philip Massinger, although their names appear on the title-page of 1656. By 1602 he had become one of Philip Henslowe's established playwrights. The pages of Henslowe's *Diary* contain notes of plays in which he had a hand, and in the year 1607–1608 he produced six comedies of London life, which he knew as accurately as Dekker and was content to paint in more realistic colours. In 1613 he devised the pageant for the installation of the Lord Mayor, Sir Thomas Middleton, and in the same year wrote an entertainment for the opening of the New River in honour of another Middleton. He was frequently employed to celebrate civic occasions, and in 1620 he was made city chronologer, performing the duties of his position with exactness till his death.

At the Globe theatre in 1624 he produced a political play, *A Game at Chesse,* satirizing the policy of the court, which had just received a rebuff in the matter of the Spanish marriage, the English and Spanish personages concerned being disguised as the White Knight, the Black King, and so forth. The play was stopped, after nine performances, in consequence of remonstrances from the Spanish ambassador, and the dramatist and the actors were summoned to answer for it. It is doubtful whether Middleton was actually imprisoned, and in any case the king's anger was soon satisfied and the matter allowed to drop, on the plea that the piece had been seen and passed by the master of the revels, Sir Henry Herbert. Middleton died at his house at Newington Butts, and was buried on July 4, 1627.

He worked with various authors, but his happiest collaboration was with William Rowley, this literary partnership being so close that F. G. Fleay (*Biog. Chron. of the Drama*) treats the dramatists together. The plays in which the two collaborated are *A Fair Quarrel* (printed 1617), *The World Lost at Tennis* (1620), an ingenious masque, *The Changeling* (acted 1624, printed 1653), and *The Spanish Gipsie* (acted 1623, printed 1653). The main interest of the *Fair Quarrel* centres in the mental conflict of Captain Ager, the problem being whether he should fight in defence of his mother's honour when he no longer believes his quarrel to be just. The underplot, dealing with Jane, her concealed marriage, and the physician, which is generally assigned to Rowley, was suggested by a story in Giraldi Cinthio's *Hecatommithi. The Changeling* is the most powerful of all the plays with which Middleton's name is connected. The plot is drawn from the tale of Alsemero and Beatrice-Joanna in Reynolds's *Triumphs of God's Reveng against Murther* (bk. i., hist. iv.), but the story, black as it is, receives additional horror in Middleton's hands.

With Thomas Dekker he wrote *The Roaring Girle, or Moll Cut-Purse* (1610). The frontispiece represents Moll herself in man's attire, indulging in a pipe of tobacco. She was drawn or idealized from life, her real name being Mary Frith (1584–1659?), who was compelled to do penance at St. Paul's Cross in 1612. In the play she is the champion of her sex, and is equally ready with her sword and her wits. Middleton is also credited with a

share in Thomas Dekker's *Honest Whore* (pt. i., 1604). *The Witch*, first printed in 1778 from a unique ms., now in the Bodleian, has aroused much controversy as to whether Shakespeare borrowed from Middleton or vice versa. The distinction between the two conceptions has been finely drawn by Charles Lamb, and the question of borrowing is best solved by supposing that what is common to the incantations of both plays was a matter of common property. *The Mayor of Quinborough*, the scene of which is laid in ancient Britain, was published with Middleton's name on the title-page in 1661; it may date from about 1606. One of its editors, Havelock Ellis, thinks the proofs of its authenticity as Middleton's work very slender.

The plays of Middleton still to be mentioned may be divided into romantic and realistic comedies of London Life. Dekker had as wide a knowledge of city manners, but he was more sympathetic in treatment, readier to idealize his subject. *Two New Playes. Viz.: More Dissemblers besides Women. Women beware Women*, of which the former was licensed before 1622, appeared in 1657. The plot of *Women beware Women* is a double intrigue from a contemporary novel, *Hyppolito and Isabella*, and the genuine history of Bianca Capello and Francesco de Medici. This play, which ends with a massacre appalling even in Elizabethan drama, may be taken as giving the measure—no mean one—of Middleton's unaided power in tragedy.

The remaining plays of Middleton are: *Blurt. Master-Constable, Or the Spaniards Night-walke* (1601–02); *Michaelmas Terme* (1606?), described by A. C. Swinburne as an excellent Hogarthian comedy; *The Phoenix* (1607), a version of the Haroun-al-Raschid trick; *A Trick to catch the Old One* (1606–07); *The Famelie of Love* (played between 1604 and 1607: pr., 1608); *A Mad World, my Masters* (c. 1606; pr., 1608); *Your five Gallants* (1607?, pr. 1608); *A Chast Mayde in Cheapside* (1612? pr., 1630), notable for the picture of Tim, the Cambridge student, on his return home; *Anything for a Quiet Life* (c. 1617, printed 1662); *No Wit, No Help like a Woman's* (c. 1613, printed 1657); *The Widdow* (printed 1652), on the title-page of which appear also the names of Ben Jonson and John Fletcher, though their collaboration may be doubted; Bullen puts the date of its performance in 1608–09. Eleven of his masques are extant. A tedious poem, *The Wisdom of Solomon paraphrased, by Thomas Middleton*, was printed in 1597, and *Microcynicon. Six Snarling Satires by T. M. Gent*, in 1599. Two prose pamphlets, dealing with London life, *Father Hubbard's Tale* and *The Black Book*, appeared in 1604 under his initials. Thus non-dramatic work, even if genuine, has little value.

AUTHORITIES.—His works were edited by Alexander Dyce (5 vols., 1840), with a valuable introduction quoting many documents, and by A. H. Bullen (8 vols., 1885). *The Best Plays of Thomas Middleton* were edited for the Mermaid series (1887) by Havelock Ellis with an introduction by A. C. Swinburne. *See* also P. G. Wiggin, *Inquiry into the Authorship of the Middleton-Rowley Plays* (Boston, 1897), the notice on Middleton in Professor A. W. Ward's *Hist. of Eng. Dram. Lit.* (ed. 1899; ii., 493–540), which contains a full account of Middleton's *Game at Chesse;* and, for the chronology and bibliography of the earlier plays, E. K. Chambers, *Elizabethan Stage*, vol. iii. A careful examination of the parallelisms between the plays of Shakespeare and Middleton is made by D. Hugo Jung in "Das Verhältnis Thomas Middleton's zu Shakspere" (*Münchener Beiträge zur roman. u. engl. Phil.* vol. xxix., 1904).

MIDDLETON, market town, municipal borough, Prestwich and Middleton parliamentary division, Lancashire, England, on the Irk, near the Rochdale canal, and on the L.M.S. railway, 6 m. N.E. of Manchester. Pop. (1931) 29,189. The tower arch of St. Leonard's church is 12th century, the rest dates from 1412, save for the south aisle built in 1524. Two chapels in it are named after two ancient Lancashire families, the Asshetons and the Hopwoods. The Queen Elizabeth grammar-school (Tudor style) was founded in 1572 by Nowell, dean of St. Paul's, London. The prosperity of the town dates from the close of the 18th century. The staple trade is the spinning and weaving of cotton, and the other industries include silk weaving, calico-printing, bleaching, dyeing, iron-founding and the manufacture of soap and chemicals. There are collieries in the neighbourhood. The town was incorporated in 1886. Area, 4,775 acres.

MIDDLETOWN, a city of Connecticut, U.S.A., the county seat of Middlesex county; on Federal highway 5 and the west bank of the Connecticut river, 15 m. S. of Hartford. It is served by the New York, New Haven and Hartford railroad and coasting steamers. Pop. (1920) 13,638 (27% foreign-born white, nearly half from Italy); 1930 Federal census 24,554. Hills and woods add charm to the surroundings, and 3 m. E. are the "narrows" of the Connecticut, an impressive gorge more than a mile long, cut by the river through a rocky barrier. The city is the seat of Wesleyan university (Methodist Episcopal; 1831) which has an endowment of $4,500,000; the Connecticut State hospital (for the insane) with accommodations for 2,180 patients; Long Lane farm, the State industrial school for girls; and the Middlesex hospital. It has diversified manufactures, with an output in 1925 valued at $19,312,494. Middletown occupies the site of an Indian village, Mattabesec or Mattabesett, and was at first known by that name. Settlement by the whites began in 1650. The town was incorporated in 1651 and the city was chartered in 1784. It became a ship-building and commercial centre.

MIDDLETOWN, a city of Orange county, New York, U.S.A., on the Wallkill river, 67 m. N.N.W. of New York city, at an altitude of 700 feet. It is served by the Erie, the Middletown and Unionville and the New York, Ontario and Western railways. Pop. (1920) 18,420 (87% native white); 21,276 in 1930, Federal census. It is surrounded by fertile farming country, rich in beautiful scenery, and there are many summer homes and hotels in the vicinity. The city has railroad shops and a great variety of manufacturing industries, with an output in 1925 valued at $6,154,256. It is the seat of a State homeopathic hospital for the insane, which has about 3,000 patients. Middletown was settled about 1796. It was a half-way house (whence the name) on the Minisink road to western New York, and for a time was a terminus of the Erie railroad. The village was incorporated in 1848 and chartered as a city in 1888.

MIDDLETOWN, a city of Butler county, Ohio, U.S.A., on the Miami river, midway between Cincinnati and Dayton (whence the name). It has a municipal airport, and is served by the Baltimore and Ohio, the Big Four, the Erie and the Pennsylvania railways, inter-urban trolleys and motor-bus lines. Pop., 23,594 in 1920 and 29,992 in 1930. It is the trade centre of a rich and beautiful agricultural region, producing chiefly tobacco, wheat, oats and corn; and has large and varied manufacturing industries (for which the river supplies water-power) with an output in 1925 valued at $56,732,394. Corrugated and sheet steel, paper, paper bags, boxes and gas engines are leading products. The city was laid out in 1802 and incorporated in 1833. It has a commission-manager form of government.

MIDDLETOWN, a borough of Dauphin county, Pennsylvania, U.S.A., on the E. bank of the Susquehanna river, 9 m. below Harrisburg. It is served by the Pennsylvania and the Reading railways. Pop. (1920) 5,920 (90% native white); and 6,085 in 1930 by the Federal census. It has large steel plants, car works, furniture and shoe factories and hosiery mills. The town has an intermediate depot of the Army Air Corps, including Olmstead field. Middletown was founded in 1755 by Quakers and Scotch-Irish, and was incorporated in 1828. It was named from its position midway between Lancaster and Carlisle.

MIDDLE WEST, THE, the northern portion of the central United States and more specifically the States of Ohio, Indiana, Illinois, Michigan, Iowa, Wisconsin and Minnesota.

In his *American Commonwealth* (1888), James Bryce observed that in the United States there were four areas which were diverse in cultural aspects. After a long generation the most recent serious commentator on American affairs, André Siegfried, is still able to note the differentiation that Bryce described. There is an East, a South, a Far West and a Middle West.

The four cultural areas are by no means equal in their social weight. Of the 105 millions of people resident in the States in 1920, the South, with 37 million, led the groups; the East, counting from Philadelphia and Pittsburgh, had 29 million; the Middle West had 26 million, and the Far West 13 million. There is no greater equality in the areas which they roughly occupy; and there is an inversion of order. Of the 2,974,000 sq.m. of land which they cover, the Far West has nearly half, or 1,483,000; the South 947,000, the Middle West 382,000 and the East 162,000. The Middle West thus covers about 13% of the area of the United States and contains nearly 25% of the population. At the time when Bryce wrote their proportion of the population

was already about 25%, as it had been a generation earlier, at the opening of the Civil War in 1860. For 60 years or more these States—Ohio, Indiana, Illinois, Michigan, Iowa, Wisconsin and Minnesota—have retained their constant proportion of the American people and have been regarded, as Bryce regarded them, as "the most distinctively American part of America," and as "one of the most interesting subjects of study the modern world has seen." (*American Commonwealth*, 3rd. ed. 1895.)

It has been noted (under AMERICAN FRONTIER) that the United States was occupied in the 17th century, along its eastern front, where the Atlantic rivers meet arms of the ocean and afford easy lodgment at numerous places between Florida and Nova Scotia. Before the 13 English colonies asserted their independence their people had spread thinly over the Atlantic coastal plain, had passed beyond the geographers' "falls line," and had begun the penetration of the parallel valleys of the Appalachians that open corridors running north-east and south-west between Albany, N.Y., and Chattanooga, Tenn. In the older sections of these original colonies there were already aristocracies of standing before the Continental Congress at Philadelphia undertook to direct their common effort against England. This tidewater section, and its immediate *hinterland*, was to become the East, when a West should arise behind it. It has remained the East until to-day, containing by a natural social drainage the administrative heads of many American institutions, the agencies of control of the wealth of the United States, the executive and legislative establishments of the Government of the United States, and the oldest and most crystalline society that the United States can display. It has also, by its location, received the inflow of immigrant people that have affected all percentages of population, and it has put the immigrant workers into the industrial machine that was the great product of the 19th century. Its constant drift has been towards the social and economic standards of western Europe; and its international commitments in finance have here been paralleled by the strongest of the American sentiments for internationalism in government and a world league.

Out of this old East, came the young West. The American Revolution did not stop, or seriously check, the pioneer process whereby the young, and the landless, and the ambitious among the people of the East sought to better themselves and gain economic independence. The new communities west of the Appalachians began to take shape while the Revolution was under way; and at its close Kentucky and Tennessee were growing rapidly towards statehood. A few years more, and the organization of the territory north-west of the Ohio river became a step that led to other new States in Ohio, Indiana and Illinois. All of these regions came to be known as West; and by this fact gave significance to the term East, which had no special meaning as long as there was no West to contrast with it. The East was the starting point; the West was the derivative. The East was becoming a stable community; the West was on the make. Wealth in the East was showing itself, and was shaping society to its conditions; poverty and debt were the universal qualities of the pioneer West. The people of the East were differentiating, according to their duties and opportunities in life; the West started uniform, and retained its uniformity throughout the greater part of the cycle of pioneer development. For something more than a generation the American sectional antithesis was East and West.

From the point of view of the West, the rise of the South is significant because the process drew away part of the West from the section bearing this name, and although not entirely altering its interests identified it primarily with the States bordering upon the Gulf of Mexico. It was after the second war with England (1812–14) that this differentiation became most apparent, and before the election of Andrew Jackson the result was both visible and ominous. The South stretched across the continent from the tidewater bases in Maryland, Virginia, the Carolinas and Georgia. It thrust itself into the open lands of the public domain as far as these were capable of normal agriculture, and came to an end only along the eastern margin of the high plains of western Texas. It did not provide for the area of the West a precise southern limit, for there was developed a twilight zone running from Kentucky and Tennessee into Missouri where there was a clash of West and South that has not yet subsided. Here, men groped for the key to American politics during the middle third of the 19th century. By its outspoken southern preferences it encouraged the leaders of the South when they thought of secession; by its essential western interests it discouraged them when the issue came to a head in the Civil War. It is to-day so southern that it cannot fairly be described as Middle West; but it is so western that it is no longer a dependable ally of the solid South.

At the outbreak of the Civil War the dominant American sections were East, South and West; and beyond the West there stretched to the Pacific a zone of plain and mountain sparsely sprinkled with inhabitants and not yet organized to any type. When during and after the Civil War this region developed into another new West there was confusion in terminology for it was nearly as different from the West of the middle period as the West was from the East or South. Time brought the nomenclature. The plains and the cow country, the mining camps, and the Pacific slope became the Far West; and Middle West came haltingly into use to describe what had before been West.

There is a topographic unity that helped to shape the old West, and that has not ceased to operate now that it has become the Middle West. The unity began to have an influence when the earliest pioneers crossed the Appalachians. These were not entirely free to choose their crossings. At two or three places the valley roads were designated by easy passes across the mountains. The military leaders of the colonial period had discovered one of them; and in the wake of the armies of Braddock (1755) and Forbes (1758) a procession of homeseekers advanced up the tributaries of the Potomac and Susquehanna until among the hills they met the southern tributaries of the Ohio river, the Youghiogheny and the Monongahela. Half a century later the Cumberland road, following this trail, was the first great Federal venture in internal improvements. It was a venture that had no real rivals until the Erie canal (1825) became effective through New York, and the central trunk line railroads reached the Ohio river at Pittsburgh and Wheeling a quarter-century later. The other great gateway to the Middle West was blazed by Daniel Boone for a land company in 1775, and emptied through Cumberland Gap into the Blue Grass region of Kentucky, the social overflow from Virginia and the Carolinas. Once through these gateways, the pioneer of the Middle West found himself cut off from easy access east by a mountain wall, and thrown into local alignment west by the fact that the rivers of the western slope of the Appalachians start separately as Allegheny and Monongahela, Kanawha, Cumberland and Tennessee, only to end as the Ohio river and to pass as a single stream into the Mississippi. From the Great Lakes to Muscle Shoals of the Tennessee river there was a necessary unity of need, a set of agricultural and climatic similarities, and a fact of separateness from the East. The mountain wall was not too high for the migrant; but it was too high, and the road was too long, for the farm surplus of the West to reach an Eastern market. The uniformities that thus resulted may be studied in detail from the time of the rebellion of Western farmers against the whisky excise (1794) until the time of their demand that greenback money be used to pay the debts of the Civil War (1868); they show themselves in the conspiracies for the opening of the Mississippi river to up-river trade, and in the zest for the conquest of Canada and the control of the St. Lawrence route. In the decade after the war of 1812, their greatest leader, Henry Clay, developed a theory of national integration for their special benefit, but called his programme the "American System," because both he and they genuinely fancied themselves to be America. Never, until the railroad cut across the natural routes indicated by topography, did the West free itself from the coercive control over its destinies, resources and ideas exercised by the Ohio river and the Mississippi. And when at last the railroads brought geographical dominance to an end, the Middle West had acquired a habit of thinking alike; and found a continuing influence to uniformity in a debtor relationship that could not easily be shaken off.

Southern Orientation.—The struggle for the control of

the Federal Government that took shape in the Presidential contest of 1824, and that resulted in Jacksonian victory in 1828, indicated not only a sharp and unified western point of view, but a possible shift in the direction of American destiny. Thereafter the tri-sectionalism of American life and politics was complete, with the West more nearly retaining the same old attitude and faith than either of the other sections. While the South advanced into cotton economics, and all that that implied, the East lost its nearly solid agricultural condition, and was transformed by the rise of manufactures, the accumulation of investable capital, the drift of population into the cities, and the appearance of a social aristocracy founded upon wealth and luxury. By the time of the Mexican War the Astor and Vanderbilt fortunes were ploughing new channels through the field of American business, and establishing new dynasties whose social flowering was to occur after the Civil War. More and more the Eastern cities took on traits of European social organization. Their natural position that made them the receiving hoppers for the influx of aliens after 1840, enabled them to retain large shares of the alien population as permanent members of their society, and from the aliens came traits and customs novel to the older Americanism.

The leaders of Eastern thought continued to think of their section as the legitimate and normal United States. Their Universities, responding to the nourishment of wealth, educated not only their own people but also the youth of all sections, and left an Eastern stamp wherever they made a contact. Their control of capital for investment, whether of their own accumulation or borrowed from Europe, gave Eastern financiers a power of direction and exploitation over the West that they exercised with little check or sympathy for the remainder of the century. Their opportunities for communication made them the centre of journalism and literary production, whose natural tone was that of cultural superiority. They were recruited continuously by a procession of successful Americans from the other sections, who had reached a level at which they demanded larger fields of activity or more sophisticated standards of life; and these generally made haste to slough off the traits of West or South, and to accommodate themselves to the Eastern type with all the ardour of the convert. The differentiation among the sections that had been begun by the rise of the West and the deviation of the South was perpetuated by the absorption of the East within the main currents of the industrial revolution.

Youth was another condition of the pioneer. The heavy labour of frontier development was no task for the old or the infirm. The normal frontier unit was the young or youngish family, all of whose members worked at the common tasks in and outside the cabin home. There were few of the dependent old, or of the middle-aged workers, among them. The mental traits of any pioneer group were those of youth and unbroken spirit. Hope and enthusiasm went with youth and poverty into the making of a Western settlement. It took hope, courage and a willingness to run risks to make a pioneer. One may suppose that, other things remaining equal, the brothers and cousins of an Eastern family who made the break from custom, and sought new homes in the West, were somewhat more adventurous than those who stayed at home. There are "pockets" in the East to-day where sociologists believe that they find a stagnant life that may be attributed to the long-repeated drift of the able and the enterprising to the West or to the cities. The West was enriched, and often was surcharged with an enthusiasm that bore too many traits of youth and lack of information.

Bearing these resemblances, and bound together by the geographic bonds of the Upper Mississippi valley, the people of the Middle West developed a great community whose centre and whose highest uniformity lay within the radius of 500 m. of the tip of Lake Michigan. They were held to their similarities because of their agriculture and because of their financial bonds. There was no great force operating among them which, like the plantation of the South, tended to separate the magnate from the common man: or, like the industry of the East, tended to raise the rich above the poor. Those who became rich were likely to move to the Eastern centres; those who remained in the West continued in a wide and real substantial unity. They lacked both depths and heights. There were few of the very rich; but the very poor were lacking. They were not peasants or proletarians; yet they lacked that acceptance of the going world that makes the bourgeois mind. They were citizens and democrats, and saw nothing incongruous in a Lincoln advancing from the cabin to the White House or in a Grant rising from the tan-yard to be a general of the army. They believed in opportunity, which they had themselves enjoyed; and they conserved it for their children by devoting to their schools and universities the greater portion of their public revenues.

The hundred years that have elapsed since the election of Andrew Jackson have seen this Upper Mississippi valley pass through three generations, and three distinct cultural phases, without losing the high concentration of westernism that was its main characteristic. For the first generation, it was the West, with the other sections of the United States emphasizing its nature by developing along contrasting lines. In the second generation, between the Civil War and the first defeat of William Jennings Bryan (1896) it became imperceptibly the Middle West; not because it was greatly changing in its point of view, but the emergence of the Far West made necessary a change of epithet. And it retained its character largely because it continued to be agricultural, and its unlike or unusual elements tended to be drafted into the East. In the third generation the old spirit has been thrown upon the defensive, as an industrial organization, a working class and an economic independence have broken into the old uniformities. It is likely enough that within the generation to come it will be largely absorbed, and will cease to exist as a geographical section. The whole United States is moving towards class stratification in place of geographic regionalism and the Middle West cannot forever hold its own against the tendencies of the times. Andrew Jackson was the first great indigenous prophet of the West; Robert M. LaFollette was perhaps the last.

Among the conditions whose influence has been to perpetuate the sectional consciousness of the Middle West, there is none that ranks higher or has been more pervasive than that of economic dependence. The frontier was always in debt. In this it did not differ greatly from a large part of society everywhere; but it was unique in the universality of the dependence. By definition, there were few residents in the frontier who possessed free capital. Those who had it stayed away from the frontier. Each new region was built out of the hopes of pioneers and the capital of the East. The poor equities of the West or Middle West, made the eastern capitalist loath to part with his wealth except at a high interest rate and often with bonus to boot. The Westerner, in the period of enthusiasm, was ready to agree to any rate, and inclined to believe that his soil could earn it. But inevitably there came the moment of liquidation. Much of the apparent wealth of the growing Western communities was derived not from the produce of the soil but from the enhancement of nominal land values as population increased. When the sad moment arrived when the Western borrower found himself unable to meet his interest charges, uniformity turned his condition of economic dependence into social or political reactions.

In the more complex East, debtor lived next to creditor, and the tone of his society was commonly dictated by the solvent members. It was hard for repudiation movements to get under way. But when one Westerner was in debt and insolvent, his neighbour was in the same condition. And absenteeism made it as easy to diabolize his creditor as common trouble made it easy for self sympathy to become a local virtue. In two ways at least this tendency has affected the Middle West. Here have originated movements of currency inflation. In the Jackson generation, the West enthusiastically backed up the wrecking of the Second Bank of the United States, largely because it operated as a check upon easy money and Western banks of issue. In the Civil War period, the same Middle West saw no defect in the scheme to pay the creditor of the nation and the holder of Western obligations in legal tender paper money, manufactured by the printing press. Towards the end of the 19th century Bryan swept the Western States with free silver inflation as his panacea for the

common man. Eastern interest in Western investments has tended to hold the sections apart, while Eastern distrust of Western economic theory has tended to confirm the Easterner in his assumption of his own superiority of intellect and virtue.

The Western liability to inflation finance has kept the West apart in a second way: it has created and developed a jealous suspicion of Eastern motive. Under best conditions it is hard for a debtor to love his creditor; under Western conditions of debt it was inevitable that he should hate him. The Eastern centres that controlled the lending of money, and the collection of debts, became synonyms for greed. The Second Bank was an "octopus"; the Civil War bond-holder was "inflated" and grasping; the "gold-bug," if not actually in the pay of Britain, was at least party to a conspiracy of Wall street. Eastern suspicion and Western jealousy came naturally to accentuate the sectionalism, and to prolong the existence of the Middle West. By the very nature of its existence, the Middle West has had few reflective and discriminating exponents of its point of view. Its active fighting leaders have been partisans. The East has drawn off and adopted a large share of its exceptional individuals. The market for literary and artistic wares has forced the Western maker of these to invade the East, and to adapt his output to his custom. The result has been that the Middle West has drawn few conscious pictures of itself, and the historian or literary artist who seeks to identify it must generally work among either the unconscious records of events that were transpiring in the West, or the jaundiced expressions of the alien who visited it and frequently did not like it. It can best be understood when one realizes that the qualities that identify the Middle West are the old qualities engendered along the fighting frontier of the United States in the period when the struggle for existence was a reality; that these qualities, by accident, survived beyond their normal expectation of life; that their uniformity gave them vividness and permanence; and that their normal reflexes are still capable of flaring up to influence affairs to-day, even in an industrialized society.

Bibliography.—Prof. Turner has discussed the Middle West in his *Frontier in American History* (1920); and the literary histories have tried to evaluate it in R. L. Rusk, *The Literature of the Middle Western Frontier* (1925); and L. L. Hazard, *The Frontier in American Literature* (1927). (F. L. P.)

MIDDLEWICH, urban district, Northwich parliamentary division, Cheshire, England, 166 m. N.W. of London, on the L.M.S. railway. Pop. (1931) 5,458. It lies in open country near the river Dane, having water communications with the Trent and Mersey canal, and the Shropshire Union canal. The church of St. Michael and All Angels is of various periods and contains numerous monuments. Old buildings and fine timbered houses occur in the neighbourhood. Middlewich shares in the salt industry common to several towns, such as Northwich and Winsford, in this part of the county; there are also chemical works and a manufactory of condensed milk.

MIDDLINGS, a term applied to various commercial products which may be regarded as occupying a middle position between two other articles. This idea covers the origin of the term when it is applied to wheaten products. Prior to the middle of the 19th century millers used millstones for grinding wheat, and sought at one operation to obtain as much finished flour and finished by-products, *e.g.*, bran, as possible. But they could not by such means avoid making a granular intermediate product, which they called "middlings." This was sold with or without further treatment either for use ultimately as human food or as pigs' food. These alternative purposes are reflected in the present confusing uses of the term. When modern methods of milling were introduced, and particularly when the machines known as "purifiers" were first used, millers were enabled to obtain from "middlings" flours of the greatest excellence, so they then sought to make as many as possible. Ultimately they adopted methods of "gradual reduction" and at an early stage of the milling process are able to granulate the kernel of the wheat berry. (*See* Flour and Flour Manufacture.) These granular products known as semolina (*q.v.*) middlings and dunst are essentially the same in constitution, differing only as to size of particle. For example, semolinas will pass through a mesh of say 20 per lineal inch, middlings through a mesh of say 56 per lineal inch, and dunst through a mesh of say 88 per lineal inch. Middlings so produced are, during the later stages of milling, resolved into finished flour and finished by-products. With recent changes in marketing the term may cease to apply to a by-product of milling.

(A. E. Hu.)

MIDHAT PASHA (1822–1884), Turkish statesman, the son of a civil judge, was born at Constantinople in 1822. His father trained him for an administrative career, and at the age of 22 he was attached as secretary to Faïk Effendi, whom he accompanied in Syria for three years. On his return to Constantinople Midhat was appointed chief director of confidential reports, and after a new financial mission in Syria was made second secretary of the grand council. His enemies caused him to be given the nearly impossible task of settling the revolt and brigandage rampant in Rumelia. His measures were drastic and their success was startling and the Government made him an official of the first rank and restored him to his place in the grand council. He restored order in Bulgaria in 1857. In 1860 he was made vizier and pasha, and entrusted with the government of Nisch, where his reforms were so beneficial that the sultan charged him, in conjunction with Fuad Pasha and Ali Pasha, to prepare the scheme for adapting them to the empire which was afterwards known as the law of the vilayets. He organized the council of State in 1866, and was then made governor of Baghdad, where his success was as decisive as at Nisch, but attended with much greater difficulties. In 1871 the anti-reform influence of the grand vizier, Mahmoud Nedim, seemed to Midhat a danger to the country, and in a personal interview he boldly stated his views to the sultan, who appointed Midhat grand vizier in place of Mahmoud. Too independent, however, for the court, Midhat remained in power only three months, and after a short governorship of Salonica he lived apart from affairs at Constantinople until 1875.

While sympathizing with the ideas and aims of the "Young Turkey" party, Midhat was anxious to restrain its impatience, but the sultan's obduracy led to a coalition between the grand vizier, the war minister and Midhat Pasha, which deposed the sultan in May 1876, and he was murdered in the following month. His nephew Murad V. was in turn deposed in the following August and replaced by his brother, Abdul Hamid II. Midhat Pasha now became grand vizier, reforms were freely promised, and the Ottoman parliament was inaugurated with a great flourish. In the following February, however, Midhat was dismissed and banished for supposed complicity in the murder of Abdul Aziz. Again recalled in 1878, he was appointed governor of Syria, and in August exchanged offices with the governor of Smyrna. But in the following May the sultan again ordered him to be arrested, and although he effected his escape and appealed to the Powers, he shortly afterwards surrendered, claiming a fair hearing. The trial took place in June, when Midhat and the others were sentenced to death. On the intercession of the British Government the sentence was commuted to banishment. The remaining three years of his life were spent in exile at Taif in Arabia, where he died, probably by violence, on May 8, 1884. To great ability, wide sympathies and patriotism he added absolute honesty.

(G. F. B.)

MIDHURST, town, Sussex, England, 12 m. N.E. of Chichester by rail. Pop. (1921) 1,890; rural district (1931) 15,018. Situated near the river Rother. The name of Midhurst (Middeherst, Mudhurst) first occurs under Henry I. It was governed by a bailiff until early in the 19th century. No charter of incorporation is known. In the reign of Henry VI. a market was held every Thursday, and a fair on Whit-Tuesday. Pleasure-fairs are still held on April 6 and Oct. 29, but there is no market. The church of St. Mary Magdalen and St. Denis is Perpendicular. A grammar-school was founded at Midhurst in 1672 and reopened in 1880.

MIDIAN. One of the peoples of North Arabia whom the Hebrews represented as sons of Abraham's wife Ketūrah. The Midianites appear in connection with the gold and incense trade from Yemen (Isa. lx. 6), and the trade between Egypt and Syria (Gen. xxxvii. 28, 36); also as warriors invading Canaan from the

eastern desert, and ravaging the land as similar tribes have done in all ages when Palestine lacked a strong government (*see* GIDEON). Again, they are described as peaceful shepherds, and the pastures of the branch of Midian to which Moses's father-in-law belonged, lay near Mount Horeb (Exod. iii. 1) (*see* KENITES, BALAAM, EDOM.)

MIDLAND, a city of Michigan, U.S.A., on the Titabawassee river, at the mouth of the Pine and the Chippewa, 25 m. N.W. of Saginaw; the county seat of Midland county. It is on federal highway 10, and is served by the Michigan Central and the Pere Marquette railways. The population was 5,483 in 1920 and 8,038 in 1930. It is in a farming, dairying and coal-mining region; has factories making automobile and aeroplane parts, machine tools, toys, guns, etc.; and salt-brine wells of chemical value.

MIDLAND, a manufacturing borough of Beaver county, Pennsylvania, U.S.A., on the Ohio river and the Pennsylvania railroad, 30 m. N.W. of Pittsburgh. Pop. (1920) 5,452 (42% foreign-born white); it was 6,007 in 1930.

MIDLAND BANK LIMITED. This British joint-stock company was in 1928 the world's largest commercial banking institution and had for chairman the Right Hon. Reginald McKenna, a former chancellor of the exchequer during the World War. It had 13,000 employees, with 2,000 branches in England and Wales and over 1,250,000 customers.

The bank was formed under a deed of settlement in 1836 and opened in Birmingham under the title of "The Birmingham and Midland Bank," with a paid-up capital of £28,000. A first dividend of 6% was paid in 1837, and thereafter the rate was raised from time to time until it reached a maximum of 23% in 1876. During this period the paid-up capital had been increased to £300,000 by capitalizing undivided profits and by issuing further shares.

In 1851 and 1862 the bank undertook its first two amalgamations, and in 1873 was registered as an unlimited company under the Companies Act of 1862. In 1880 it became a limited company with an issued capital of 24,000 shares of £60 each, of which £12½ was paid up, £12½ callable and £35 reserved. It then had only three branches, besides its head office in Birmingham, but thereafter the twin policies of amalgamation and branch extension came into full play. The inspiration for this policy came mainly from Mr. (later Sir) Edward H. Holden, who, joining the bank as accountant in 1881, occupied in succession various important positions until finally (1908–1919) he held the dual office of managing director and chairman of the board. To his foresight was due very largely the progress of the bank and its development as a British national institution.

A third absorption was effected in 1883, but from 1889 amalgamations followed rapidly. The policy pursued was distinctive, 30 of the 33 institutions taken over were joint-stock banks as opposed to private firms. Moreover, fusions were complete, with managerial control centralized in the head office of the absorbing bank. The most important of the earlier amalgamations was that with the Central Bank of London, in 1891, which gave the provincial institution a footing in the metropolis and a seat in the London Bankers' Clearing House, and resulted in the transfer of the head office to London. The name was changed to "The London and Midland Bank Limited," and in this year the bank, under the Companies (Memorandum of Association) Act, 1890, substituted a memorandum and articles of association for its old deed of settlement. The position was further reinforced by the absorption of The City Bank in 1898, when the title became "The London City and Midland Bank Limited." The largest amalgamation, that with The London Joint Stock Bank, in 1918, led to a further change to "London Joint City and Midland Bank Limited." The present name was adopted in 1923. Meanwhile, in 1917 the control of the Belfast Banking Company had been secured by an exchange of shares, and in 1920 and 1923 the Clydesdale Bank and the North of Scotland Bank were also acquired. The Midland owns the capital of these affiliated banks, which, however, have preserved their autonomy. In August 1928 the Midland group possessed 2,450 offices. None of these was outside the United Kingdom.

In 1905 the overseas business of the bank was concentrated in a special department, later known as the overseas branch. This branch has sub-offices in important industrial centres and in three Atlantic liners, and a shipping department. The Midland Bank Executor and Trustee Company Limited was formed in 1909. It has a paid-up capital of £200,000, all held by the bank, a reserve fund and undivided profits of £163,000, and branches in four large provincial centres. Various other departments were formed from year to year, and the progress of the bank is thus indicated:

Year	Paid-up capital	Reserve fund	Deposits	Cash	Advances	Net profits	No. of branches
	£ Millions						
1879	·3	·2	2·2	·5*	1·4	·06	4
1900	2·5	2·5	38·3	7·0	19·8	·6	317
1925	12·7	12·7	350·4	53·6	196·7	2·5	1,855
1926	12·7	12·7	368·2	53·0	200·5	2·5	1,904
1927	12·7	12·7	376·1	49·8	206·5	2·6	1,980

*Includes money at call and short notice.

The paid up capital was £13,320,000 in 1928, held by 65,000 individual shareholders. The new head office is in Poultry, London.
(L. C. M.)

MIDLETON, WILLIAM ST. JOHN FREMANTLE BRODRICK, 1ST EARL OF, cr. 1920 (1856–), Conservative statesman, the son of the 8th viscount, was educated at Eton and Balliol college, Oxford, and was president of the Oxford Union. He entered parliament in 1880. He was secretary of state for war (1900–03); and for India (1903–05). He lost his seat for the Guildford division in 1906. In March 1907 he was made an alderman of the London County Council. In that year his father died, and he entered the House of Lords. He was prominent as leader of the southern Unionists of Ireland, in virtue of his position as a landowner in County Cork. In the Irish Convention of 1917–18 this group separated themselves from Ulster, and expressed a readiness to concede a unitary Home Rule government for Ireland, subject to safeguards for the minority of loyalists.

MIDLETON, a town of co. Cork, Ireland, on the River Owenacurra, 13 m. E. of Cork. Pop. (1926) 2,731. The river enters a branch of Cork harbour. Trade is in agricultural produce and there are also whisky-distilleries. Ballinacurra, 1½ m. south, serves as a small port. The grammar school was founded here in 1696.

MIDLOTHIAN or **EDINBURGHSHIRE,** eastern county, Scotland, bounded north by the Firth of Forth, east by the shires of Haddington, or East Lothian, and Berwick, south-east by Roxburghshire, south by Selkirkshire, Peeblesshire and Lanarkshire, south-west by Lanarkshire, and west by Linlithgowshire or West Lothian. Its area (excluding water) is 234,325 acres. The island of Cramond belongs to the county. The Pentland Hills rise boldly in the south-west to heights of nearly 1,900 ft., and extend to within 5 m. of the sea. They are generally of rounded form, and covered with heath or grass. In them the Silurian strata characteristic of the south of the county, and of the southern uplands of Scotland generally, are covered unconformably by lower Old Red Sandstone rocks. The Carboniferous beds are thrown off to the north-west and south-east from the palaeozoic ridge. The Moorfoot Hills, in the south-east, belong to the Silurian area and are a continuation of the Lammermuirs, and attain in Blackhope Scar a height of 2,136 ft. A volcanic series extends from West Kip in the Pentlands to the Braid Hills and isolated heights, prominent in the scenery, are due to this intrusion of igneous rocks, mostly of the age of the calciferous sandstones, which cover a fairly wide area and in their upper portion include valuable oil shales. Of the rivers the Gala flows south to join the Tweed, and the Tyne after a course of 7 m. passes into Haddingtonshire. The others flow into the Firth of Forth. The Esk, which is the longest, drains the district between the Pentlands and the Moorfoot Hills, and reaches the sea at Musselburgh. The Water of Leith flows past Edinburgh to Leith. The Almond forms the boundary between Midlothian and Linlithgowshire. Several of these streams, especially the Esk and the Water of Leith, furnish water power. The only loch is that at Duddingston, but there are several large

reservoirs supplying Edinburgh. Cobbinshaw reservoir supplies the Union Canal connecting the Forth with the Clyde.

Agriculture.—High farming is the rule in the three Lothians. All the area on which wheat can be profitably grown is so occupied; oats, however, is the predominant grain crop, though barley is also raised. Turnips and potatoes are the chief roots. Near Edinburgh sewage farming has been largely developed. The produce consists principally of natural grasses. Sheep and cattle raising and horse breeding are important pursuits. In the neighbourhood of the capital dairy farming is conducted on an extensive scale. Pig-keeping has grown considerably and poultry-farming is carried on near Edinburgh. The nursery gardens are extensive, and there are many orchards.

Other Industries.—Coal is extensively mined on the North Esk. Some iron-stone is obtained and fire-clay occurs at various points. Paraffin is made near West Calder, where valuable oil-bearing shale is worked. Limestone is quarried at Mid Calder, Balerno, Loanhead, Craigmillar, Ratho, etc., and cement is made near Cranston. Freestone is quarried at Penicuik, near Edinburgh, and elsewhere. It is used for pavements and stairs, and for the great docks at Leith, and a number of smaller quarries for the supply of road-material are scattered throughout the county. Owing no doubt to the growth of printing and publishing in the metropolis, the chief manufacturing industry in Midlothian is paper-making. The most important mills, some of them dating from the beginning of the 18th century, are situated on the North Esk at Penicuik and Lasswade. At Balerno, Currie and elsewhere on the Water of Leith there are several mills, as well as near Mid Calder and in Edinburgh. There are carpet factories at Roslin, Bonnyrigg and Dalkeith. The manufacture of gunpowder is also carried on at Roslin and Calder. Iron foundries exist at Dalkeith and around Edinburgh. Dalkeith is famous for oatmeal. The shipping trade is concentrated at Leith and Granton, and there are fishing fleets at Fisherrow and Granton.

Population and Government.—The population was 507,666 in 1911 and 526,277 in 1931, of whom 3,269 spoke both Gaelic and English, and 19 Gaelic only. The chief towns, besides Edinburgh (pop. 1931, 438,998), are Bonnyrigg and Lasswade (4,483), Dalkeith (7,502), Loanhead (3,940), Musselburgh (16,996) and Penicuik (2,750). The county forms a single parliamentary constituency with Peebles, exclusive of Edinburgh county and Leith and Musselburgh burghs. It has been divided by the county council into three county districts (Calder, Gala Water, Lasswade). The shire is under school-board jurisdiction.

History and Antiquities.—Cramond was once a Roman seaport, and various Roman objects have been discovered in its vicinity and along the banks of the Almond. On several heights are remains of early military works—the most important being that on Dalmahoy Hill, Braidwood Castle in the parish of Penicuik, and Castle Greg on the Harburn estate in Mid Calder parish. Picts' houses are found at Crichton Mains, at Borthwick Castle, near Middleton House and elsewhere, the first being especially interesting from the fact that some of the stones bear marks of Roman masonry. There are hut-circles and a fort on Kaimes Hill, near Ratho; a large tumulus, with three upright stones, at Old Liston; a smaller tumulus at Newbattle; a cistvaen or stone burial chest at Carlowrie; and standing stones at Lochend, at Comiston (the Caiy stone), and the "Cat Stane" near Kirkliston. Temple, on the South Esk, was at one time the chief seat of the Knights Templars in Scotland for whom David I. here built a church, now in ruins. (*See* EDINBURGH.)

MIDNAPORE, a town and district of British India, in the Burdwan division of Bengal. The town has a station on the Bengal Nagpur railway. Pop. (1921) 28,965.

The DISTRICT OF MIDNAPORE has an area of 5,055 sq.m. and a population (1921) of 2,666,660. The greater part consists of a large open plain under cultivation but the country along the western boundary, known as the Jungle Mahals, is undulating and in the N.E. corner some hills rise to over 1,000 ft. in height. The eastern and south-eastern portions are swampy, richly cultivated, and thickly populated. The west, which has a lateritic soil partly covered by jungle, is sparsely inhabited. The chief rivers of the district are the Hoogli and its three tributaries, the Rupnarayan, the Haldi and the Rasulpur. The main line of the Bengal-Nagpur Railway passes through the district from east to west; from Kharagpur the East Coast section goes to Madras and the line to Gomoh branches off north to Chota Nagpur. Kharagpur contains the railway workshops and has a population (1921) of 25,280. There are three canals, the Midnapore canal, the Hijli tidal canal, and part of the Orissa coast canal. Drainage works have been constructed for a water-logged area in the south; there is also an extensive system of embankments. Silk, mats and brass and copper utensils are manufactured.

The early history of Midnapore centres round the ancient town of Tamluk (*q.v.*). In the 16th century it was eclipsed by Hijli which had Portuguese and Dutch settlements. In 1687 Job Charnock occupied Hijli and sustained a long siege by the Mughal forces. The British administration of the district dates from 1760, when Mir Kasim ceded it to the East India Company with Chittagong, and Burdwan when he became Nawab of Bengal.

MIDNIGHT SUN: *see* TWILIGHT.

MIDRASH, lit. "exposition" (*cf.* 2 Chron. xiii., 22: xxiv., 27) or intensive study (*derūsh*) of the spirit of a passage, frequently used of homily and parable in opposition to literal interpretation (*Peshaṭ*): term applied to certain methods of scriptural exegesis and to a class of Jewish writings illustrating these methods. The importance of Midrash to an understanding of Judaism is being recognized more generally. It is now realized that Judaism must be studied from its own sources and that apocrypha and apocalypse, though exceedingly valuable for the light they shed on dissenting sects or shades of quasi-orthodox opinion, do not reflect normal Judaism. These extra-canonical books were excluded just because they were abnormal. The last generation, which was occupied in their recovery and study, tended to overstate their application. To-day stress is laid on material which bears the warrant of unbroken tradition and which is therefore a more faithful mirror of the main body of Judaism.

This material may be divided into three groups:—(1) the rules of the traditional law or *Halakhah* which is systematized in the *Mishnah* (*see* GĀON; TALMUD); (2) the Midrash of the Schools, often called Halakhic (*see* HAGGADAH) or Tannaite (*i.e.*, Mishnaic) Midrash: this may be defined as the scholastic deduction of the traditional from the written law and consists of several works differing in character and style from (1) and from (3), the Haggadic (*see* HAGGADAH) or homiletical *Midrashim,* which are collections of short sermons, of an ethical rather than of a legal nature. The Haggadic Midrash was highly esteemed but it was not as authoritative as the Halakhic. This was natural from the essential difference between the two. *Halakhah* may be dull and legalistic but it is sober, whereas *Haggadah* is rarely dull, often highly imaginative and edifying, but it does not insist on sobriety. It includes many elements of extreme interest in folk-lore, archaeology and history. For example, I. Ziegler's *Königsgleichnisse des Midrasch* (Breslau, 1903) shows how vividly the Midrash illustrates the life and manners of Imperial Rome, especially in the provinces.

The *Halakhah* is deeply spiritual and is designed to stress the divine immanence, simple piety and the saintly life. The parables are mostly homely and the sayings terse, frequently in Aramaic, at one time the vernacular, and not in Hebrew, the language of the schoolmen. But there is also unrestrained fantasy, *e.g.*, stories of the Sindbad the Sailor type, which were not meant to be believed literally. Naturally great play with these has been made by opponents of the Jews, but the authority of the *Haggadah* has never been absolute. It stands in the same relation to theology as a mediaeval miracle-play to canon law or decretals. Thus, on July 20–24, 1263, at the great disputation at Barcelona between R. Moses b. Naḥman and the dominican Pablo Christiani, the former disarmed his opponent by repudiating the *Haggadah,* on which Pablo had based his case, and by declaring that the fables were merely points in sermons, expressing at most the individual opinions of the preacher and lacking the sanction of authority.

Nevertheless, the extent of the fantastic must not be exaggerated. In addition to strict truth and sheer fiction, *e.g.*, between

a genuine fact of archaeology or lexicography, recovered in a parable or exemplified in a saying, and an angelic digression of apocalyptic exuberance, there is an intermediate portion which must neither be categorically denied nor accepted absolutely. This element has been described as pragmatic historiography. There are three types of historical writing, the genetic or scientific, the purely narrative and the pragmatic. Religious historians write pragmatically, but this does not mean fraudulently. Their mental environment subconsciously influences them and they tend to prefer that record which appeals to their own age. They expect to find in the past elements mature only in their own day. But ancient historians must not be brushed aside because they fail to conform to modern standards. Their writings must be carefully tested. This is the way to treat the quasi-historical portions of Midrash. Here we find subjective history but earlier examples may be seen in the Bible, by examining Chronicles, which is a "Midrash" to Kings. Thus the life of Joash in 2 Chron. xxiii. differs in some details from that in 2 Ki. xi. and affords an illustration of the chronicler's methods. (On the Midrashic nature of *Chronicles, see* W. A. L. Elmslie's *Introduction* in *Camb. Bible, Chronicles,* 1916.) Probably the chronicler had access to sources now lost and in the account of Joash a Midrash is actually mentioned. But such Midrashic compilations can be traced even before his date (4th century B.C.).

Pragmatic historiography is exemplified in the various Deuteronomic writers. Similarly the relation between Genesis and the Book of Jubilees should be noted. The Apocrypha to some extent fills the gap between the Old Testament and the Rabbinic *Midrashim*, but, as has been stated, it must be used with care. Judiciously used, the Midrash and the Apocrypha may sometimes present a clue to a lost line of tradition: this tradition may or may not be valuable historically but its recovery is of interest, since it lay before the particular O.T. writer who discarded it or used it only incidentally. Thus Gen. xlviii., 22, contains a cryptic allusion to the capture of Shechem. In Jubilees xxxiv. (about 2nd century B.C.) a story of this war is detailed and similar accounts are preserved in various *Midrashim*. It is unlikely that these were mere elaborations of Gen. xlviii. 22: it may be inferred that an extracanonical tradition continued to survive the compilation of Genesis and ultimately assumed the exaggerated forms now extant. Again, Jewish traditions of Abraham in Ur of the Chaldees recur in the Targums, *Midrashim* and Jubilees (ch. xii., ed. Charles, p. 91; *cf.* also Judith, v., 16 *sqq.*). The legends of his escape from a fiery furnace may have a philological basis, for *'ur* can be interpreted as fire, but the allusion to the redemption of Abraham in Isa. xxix., 22, seems to indicate that older tradition was fuller than the present records in Genesis.

Midrashic exposition was based on the theory of progressive interpretation. Every word of the scriptures had a definite meaning, nay, no single letter was otiose; moreover every word had "70 aspects." This means that generation after generation would extract new lessons, all of which were deemed latent or implicit. Some of these interpretations were arbitrary but more often the arbitrariness lay not in the teaching but in the deduction. When it was desired to point a moral or elicit a law not always the best exemplar was adopted. Thus faulty proof rather than faulty inference is illustrated when the rare word *Be-mikhṣath,* "in-number" (Exod. xii. 4), was used to confirm the *Halakhah* that the man who killed the paschal lamb must know how many people were about to share it. (*Jew. Enc.* VIII., 570.) Many cases of apt deduction can be adduced and deductions, similarly apt or far-fetched, occur also in the N.T. Thus emphasis on a single word is illustrated by Gal. iii. 16, where the argument rests on the word "seed" (and not the plural "seeds") in the proof-text and the same word in Rabbinical writings is used to support other arguments (*cf.* Mishnah, *Ṣanhedrin,* iv., 5: *see* A. Geiger, *Z.D.M.G.* 1858, pp. 307 *sqq.:* S. R. Driver, *Expositor,* IX. [1889], pp. 18 *sqq.*). By the allegorical method Isa. lxi. is applied to Jesus (Luke iv. 16–22).

The more important *Midrashim* are:—

A. Halakhic or Tannaite *Midrashim:*

(1) *Mekhilta,* on Exodus. This begins at xii., the first legislation (the ordinance of the Passover). The later portions of Exodus are not commented on (as they are historical) in the present work, but there is reason to believe that the original was fuller. This famous Midrash was of the school of R. Ishmael, but it was concluded in the school of the patriarch Judah in the 2nd century A.D. (Text, M. Friedmann, Vienna 1870: I. H. Weiss, Vienna, 1865. German trans., J. Winter and A. Wünsche, Leipzig, 1909.)

(2) Another recension of the *Mekhilta,* cited by mediaeval authors, was that of Simeon ben Yoḥai—ed. D. Hoffmann (1905).

(3) *Midrash hag-Gadol,* a composite work on the Pentateuch, compiled in the 13th century, recently discovered in Arabia, contains much lost material. The Midrash is edited in part. (S. Schechter, Camb. 1902: D. Hoffmann, Berlin, 1913.)

(4) *Ṣifra (de-Be Rab),* on Leviticus, which it follows almost verse by verse. Probably redacted by R. Ḥiyya in the beginning of the 3rd century A.D. (Text, M. L. Malbim, Bucharest, 1860: I. H. Weiss, Vienna, 1862. Latin trans. [faulty in parts] in Ugolinus [Thesaurus] xiv.)

(5) *Ṣifre,* on Numbers and Deuteronomy (2nd and 3rd centuries). (Text, M. Friedmann, Vienna, 1864: H. S. Horovitz, Part I., Leipzig, 1917. Germ. trans. [on Deut.] G. Kittel, Stuttgart, 1922.)

B. Haggadic *Midrashim:*

(1) *Midrash Rabba,* on the Pentateuch and Five Rolls. Ed.-princeps, Constantinople, 1512: frequently reprinted, Crit. ed. of Genesis Rabba by J. Theodor (unfinished), (Berlin, 1903– . Germ. trans., A. Wünsche, *Bibliotheca Rabbinica,* Leipzig, 1880–).

(2) *Tanḥuma* (2 recensions) on the Pentateuch, one of the oldest *Midrashim:* mentioned once in the Talmud. (Text, ed. S. Buber, Wilna, 1885: the other recension, Constantinople, 1520–22.)

(3) *Pesiqta (de Rab Kahana),* 33 homilies on the festivals (lectionary, etc.). (Text, ed. S. Buber, Lyck, 1868. Germ. trans. A. Wünsche, Leipzig, 1885.)

(4) *Pesiqta Rabbathi,* a similar but separate collection of 51 homilies of which 28 have a Halakhic exordium. (Text, ed. M. Friedmann, Vienna, 1880.)

(5) Midrash *Shoḥar Ṭōbh* on Psalms, text, Warsaw, 1875.

(6) *Yalquṭ* or "Wallet," title of several midrashic collections.

BIBLIOGRAPHY.—Articles (main and subsidiary) in *Jew. Enc.,* Hastings, *D.N.B.* and *E.R.E.,* G. M. Moore, *Judaism,* I. 125 foll. Cambridge (Harvard), 1927.

MIDSHIPMAN is the title given to the officer ranking below the lowest commissioned officer, which in the British Navy is a sub-lieutenant. A midshipman in the British Navy is senior only to a naval cadet.

Originally a midshipman was a petty officer, but after the Restoration, in 1660, Charles II. with his brother James, Duke of York as Lord High Admiral, decided to train officers for the sea service from an early age. Young lads were sent as volunteers with a "letter of service" instructing the admirals and captains of the warships to which they were drafted that the bearer was to be shown "such kindness as you shall judge fit for a gentleman, both in accommodating him in your ship and in furthering his improvement." Until 1720 these young gentlemen were known as "king's letter boys." Originally, the future officers entered the service at a very youthful age, but at a later stage no boy could be borne on a ship's books until he was 13, except in the case of an officer's son, who might be entered at 11.

First class volunteers were permitted to wear naval uniform. They were generally styled "youngsters" and came directly under the care of the gunner, who was supposed to superintend their mess and general welfare. Their nautical studies were attended to by a school master, or in his absence the captain was expected to take a personal interest in them. At the age of 15, when promoted to midshipmen, they became known as "oldsters" and formed a mess among themselves with the mates. After serving two years they became eligible for promotion to master's mate.

The practice of sending boys to sea at such a very early age proved unsatisfactory, and a Naval Academy was founded at

Portsmouth in 1729, in which forty lads were trained for sea service. In 1773 the school was reorganized and the number increased from forty to seventy. In 1806 it was again reorganized and became known as the Naval College. The number of midshipmen borne in a man of war in 1815 was in proportion to the size of the ship. Thus a first rate was allowed 24, a second rate 15 and a third rate 12 and so on in proportion.

In 1837 the practice of sending boys direct to sea under instructors in the ships superseded the school, but in 1857 the system of preliminary training was reverted to and remains the basis of the supply of officers to the executive branch of the navy to this day. It was in this year that the training ship "Britannia" was established. As the numbers became too great for the one ship, in 1864 a second ship, the "Hindustan" was linked up. It shares the name of the parent ship.

In 1902, under the aegis of Admiral Sir John Fisher, entry into the navy was completely reorganized, the preliminary training being modernized, while the period was extended from two years to about four. The first half of the course was spent at the Royal Naval College at Osborne, Isle of Wight, and the remainder at the newly-built Royal Naval College, Dartmouth. In 1921 Osborne College was abolished and the preliminary training for the greater part of the executive branch of the navy is now carried out at Dartmouth College alone.

Cadets now (1928) join the College, after a competitive examination, at about 13½ years of age. They do 3⅔ years there, after which they are appointed to sea-going ships. When they have served eight months afloat they are rated midshipmen. Special entry cadets, limited in number, enter the service by competitive examination about the age of 17. They do twelve months in a training ship before being rated midshipmen.

As a midshipman an officer serves two years and four months before he is qualified to pass the first of a series of five examinations for eventual promotion to lieutenant. The initial examination is one to test his ability as a seaman. If he proves this to the satisfaction of a board of captains and commanders, he is given the acting rank of sub-lieutenant. He is confirmed in this rank when he has also passed examinations in general education, gunnery, torpedo, navigation and pilotage. Although a midshipman is regarded as being to a large extent under instruction, he is given very definite, if not unduly weighty, responsibilities as an officer, including such duties as complete charge of one of the ship's boats, sometimes one of the smaller guns, a fire control or ammunition supply party, while in the administrative work of the ship he is the principal assistant to lieutenants of divisions and officers of quarters.

Midshipmen selected for the engineering branch of the Navy go to the Royal Engineering College, Keyham, Devonport, where, after duly qualifying, they are promoted to sub-lieutenant.

Paymaster midshipman is the present day title of the subordinate officer who used to be called a clerk R.N. He enters as a paymaster cadet and is promoted after twelve months service afloat.

See Falconer, *Marine Dictionary; King's Regulations and Admiralty Instructions* (H.M. Stationery Office); *Appendix to the Navy List* (H.M. Stationery Office). (E. A.)

THE UNITED STATES

In the U.S. Navy midshipman is the title given to the student undergoing the course at the U.S. Naval Academy (*q.v.*), preparatory to entering the lowest commissioned ranks. As such he is an officer in a qualified sense. He is appointed a midshipman in the Navy, not merely at the Naval Academy, is subject to the orders and regulations of the Navy Department, but does not participate in the benefits of retirement or longevity. He may be ordered to sea duty, although this is not customary except on practice cruises. He ranks after a commissioned warrant officer, and ahead of a warrant officer.

When the naval forces were first established, midshipmen were seagoing officers in training for commissions, with rank and duties similar to those of the British Navy of that time. In the Revolutionary War midshipmen were appointed by the commanders of vessels, but practically all were discharged at the end of the war. In the great expansion after the authorization of a new national navy in 1794, the president was empowered to appoint as many midshipmen as desired. They were appointed from civil life without special regard to education or aptitude, but in the ensuing naval wars with France and the Barbary States, and the War of 1812, theirs was a record of great activity and gallantry. Age at entry was generally 14 to 20, but this varied. Stephen Decatur was warranted a midshipman at 20, and commissioned a lieutenant at 21. David G. Farragut entered at 9, and became a lieutenant at 24. In 1827 the grade of passed midshipman was established. At the age of 20, and having served three years at sea, a midshipman was eligible for promotion to passed midshipman. The time of promotion to lieutenant varied, depending on the vacancies.

In the Navy regulations of 1802, commanding officers were enjoined to consider the midshipmen as "meriting in a special degree the fostering care of their Government," and to see that the schoolmasters (at that date the chaplains) were diligent in instructing them. Later, schoolmasters were added to the ships. However, the system of giving instruction on board ship did not prove satisfactory. This led to proposals from many sources often from the service itself, for a naval school similar to the Military Academy established in 1802. Nearly every secretary of the navy from 1814 to 1845 recommended it. In the meantime the midshipmen received such instruction as the system permitted, at sea, and at the navy yards at Boston, New York, Norfolk and Philadelphia, where professors of mathematics and languages were stationed.

With sail as the motive power, and the old smooth-bore ordnance, "the young gentlemen of the watch" could master the elements of their profession at sea, even if they did not acquire a liberal education. But the advent of steam and the swift advances in the arts and sciences soon made more efficient instruction imperative. Congressional action continually failed, but in 1845 secretary of the navy George Bancroft set up a naval school on the site of Ft. Severn, Annapolis, Md., by concentrating there all the equipment and instructors available, and ordering the attendance of all midshipmen undergoing instruction at the navy yards. Acting midshipmen, aged 13 to 16, attended one year; they were then warranted midshipmen and served at sea for three years; then returned for another year's study, final examinations and promotion to passed midshipmen. In 1850-51 the Naval school was reorganized as the U.S. Naval Academy.

For many years the Navy Department had been free to appoint as many midshipmen as it pleased. In 1845, Congress provided that midshipmen should be appointed from each State or Territory in proportion to the number of representatives and delegates. This principle has been adhered to.

The students at the Naval Academy have been called, in turn, acting midshipmen, midshipmen, cadet midshipmen and cadet engineers, naval cadets, and again, midshipmen. From 1873 to 1912 the academic course was six years, the last two of which were spent at sea. In 1912 the course was reduced to four years, the midshipmen, upon graduation, being commissioned as ensigns in the line or staff corps of the Navy, or as second lieutenants in the Marine Corps.

MIDSOMER NORTON, an urban district in Somersetshire, England, 12½ m. S.S.W. of Bath on the G.W. railway. Pop. (1931) 7,490. The town is situated between two branches of the river Somer. The church of St. John the Baptist, mainly Perpendicular, has in its tower three bells presented by Charles II. Both this town and the adjacent urban district of RADSTOCK (pop. 3,661) have a considerable trade in coal, which is mined in the vicinity. The coalfield extends north-westward towards Bristol. The industries include manufacturing of textiles and leather goods.

MIDWIFERY: *see* OBSTETRICS.

MIDWIFE-TOAD: *see* ALYTES.

MIERES, a town of northern Spain, in the province of Oviedo, 12 m. by rail S.E. of Oviedo, on the river Caudal, a tributary of the Nalon. Pop. (1920), 40,560. Mieres is the chief town of a mountainous, fertile and well-wooded region in which coal, iron and copper are extensively mined and sulphur and cinnabar are obtained in smaller quantities. The town contains large iron foundries and chemical works, and has an active trade in fruit, cider, timber and live stock.

MIEREVELT (MIEREVELD or **MIREVELDT), MICHIEL JANSZ VAN** (1567–1641), Dutch painter, was born at Delft on May 1, 1567, the son of a goldsmith, who apprenticed him to the copperplate engraver J. Wierix. He subsequently became a pupil of Willem Willemz and Augustyn of Delft, until Antonio van Montfort (Blockland), who had seen and admired two of Mierevelt's early engravings, "Christ and the Samaritan" and "Judith and Holofernes," invited him to enter his school at Utrecht. He remained at Utrecht till the death of Montfort (1583), and then settled at Delft. Devoting himself first to still life, he eventually took up portraiture, and the many commissions entrusted to him necessitated the employment of numerous assistants, by whom hundreds of portraits were turned out in factory fashion. The works which are certainly his are remarkable for sincerity, severe drawing and harmonious colour, but comparatively few of the two thousand or more portraits that bear his name are wholly his handiwork. He went frequently to The Hague, where he entered the guild of St. Luke in 1625. Though Mierevelt is chiefly known as a portrait painter, he also executed some mythological pieces. Many of his portraits were reproduced by Dutch engravers. He died at Delft on June 27, 1641.

The Ryks Museum in Amsterdam has the richest collection of Mierevelt's works, chief of them being the portraits of William, Philip William, Maurice and Frederick Henry of Orange, and of the count palatine Frederick V. At The Hague Museum are the portraits of four princes of the house of Orange, of Frederick V., king of Bohemia, and of Louise de Coligny as a widow. Other portraits by him are at nearly all the leading continental galleries, notably at Brunswick (2), Schwerin (1), Munich (2), Paris (Louvre, 4), Dresden (4), Berlin (2), Hanover (2), London Portrait gallery (7). The town hall of Delft has numerous examples.

MIERIS, FRANZ VAN, called the elder (1635–1681), son of Jan van Mieris, and chief member of a family of Leyden painters, was born, according to Houbraken, at Leyden on April 16, 1635, and died there on March 12, 1681.

Franz took service with Abraham Torenvliet, a glazier who kept a school of design. In his father's jewellery shop he became familiar with the ways and dress of people of distinction. His eye was fascinated in turn by the sheen of jewellery and stained glass; and, though he soon gave up the teaching of Torenvliet for that of Gerard Dou and Abraham van den Tempel, he acquired a manner which had more of the finish of the exquisites of the Dutch school than of the breadth of the disciples of Rembrandt. He seldom chose panels of which the size exceeded 12 to 15 in. Mieris never ventured to design figures as large as life. Characteristic of his art in its minute proportions is a shiny brightness and metallic polish. The subjects which he treated best are those in which he illustrated the habits or actions of the wealthier classes; but he sometimes succeeded in homely incidents and in portrait, and he sometimes ventured on allegory. He often rivalled Ter Borch in the faithful rendering of rich and highly-coloured woven tissues. In the form of his composition, which sometimes represents the framework of a window enlivened with greenery, and adorned with bas-reliefs with figures to the waist, his model is Gerard Dou.

One of his best-known pieces, a party of ladies and gentlemen at an oyster luncheon, in the Hermitage at Leningrad, bears the date of 1659. Another beautiful example, the "Doctor Feeling a Lady's Pulse" in the gallery of Vienna, is dated 1656. In the same gallery is one of his masterpieces "the Cavalier and the Lacemaker," dated 1660. In 1657 Mieris was married at Leyden. On May 14, 1658 he was elected a member of the Guild at Leyden. Of the numerous panels by Mieris, twenty-nine at least are dated —the latest being an allegory, long in the Ruhl collection at Cologne, showing drinking, smoking and dicing, in the year 1680.

Mieris received valuable commissions from Archduke Leopold, the elector-palatine, and Cosimo III., grand-duke of Tuscany. His practice was large and lucrative. If there be a difference between the painter's earlier and later work, it is that the former was clearer and more delicate in flesh, whilst the latter was often darker and more livid in the shadows.

MIFFLIN, THOMAS (1744–1800), American soldier and politician, was born in Philadelphia (Pa.), on Jan. 10, 1744. Mifflin was a member of the Pennsylvania house of representatives in 1772–75, and was sent as a delegate to the first Continental Congress. He entered the continental service in June 1775, was appointed quartermaster-general in August, became a brigadier-general in May 1776, and major-general in Feb. 1777. In the autumn of 1777 Mifflin was a leader of the Conway Cabal which attempted to replace Washington by Horatio Gates. The faction gained sufficient power to secure the appointment of Gates as head and of Mifflin as a member of the board of war. In March 1778, Nathanael Greene superseded Mifflin as quartermaster-general; in October he was removed from the board of war; and in Feb. 1779, he resigned as major-general. Mifflin was a delegate in Congress in 1783 and in November of the same year was made president of that body. He was speaker of the Pennsylvania general assembly (1785–88), president of the State supreme executive council (1788–90) and the first governor of the State (1790–99). He died at Lancaster on Jan. 20, 1800.

See William Rawle, "Sketch of the Life of Thomas Mifflin," in *Memoirs of the Historical Society of Pennsylvania* (vol. ii. part 2, Philadelphia, 1830); and J. H. Merrill, *Memoranda Relating to the Mifflin Family* (Philadelphia, 1890).

MIGNARD, PIERRE (1610–1695), called—to distinguish him from his brother Nicholas—Le Romain, French painter, was born at Troyes in 1610, and came of a family of artists. In 1630 he left the studio of Simon Vouet for Italy, where he spent twenty-two years, and made a reputation which brought him a summons to Paris. Successful with his portrait of the king, and in favour with the court, Mignard pitted himself against Le Brun, declining to enter the Academy of which he was the head, and organizing the opposition to its authority. The history of this struggle is bound up with that between the old gilds of France and the new body which Colbert, for political reasons, was determined to support. Shut out, in spite of the deserved success of his decorations of the cupola of Val de Grace (1664), from any great share in those public works the control of which was the attribute of the new Academy, Mignard was chiefly active in portraiture. Turenne, Molière, Bossuet, Maintenon (Louvre), La Vallière, Sévigné, Montespan, Descartes (Castle Howard), all the beauties and celebrities of his day, sat to him. His readiness and skill, his happy instinct for grace of arrangement, atoned for want of originality and real power. With the death of Le Brun (1690) the situation changed; Mignard deserted his allies, and succeeded to all the posts held by his opponent. These late honours he did not long enjoy; in 1695 he died whilst about to commence work on the cupola of the Invalides. His best compositions were engraved by Audran, Edelinck, Masson, Poilly, etc.

MIGNE, JACQUES PAUL (1800–1875), French priest and publisher, was born at St. Flour, Cantal, on Oct. 25, 1800. He studied theology at Orleans, was ordained priest in 1824 and placed in charge of the parish of Puiseaux, in the diocese of Orleans. In 1833 he went to Paris, and started *L'Univers religieux.* Three years later, he opened at Petit Montrouge, near Paris, the great publishing house which brought out in rapid succession numerous religious works at popular prices. The best known of these are: *Scripturae sacrae cursus completus,* and *Theologiae cursus* (each in 28 vols., 1840–1845); *Collection des auteurs sacrés* (100 vols., 1846–1848); *Encyclopédie théologique* (171 vols., 1844–1866); *Patrologiae cursus completus,* Latin series in 221 vols. (1844–1855, 2nd edition, 1878 *seq.*); Greek series, first published in Latin (85 vols., 1856–1861); with Greek text and Latin translation (165 vols., 1857–1866). Unfortunately these editions do not come up to the requirements of modern criticism. By far the most noteworthy is the Patrology, which was superin-

tended by the learned Benedictine J. B. Pitra. Its vast scope leaves it still unique and valuable, where other editions of special works do not exist. The indices in 3 vols. are arranged so that one may easily find any reference in the patristic writings. In February 1868 a great fire destroyed the whole of Migne's printing premises, but he established a new house in Paris, which was purchased in 1876 by the publishers Garnier Frères. He died in Paris on Oct. 25, 1875.

For a more complete account of Migne's life, *see* the article in the *Catholic Encyclopaedia* (New York, 1906 *seq.*).

MIGNET, FRANÇOIS AUGUSTE ALEXIS (1796–1884), French historian, was born at Aix-en-Provence on May 8, 1796, and died in Paris on March 24, 1884. His father, a Vendean by birth, was a locksmith. François studied at Avignon in the *lycée* where he was afterwards professor (1815); he returned to Aix to study law, and in 1818 was called to the bar. His memoir on *Les Institutions de Saint Louis* was crowned in 1821 by the Académie des Inscriptions et Belles Lettres. He then went to Paris, where he was soon joined by his friend and compatriot, Adolphe Thiers, the future president of the French republic. He became a member of the staff of the *Courrier Français* which carried on a fierce warfare against the Restoration. In 1830 he founded the *National* with Thiers and Armand Carrel. He then became director of the archives at the Foreign Office, where he stayed till the revolution of 1848, when he was dismissed. He had been elected a member of the Académie des Sciences Morales et Politiques, re-established in 1832, and in 1837 was made the permanent secretary; he was also elected a member of the Académie Française in 1836. With the exception of his *Histoire de la Révolution française* (1824), a political manifesto, all his early works refer to the middle ages. For a long time he was occupied with a history of the Reformation, but only one part of it, dealing with the Reformation at Geneva, has been published. His *Histoire de Marie Stuart* (2 vols., 1851) is well worth reading; the author made liberal use of some important unpublished documents, taken for the greater part from the archives of Simancas. He devoted some volumes to a history of Spain, which had a well-deserved success—*Charles Quint, son abdication, son séjour, et sa mort au monastère de Yuste* (1845); *Antonio Perez et Philippe II.* (1845); and *Histoire de la rivalité de François I. et de Charles Quint* (1875). At the same time he had been commissioned to publish the diplomatic acts relating to the War of the Spanish Succession for the *Collection des documents inédits;* only four volumes of these *Négociations* were published (1835–42), and they do not go further than the peace of Nijmwegen; but the introduction is celebrated, and Mignet reprinted it in his *Mélanges historiques.*

See the eulogy of Mignet by Victor Duruy, delivered on entering the Académie Française on June 18, 1885, and the notice by Jules Simon, read before the Académie des Sciences Morales et Politiques on Nov. 7, 1885.

MIGNON, ABRAHAM (1640–1697), Dutch painter, was born at Frankfort. His father, a merchant, placed him under the still-life painter Jacob Merrel, by whom he was taken to Holland about 1660. He then worked under de Heem at Utrecht, where in 1675 he married the daughter of the painter Cornelis Willaerts. Sibylle Merian (1647–1717), daughter of the engraver Matthew Merian, became his pupil and achieved distinction as a flower painter. He died at Wetzlar. Mignon devoted himself almost exclusively to flowers, fruit, birds and other "still life," though at times he also attempted portraiture. His flower pieces are marked by careful finish and delicate handling. His favourite scheme was to introduce roses against a dark background. Fifteen paintings (twelve signed) are at Dresden; six at the Louvre, four at the Hermitage, and others at the museums of Amsterdam, The Hague, Rotterdam, Brussels, Munich, Karlsruhe, Brunswick, Cassel, Schwerin, Copenhagen and Turin.

MIGNONETTE or **MIGNONNETTE** (*i.e.,* "little darling"), the name given to a popular garden flower, *Reseda odorata* (family Resedaceae), highly esteemed for its delicate but delicious perfume. The mignonette is generally regarded as an annual and is a plant of diffuse decumbent twiggy habit, scarcely reaching a foot in height, clothed with bluntish lanceolate entire or three-lobed leaves, and bearing longish spikes—technically racemes—of rather insignificant flowers at the ends of the numerous branches and branchlets. The plant thus naturally assumes the form of a low dense mass of soft green foliage studded over freely with the racemes of flowers, the latter unobtrusive and likely to be overlooked until their diffused fragrance compels attention. It is probably a native of north Africa and was sent to England from Paris in 1742; and 10 years later it appears to have been sent from Leiden to Philip Miller at Chelsea. The small six-petalled flowers are somewhat curious in structure: the two upper petals are larger, concave, and furnished at the back with a tuft of club-shaped filaments, which gives them the appearance of being deeply incised, while the two lowest petals are much smaller and undivided; the most conspicuous part consists of the anthers, which are numerous and of a brownish red, giving the tone of colour to the inflorescence. In the varieties named Golden Queen and Golden Machet the anthers have a decided tint of orange-yellow, which imparts a brighter golden hue to the plants when in blossom. A handsome proliferous or double-flowered variety has also been obtained, which is a very useful decorative plant, though only to be propagated by cuttings; the double white flowers grow in large massive panicles (proliferous racemes), and are equally fragrant with those of the ordinary forms.

Though practically an annual in Great Britain, as already noted, since it flowers abundantly the first season, and is destroyed by the autumnal frosts, and though recorded as being annual in its native habitat by Desfontaines in the *Flora Atlantica,* the mignonette, like many other plants treated in England as annuals, will continue to grow on if kept in a suitable temperature. Moreover, the life of this and certain other plants of this semi-annual character may be prolonged into a second season if their flowering and seeding are prevented. The young plants are grown under glass, and their flowering prevented by nipping off the blooming tips of the shoots, so that they continue their vegetative growth into the second season.

In classifying the odours given off by plants Rimmel ranks the mignonette in the class of which he makes the violet the type; and Fée adopts the same view, referring it to his class of "iosmoids."

The genus *Reseda* contains about 55 species, natives of Europe and west Asia. *R. luteola,* commonly called dyer's-weed or weld, yields a valuable yellow dye. *R. alba* is a fine biennial about 2 ft. high, with erect spikes of whitish flowers.

MIGNONS, LES. In a general sense the French word *mignon* means "favourite," but the people of Paris used it in a special sense to designate the favourites of Henry III. of France, frivolous and fashionable young men, to whom public malignity attributed dissolute morals. The best known of the *mignons* were the dukes of Joyeuse and of Epernon.

MIGRAINE. *Hemicrania, migraine, megrim, brow-ague* and *sick headache* are various terms employed to describe what by some is considered to be a form of neuralgia, and by others as a paroxysmal neurosis or nerve storm. An attack may come on suddenly, but, in general, begins by a dull aching pain in the brow or temple, which steadily increases in severity and extent, but remains usually limited to one side of the head. It attains at times an extreme degree of violence, and is aggravated by movement, loud noises or bright light. There is more or less nausea, and when the attack reaches its height vomiting may occur, after which relief comes, especially if sleep supervene. An attack of this kind may last for a few hours or for a whole day, and after it is over the patient feels comparatively well. It may recur periodically, or, as is more common, at irregular intervals. During the paroxysms, or even preceding them, sensory disturbances may be experienced, especially affections of vision, such as ocular spectra, hemiopia, diplopia, etc. Gout, eyestrain and intestinal toxaemia have been put forward as causes of migraine.

MIGRATION. Migrations, or the shiftings of peoples, have been universal on the earth in space and time, but there have also been migrations or transmissions of cultural objects and ideas which frequently have little relation with the former and these may be termed cultural drifts.

Most primary migrations of mankind may be traced to need

of food. The practice of tilling the soil, in order to obtain a more or less reliable supply of food, by its nature tends to anchor a people to the land, and all permanence of work with a reliable food supply forms an essential condition for continuous residence in one spot; when these fluctuate, unrest arises and individuals or communities are set in motion.

For the greater part of the very long time that man has been in existence he has been merely a collector of food or a hunter. Where game was plentiful or wild vegetable food abundant he could live in moderate sized communities, but normally any country would be very sparsely inhabited, therefore there would be a necessity for migration when the population grew too numerous for the food supply. Usually the game migrate seasonally to seek fresh feeding-grounds, or for other reasons, but this movement may be merely a backward and forward shifting within a particular range and naturally the hunters would accompany them; during the winter months the Eskimos live on the sea coast so as to be able to catch seals on which they mainly depend for food, but in the summer they shift to inland areas, where they can hunt reindeer, or, in the more northerly regions, the musk ox, and also they can then procure more varied diet. Collectors of vegetable food within their various countries have similarly to move where a particular root, seed or fruit crop is ripe. Movements of these kinds though dictated by necessity are to some extent voluntary.

Movements are compulsory when changes of climate or of geographical conditions cause a complete shifting of the flora and fauna, as, for example, during the major and minor fluctuations of temperature in the glacial periods of northern latitudes, northerly or southerly shiftings of the rain belts further south, desiccation, elevation or depression of land, changes in the coast line, and so forth. Man was forced to move as his food decreased or the climate became too rigorous, and the directions in which he moved were similarly conditioned, but in addition were determined to a large extent by open land or by barriers of various kinds. Human movements resulting from these causes may well have been slow, and archaeological evidence shows that even in very early times they extended over the greater part of the earth's surface. A warning may here be given that a similarity in stone implements, for example, does not necessarily imply a strict synchronism for these artifacts in Europe, South Africa, India or Australia. The fluctuating character of many of these phenomena acted frequently as a force-pump or as a suction-pump, at one time expelling a people from a given area at another attracting them towards it. It is obvious that in very early times we can have no historical record of such happenings, but archaeology gives sufficient indications that they occurred.

As examples of historical events of this nature the following may be cited, though what occurred in earlier times can only be inferred, but it is not unreasonable to suppose that they were analogous.

It is obvious that during the advent of a glacial period the increasing fields of snow and ice would drive the people who then lived in north-west Europe (and we have evidence that there were men in England in preglacial times) further south where livelihood was possible, and similarly there would be a southerly shifting of peoples who were accustomed to a genial climate. The formation of a northern ice-cap would result in a southerly shifting of the temperate rain- and storm-belts in proportion to the advance of the ice. Thus the wide belt of northern Africa which is now the desert of Sahara would then be a well-watered, habitable country of grass-land and savanna. The same applies to the arid areas of western Asia. There was, therefore, a continuous stretch of pleasant lands from Central Asia, through Persia, Arabia and north Africa to the Atlantic. When the ice retreated the storm-belt shifted further north and these areas once more became dry and thirsty lands. A recurrent phenomenon of this kind must have occurred with each major glaciation. If we assume that a people long habituated to live on the fringe of the ice-cap and to hunt reindeer and other arctic animals would prefer to continue its mode of existence then it would follow the retreating ice, and it seems as if this had been the case for the Eskimo. Magdalenian man in western Europe lived under arctic conditions and certainly the characters of the Chancelade skull of western France are very similar to those of the Eskimo of arctic North America, but it does not follow that the Eskimo ever lived in Europe. The savanna belt of north Africa and western Asia, just referred to, would afford an easy migration corridor between Asia and Africa, and when that area became uncomfortably dry a movement of population could take place to the north or south. If the people then living there were originally inhabitants of a temperate region they would be more likely to drift northwards than southwards. *(See* CLIMATE, HISTORY OF.)

According to Pettersson a period of maxima of tide-generating force attained its latest phase in A.D. 1434 and has a periodicity of about 1,800 years. In the 14th century the devastating storm-floods of the North sea and the Baltic coasts resulted in cold periods and inundations in the northern countries with their consequences, famine and migrations of the population. About 1,800 years earlier similar storm-floods impoverished the people of the late Bronze age of Scandinavia, and land-elevation and deterioration of climate occurred throughout the north Atlantic. About 700 B.C. the amber trade route shifted from the Elbe and Weser to the Vistula, which indicates that the supply of amber was thenceforth chiefly derived from the Baltic instead of from the North sea, which was then in a tempestuous condition. There are statements in literature which connect the invasion of the Teutons and Cimbri into Gallia and later into Italy with a big inundation of the sea which destroyed their homesteads in Jutland. These catastrophes probably began as early as the 6th century B.C. There were also traditions amongst the Druids that their ancestors had been expelled from the islands on the other side of the Rhine by hostile tribes and by a great invasion of the ocean. Pettersson regards this as the primary cause of the great migrations in the first millennium B.C. which began with the decline of the Bronze-age civilization through catastrophes in nature which forced the inhabitants of the North sea countries to emigrate, and he finds that a maximum of oceanic disturbances must have occurred about the 3rd and 4th century B.C., as also happened about A.D. 1300–1400. He adds, "Apparently a warm, iceless period, which favoured agriculture and shipping and allowed the Scandinavian races to expand in the powerful manner which characterizes the Viking age, must have occurred between the interval of the two maxima of 400 B.C. and A.D. 1400. This prosperous epoch then corresponds to the former post-glacial heat-period or the Kjökken-mödding—and the earliest stage of the Bronze age. The remembrance of the bygone civilization 2,000 years earlier lived in the myths of the German race and found its expression in the *Edda.* According to Victor Rydberg the myths of the *Edda* centre in a great catastrophe in nature, the Fimbul-winter, or "Götterdämmerung," when frost and snow ruled the world for generations. (O. Pettersson, *Ur Svenska Hydrografisk-Biol. Kom. Skrifter,* V., and *cf.* C. E. P. Brooks, *The Evolution of Climate,* p. 147, 1922; *Climate through the Ages* [1926]; *cf.* G. C. Simpson, *Q.J.R. Meteorol. Soc.* liii., p. 213, 1927.)

O. Pettersson (*Ur Svenska Hydrografisk-Biol. Kom. Skrifter,* V.) states that in the 10th and 11th centuries a strong emigration took place from Norway to Iceland and Greenland, one Viking fleet taking 750 to 1,000 persons to Greenland; at this time the climate of Iceland and Greenland was comparatively mild, as there was no ice-blockage of the north coast of Iceland or round southern Greenland. At the end of the 13th century the first signs of an ice blockade appeared and at the close of the 14th century there was a great accumulation of drift ice off the east coast of Greenland. At the close of the 13th and beginning of the 14th century there began an invasion of Eskimo from the north which eventually wiped out the colonies of Norsemen. This invasion must not be regarded as a common raid, it was the migration of a people, and like other big movements of this kind was impelled by altered conditions of nature, in this case the alterations of climate caused by the advance of the ice. The Eskimo then lived further north in Greenland and North America,

but when the climate deteriorated and the sea which gave them their living was closed by ice the Eskimo had to find a more suitable neighbourhood. It should, however, be noted that F. Nansen (*In Northern Mists*, p. ii., 95, 1911) strongly combats the view that the Eskimo gradually overpowered and exterminated the Norsemen. The settlements were almost entirely cut off from Norway, imports of corn and flour finally ceased, stock could not be renewed, and unaccustomed dietary conditions, disease and probable decreased birth-rate in his view sufficiently account for the decline of the settlements and he asserts that this was not due to "the peaceful and unwarlike Eskimo." In any case this illustrates the difficulty of maintaining an artificial migration in a country where conditions are such that Europeans, who are dependent upon fresh supplies from the home country, can barely live. The climatically induced migration of the Eskimo at least reasserted the superior viability of a people long accustomed to special local conditions.

The question whether central Asia is becoming drier has been discussed for many years. Kropotkin held that there is a gradual desiccation irrespective of periods of greater or less rainfall. Ellsworth Huntington has written repeatedly on this problem and in *The Pulse of Asia* (1907); *Palestine and its Transformation* (1911) and other writings has accumulated evidence to show that the fluctuations in the prosperity of ancient civilizations are ultimately due to climatic conditions. Thus in the Nearer East there was progress and peace, save for dynastic wars, when the rainfall was sufficient, but when it began to diminish the peoples of the poor lands and deserts were set in motion. For example, after 1700 B.C. we hear of invasions from the desert and elsewhere. Kassites invaded Media, Elam and Babylonia, and Egypt was swamped by the Hyksos, who brought their families, flocks and herds, and introduced the horse to Egypt, and we know that famine was the reason for the migration of Hebrews into Egypt. For 200 years after the expulsion of the Hyksos Egypt again prospered. About 1400 B.C. the Aramaeans invaded Syria from the south and the Hittites from the north. The second millennium was a period of depression in the ancient East; from Arabia, Central Asia and Europe new nations immigrated into the lands of ancient civilization. This universality was probably due to widespread adverse economic conditions which were beyond human control. This sort of thing has happened time after time, and analogous incidents have doubtless occurred elsewhere among peoples beyond the ken of history. The theory that the increasing aridity of parts of Central Asia is the direct result of climatic change has been disputed by several authorities (*cf.* A. Stein, *Geog. Journ.* lxv., pp. 485–490, 1925; R. C. F. Schomberg, *G.J.*, lxxii., p. 357, 1928).

Elaborate hypotheses have been promulgated about sunken continents. There is a considerable literature about "Atlantis" and Macmillan Brown adduces evidence satisfactory to himself in favour of a sunken continent or, at all events, of great land areas in the Pacific. Naturally the existence of great land masses in these oceans in human times would have had a considerable effect on migrations if, as is claimed, they belong to human times, but, on the other hand, existing distributions can, on the whole, be satisfactorily explained by present conditions.

We do know, however, that great tracts of land have been alternately submerged and elevated within relatively recent times, for example, men hunted game over what is now the North sea, and coastal areas are constantly liable to fluctuations of level. There is thus ample evidence for compulsory migrations or shiftings of populations due to causes entirely beyond the control of man.

The direction in which all migrations take place is conditioned by geographical factors. We may take it as axiomatic that people will usually seek conditions similar to those to which they have become accustomed. This is, on the whole, true for modern emigrations and colonizations. There is a distinct tendency for people to emigrate to similar latitudes or to countries with a climate which resembles that of the home country. Northern Europeans seem to experience greater difficulty in acclimatization in tropical countries than do south Europeans. The subject is a difficult one as it is complicated by habits of life and by tropical diseases, as well as by the effects of heat and moisture. Northern Europeans by taking suitable precautions can live long and healthy lives in the tropics, but it has yet to be shown that their descendants can live the whole of their lives there and indefinitely continue the race. The only definition of a "white man's country" is one which includes the latter proviso. A transplanted population which has to be continually replenished by fresh immigrants and has to be diminished by the return of the children to the home country cannot be described as a true migration, it is merely an occupation of the country. In primitive times, that is, before the period of the means of efficient overseas transport, migratory movements of a people were perforce usually very slow and thus it was possible for acclimatization to take place to some extent *en route*. But this may not have been always operative, as there seem to be indications that the Amerinds of Guiana, for example, are not yet thoroughly acclimatized to their tropical habitat.

We may take it as a general rule that voluntary migratory movement in early times took place only along lines of least resistance. Definite barriers which could not be crossed, or only to a small degree, were ice and snow, oceans, inland seas, lofty, inhospitable mountain ranges, dense forests, jungle-clad, tropical mountain regions, swamps, very poor steppes and deserts. Under exceptional circumstance or through dire necessity these might be partially negotiated by small bands, but normally they would prove to be definite obstacles to the migration of whole communities. On the other hand, grassy plains and plateaux, savanna or bush veldt, loess lands, etc., afforded highways for migration. On the whole, mountain ranges running east and west do form appreciable barriers, those running from north to south may do so for people wanting to travel east or west, but for those travelling from north to south, or vice versa, they may afford toilsome but practicable bridges along which people accustomed to a temperate climate might cross unhealthy tropical regions, all the time keeping to healthy conditions. It is, however, unwise to suggest actual routes for prehistoric migrations until geographers and others have provided maps which give the orography, climatic conditions and flora; for these determine the lines of least resistance or, at all events, the routes along which difficulties could be readily overcome, and at the same time the maps would supply information concerning routes which would be quite impracticable.

Another type of barrier is found in densely populated areas, the inhabitants of which, if strong enough, would prevent a migration across their territory. The same applies to a country which had a strong military force or contained a warrior population. There are many examples of this. Artificial barriers such as dykes and ramparts or walls may prevent movements for, at all events, some time. As Ujfalvy suggests: "The building of the great wall of China was an event fraught with the greatest consequences, and one may say without exaggeration that it contributed powerfully to the premature downfall of the Roman Empire." (C. de Ujfalvy, *Les Aryens au nord et au sud de l'Hindou-Kouch*, p. 24, 1896.) Barriers are thus relative, and only in rare cases are they insurmountable.

There are certain means of transport which greatly facilitate movements of peoples, such as beasts of burden and boats. The domestication of the few animals that could be utilized for riding and drawing of vehicles is confined to the Old World, though in Peru llamas are used to carry burdens and to a slight extent for riding, and dogs were utilized in North America to drag travaux on the plains and sledges in the arctic regions. The domestication of the reindeer for hauling sledges is confined to the arctic regions of the Old World and possibly this idea arose from the example of draught cattle. Only to a limited extent were these animals aids to movements of peoples. Probably somewhere in central western Asia before 5000 B.C. took place the domestication of camels, cattle, horses and asses. Although invaluable for arid areas the camel has a restricted use, and it is not suitable for and does not thrive in most countries or climates. Cattle can be employed almost everywhere except where there is intense cold

or great scarcity of water. Their rate of progress is slow, but we know that ox carts or wagons were used for human transportation in the Bronze age, and in our own time the trekking of the Boers in South Africa was accomplished in the same manner. A pastoral or semi-pastoral people can only migrate along a country which affords sufficient pasturage and water—mountains, deserts and swamps are practically insuperable for such peoples. A further barrier for migration is found in the tsetse fly, ticks and other insect pests, which afford intermediate hosts of the parasites of various kinds of cattle diseases; these have been especially operative in Africa. The use of the yak and sheep in Tibet as beasts of burden has had no effect on migrations. The horse on account of its speed has rendered possible rapid raids of nomad peoples, which would prepare the way for more leisurely mass movements, since communities moving with their flocks and herds cannot travel faster than the slowest of these. The horse reached Sumeria from the north about the time of Hammurabi and later the conquest of Egypt by the Hyksos was greatly facilitated by their horse-drawn war chariots, for it was not till subsequently that cavalry were employed in warfare. Wherever the horse has been taken it has facilitated human movements, and so, to far less extent, has the ass.

We may well believe that for many thousands of years large stretches of water proved very effective barriers to migration. Rivers might be crossed on floating logs and rafts; later would come dug-outs and such craft as the coracle and allied skin boats of the Old World and the bull-boat of North America, which are practically skin-covered baskets; certainly very early there were floats and incipient boats made of bundles of reeds, etc., and doubtless also bark canoes and skin floats; but none of these would be efficient for long distances on open seas. It seems improbable that the Tasmanians, for example, could have crossed Bass strait as it now is in the floats of bundles of bark that they possessed when first discovered. It was not until canoes were provided with side-planks that seaworthy vessels were available for oversea commerce, warfare and colonization. The invention of outriggers to steady such craft occurred in the Indian ocean, either in the East Indian archipelago or in India, but nowhere else; and it was by this discovery, together with that of lashing two canoes together to form a double canoe, that the migrations of the Polynesians all over the Pacific became possible. Some maintain that the invention of sea-going craft was due to the ancient Egyptians, but there is also a case to be made out for at least an independent invention in the Persian gulf or possibly in India. Peake and Fleure are of opinion that "between 4000 and 3500 B.C. the Sumerians arrived probably by sea, at the head of the Persian gulf, bringing with them for the first time into Mesopotamia herds of dairy cattle, an advanced copper culture, and a habit of decorating objects by means of inlaid slabs of mother-of-pearl and other materials." (*The Corridors of Time,* III., p. 95, 1927.) But there were two earlier civilizations in Mesopotamia.

Not only superior means of transport by land or sea, but possession of more deadly weapons or improved implements for daily needs have given their owners decisive superiority when coming in contact with worse equipped peoples. These advantages have been potent factors in producing changes of population.

It is probable that a migration induced by an attraction is much rarer than one produced by an expulsion. The simplest cases of migration by attraction are those of peoples living on poor steppes or plateaux adjoining cultivated land or rich valleys. Agricultural peoples, as a rule, are averse to and ill-prepared for war and the more prosperous their circumstances the more they are likely to be enervated by their very civilization. They are thus liable at all times to be attacked by neighbouring brigands, who in some cases retire to their barren homes with their booty, but in others remain among the conquered people, and, assimilating with them, in due course become more civilized, and in their turn are subject to invasions from their barbarian kinsmen of the borders. The walled towns of ancient Greece in the centre of valleys opening out to the sea point to a danger from the brigands of the mountains and possibly also from pirates from the sea. The inhabitants of the rich plains of Assam have always been subject to raids and settlements by the hill tribes. The earliest records of the Nearer East show (and this has continued to the present day) that the pastoral peoples have preyed upon the agriculturalists and have frequently colonized considerable areas.

Hunger and loot are not the only impulses towards migration. The restless disposition of the "winners of the West" of North America was not due to an inability to maintain an existence in the eastern States nor to an expectation of speedy riches. A craving for land is only a partial explanation; sentiment and a reaction against even the slightest of social restraints had a good deal to do with it, as it had for the trekking of the Boers. Gold rushes are different, as wealth may thus be speedily gained by rapid exploitation.

Migrations have taken place to gain freedom from social, political or religious bondage, like the exodus of the Hebrew bondmen from Egypt, the voyage of the "Mayflower" or the migration of the Flemings and Huguenots into Britain. Religious enthusiasm may stimulate race expansion and lead to shiftings of populations as seen in the histories of Buddhism, Christianity and Islam. The partnerships of the crescent and the sword, of the cross and the gold of El Dorado, have been based upon a double enthusiasm which has led to migrations.

The movements of peoples which are sufficiently dramatic for the ordinary historian to record are often of less importance than the quiet, steady drift of a population from one area into another, as, for example, the emigration from Europe to America in modern times. Movements may result in a noticeable or even fatal depletion of a country, and the parent country may remain desolate or may be filled up in course of time by an alien people as in the case of eastern Germany and the Slavs in the 4th and 5th centuries A.D.

An excellent example of the migration of cultures is given by Prof. V. Gordon Childe in his paper on "The Danube thoroughfare and the beginnings of civilization in Europe" (*Antiquity,* i. p. 79, 1927), in which he traces the spread of culture along the deposits of loess in the Danubian region. The evidence seems to point to the fact that the majority at least of the people were long established in this region before the little settlements of Aegean fishers became outposts of Troadic commerce and led to the opening up of mines of cinnabar, gold, copper and tin. Childe says: "The discovery and original exploitation of the Bohemian tin deposits and hence the inauguration of a bronze industry in Central Europe was due to explorers coming up the Danube from the south-east. Now the first dated bronze objects found in a definite context in Britain come from the graves of the so-called Beaker Folk, who reached these islands from Central Europe. It therefore seems likely that we owe our first metallurgy in the long run to those explorers from Troy whose tracks we have been following up the Danube. So not only was that river one of the routes by which a so-called 'neolithic' culture reached north-western Europe, it was also a channel in the diffusion of the arts of metallurgy northward and westward from the Ancient East."

In his *Dawn of European Civilization* (1925) Prof. Childe traces in detail the growth and spread of culture up to the Middle Bronze age. His view is that the cultures of the collectors and hunters and fishers of epipalaeolithic times do not in any real sense constitute points of transition from the palaeolithic to the neolithic culture, but that the latter gradually spread westwards. "Peasants with stone hoes and axes opened up its valleys to cultivation; hunters and herdsmen blazed the trail through its primaeval forests; mariners in dug-out canoes sailed the seas to the isles of the West; prospectors with picks of horn and flint revealed the treasures of the earth and crossed mountain passes in search of merchandise. These explorers were the forerunners of Greeks and Phoenicians; the paths they discovered have been followed by Roman roads and modern railways" (p. 14). He regards the Occident as "indebted to the Orient for the rudiments of the arts and crafts that initiated man's emancipation from bondage to his environment and for the foundation of those spiritual ties that co-ordinate human endeavours. But the peoples of the West were not slavish imitators; they adapted the gifts of the East and united the contributions made by Africa and Asia

into a new and organic whole capable of developing on its own original lines" (p. 13).

Owing to the great amount of careful archaeological investigation in Europe the cultural history of that region is becoming increasingly clear, but when data are available it will probably be found that the same general principles have obtained elsewhere. New techniques, ideas, and ideals are continually spreading, sometimes slowly, sometimes with considerable rapidity, but the recipients by no means adopt them wholesale, they accept what appeals to them and usually in so doing they modify them to their own particular needs or idiosyncrasies. We may regard this as being true for all times and all places.

With regard to customs and religious ideas and ceremonies there is probably always some personal influence, though the results may be disproportionate to the numbers of the culture-bearers; in these instances the racial drift may be inappreciable, or may not affect the physical characters of the local population in the least, while the cultural drift may be very conspicuous. A good illustration of this last is seen in the spread of European culture and religion by Christian missionaries, but it is by no means confined to these. The gradual spread of cults and customs has been proved by careful investigations among many peoples and it can be traced in action as well as by inference. Wirz has shown that in the last 50 years a secret cult has been adopted from communities on the coast, by three villages on Lake Sentani (in north New Guinea). These three villages have since drawn together and look down upon the neighbouring villages which have not adopted the cult. (*Tijds. v. Ind. Taal-Land-en Volkenkunde*, lxiii., p. 53, 1923.) There is a tradition that the teaching of ceremonies, including the elaborate death ceremonial, was introduced into the western islands of Torres straits by two culture heroes from New Guinea and there are other folk-tales of migratory culture-heroes instructing the people in better ways of living. The great religious cult of Murray Island was brought by what can only be described as the missionary zeal of the western islanders, and most of the funeral ceremonies and many sacred songs admittedly came from the west. (*Rep. Camb. Anth. Exped. to Torres Straits*, v. 1905; vi., 1908.) An interesting parallel occurred also in Fiji. Two culture heroes are reported to have distinctly stated that they went to Fiji to teach the cult associated with large stone enclosures, *Nanga* (A. B. Joske, *Internat. Arch. f. Ethnogr.* ii., p. 258, 1889). In all these instances there is not the slightest trace in tradition or elsewhere of secular aggression. A. B. Deacon has traced the spread of the Kakihan Society from Ceram to New Guinea and Melanesia (*Folklore*, xxxvi., p. 332, 1925).

Since 1911 G. Elliot Smith has affirmed the diffusion of culture from Egypt to every part of the world; his views are stated in his *The Migrations of Early Culture* (1915) and he gives an account of the development of "the new teaching" in the second edition of *The Ancient Egyptians* (1923), where he stated "There can no longer be any doubt that the essential elements of civilization did really originate in Egypt." He gives a number of arts, practices, and beliefs which he affirms were carried by Egyptian seamen to various countries. These became centres of secondary diffusion, and ultimately this culture-complex reached America across the Pacific. In *The Evolution of the Dragon* (1919) he suggests that these culture-bearers were seeking for "givers of life," which W. J. Perry is "convinced" is "one of the most important generalizations ever made in the study of human society" (*The Children of the Sun*, 1923). In this book and in several others (*The Megalithic Culture of Indonesia*, 1918; *The Growth of Civilization*, 1924, etc.), Perry has elaborated the details of the spread of this so-called "Archaic Civilization." For criticisms of this theory and the methods of its promulgators *cf.* J. L. Myres, *Folk-lore*, xxxvi., p. 15, 1925; *The Geographical Teacher*, xiii., pp. 8, 152, 155 (1925); H. St. L. B. Moss, *The Quarterly Rev.*, No. 494, and more recently Roland B. Dixon, *The Building of Cultures* (1928), in which he gives a careful discussion of the diffusions of cultures and a criticism of various theories of diffusion.

The evidence for the migrations of unlettered peoples is to be sought mainly in the physical characters of peoples, their artifacts, customs, folk-tales and language. Each of these sources of information has to be utilized with great caution as there are many dangers of erroneous interpretations of actual facts. As a rule every tribe or isolated community has definitely characteristic artifacts, but if these are found to be subject to modification it has to be determined whether there has been a local evolution or whether, as is most probable, influences have come in from elsewhere, in which case the change may be due to a "racial drift" or to the imitation of objects obtained by trade or loot, that is, a cultural drift. The introduction and methods of utilization of domestic animals and plants is analogous to the foregoing. For instance, the introduction of the horse into America was due to a racial drift, but its employment by the Plains Indians and the Amerinds of the pampas of South America was a culture drift. A good example of a simple culture drift is the spread of the use of tobacco over Africa and New Guinea. Finally, language is a criterion for racial contact, but not necessarily for a migration on a large scale.

For a general account of the main racial migrations the reader is referred to A. C. Haddon, *The Wanderings of Peoples* (1911); Grafton E. Smith, *The Migrations of the Early Culture*, London and New York, 1915; *Brief List of References on Racial Migration*, Library of Congress, Select List No. 708, Wash. 1922; *The Races of Man and their Distribution* (1924). (A. C. H.)

MODERN HISTORY

A new epoch in migration and in world history commenced with the great geographical discoveries, which opened up to Europe vast continents containing unlimited natural resources. The early movements from Europe were prompted by the spirit of adventure and the search for gold. Trading centres were next established and population began to flow from the Old World to the New Portugal and Spain established settlements in South America in the 16th century, and by 1570 it is estimated that there were 100,000 white men in the overseas empire of Spain. The first English settlements overseas date from the early 17th century. French migration to Canada also began in the 17th century. In 1664 the population of French Canada was 2,500, and by 1760, the date of the British conquest, this had reached to 70,000.

EMIGRATION TO THE UNITED STATES

The population of the United States in 1790 was 4 millions. In 1926 it was estimated at 105,000,000 (excluding the coloured population). The immigration from Europe into America during the past century, which has been mainly responsible for this growth, has been, both in its volume and its variety, the most remarkable peaceful mass movement of population in history.

The number of immigrants who entered America previous to the year 1820 is not accurately known, but it is supposed to have averaged from 5,000 to 6,000 a year and the total number of immigrants from the time of the foundation of the National Government down to 1820 was probably not more than 250,000. The total number of immigrants from 1820 to 1927 was 37,000,000, of whom 32,000,000 came direct from Europe.

In 1820 the number of arrivals was 8,385 and by 1830 it had reached over 20,000. During the decade 1830–40 some 60,000 immigrants annually were admitted, while from 1840–46 the average number was about 90,000. Down to 1846, the first 70 years in America's national life, the total number of immigrants was less than 1,600,000, whereas in that period the population of the United States grew from 3,000,000 to 21,000,000.

In 1847 the great tide of immigration began with an enormous influx from Ireland, following upon the potato famine, and two years later political troubles led to heavy immigration from Germany. From 1847 to 1854 immigration ranged between 250,000 and 400,000 per annum.

During the ten years 1847–56 approximately 3,000,000 immigrants entered America—twice the total number that had arrived during the previous seventy years. Immigration slackened during the Civil War period, but increased again thereafter, until by the year 1890 the total number of immigrants admitted to the United States had reached a figure of over 15,500,000.

The financial crisis of 1893 temporarily checked immigration, but the upward trend was resumed, and during the twenty-four years 1891–1914 the total number of immigrants was 16,500,000. In each of the six years 1905–07, 1910 and 1913–14 the number exceeded a million. The greatest number of immigrants arriving in any one year was 1,285,000 in 1907.

These figures include numbers of people who did not remain permanently in the United States, but the following table shows the population of the United States at each census, the decennial increase, and the average net immigration (*i.e.*, excess of arrivals over departures) during the period 1790–1925:—

United States Population at Each Census, Decennial Increase, and Net Immigration: 1790–1925

Census year	Population		Net immigration in the decade
	Total	Decennial increase	
	Millions	Millions	Millions
1790	3·9	..	..
1800	5·3	1·4	..
1810	7·2	1·9	..
1820	9·6	2·4	..
1830	12·9	3·3	0·1
1840	17·1	4·2	0·6
1850	23·2	6·1	1·6
1860	31·4	8·2	2·7
1870	38·5	7·1	2·4
1880	50·2	11·7	2·5
1890	62·9	12·7	4·3
1900	76·0	13·1	3·2
1910	92·0	16·0	5·6
1920	105·7	13·7	3·1
1925	115·4	9·7	2·0

The total immigration into the United States and the immigration from Europe during the period 1820–1927 by decades was as follows:—

	Total	Europe
1821–30	151,824	106,508
1831–40	599,125	495,688
1841–50	1,713,251	1,597,501
1851–60	2,598,214	2,452,660
1861–70	2,314,824	2,065,270
1871–80	2,812,191	2,272,262
1881–90	5,246,613	4,737,046
1891–1900	3,687,564	3,558,978
1901–10	8,795,386	8,136,016
1911–20	5,735,811	4,376,564
1921–27	3,278,576	2,013,304
Total 108 years 1820–1927	36,933,379	31,811,797

The proportion of the total immigrants from various countries of Europe during specified decades is shown in the following table:—

Country	(Percentages of total)			
	1861–70	1881–90	1891–1900	1901–10
Austria Hungary	·33	6·7	16·0	24·4
Italy	·51	5·9	17·7	23·3
Russia	·10	4·0	13·9	18·0
British Isles	44·90	28·0	17·9	9·8
Germany	34·00	27·8	14·0	3·9
Denmark, Norway and Sweden	5·40	12·5	10·0	5·7

A very important change took place during the period from 1880 to 1910 in the racial composition of the immigrants. Up to 1880 the peoples of northern and western Europe had predominated, but after 1880 the bulk of the immigrants came from southern and eastern Europe. In each of the two decades 1871–80 and 1901–10 the total immigrants from western Europe numbered approximately 2,000,000, whereas the total from southern and eastern Europe increased from 200,000 in the first of these two periods to over 6,000,000 (70·8% of the total) in the second. In the five years 1911–15 out of a total immigration from Europe of 3,796,000, the number from southern and eastern Europe was over 3,000,000 or 79% of the total.

Up to 1917 this enormous volume of immigration was admitted without restrictions upon the white races other than (a) the exclusion under the Immigration Act of 1882 and subsequent legislation of certain undesirable classes, *e.g.*, criminals, paupers and physical and mental defectives, etc. (b) those imposed by the Alien Contract Labour Law of 1885 forbidding the entry of any person under a contract made previously 'to perform labour or service of any kind in the United States.'

The proportion of arrivals excluded under the provisions of the various Immigration Laws was negligible, the total number debarred in 1913 being 20,000 or 1·4% of the total applicants for admission.

The problem of the assimilation of the various elements included in this vast volume of immigration was giving rise to some anxiety before the World War. A policy of restriction was advocated as far back as 1880. American labour organizations had long been in favour of some form of restriction, and a commission appointed by President Roosevelt in 1910 reported that immigration restriction "was demanded by economic, moral and social considerations" and suggested a restriction law on a percentage basis. Experience during the World War raised the issue in an acute form, and a clause was inserted in the Consolidating Immigration Act of 1917 prohibiting the entry of illiterates over 16 years of age. This proved ineffectual in producing the desired effect. It was anticipated that the close of the World War would be followed by an influx from Europe which would equal, and perhaps exceed, anything which had hitherto been experienced. That this fear was not without foundation was shown by the fact that 430,000 immigrants entered the United States in 1920 and over 800,000 in 1921.

The United States Immigration Act, 1921.—In order to meet this situation emergency legislation was passed and came into operation on June 2, 1921, which limited "the number of aliens of any nationality who may be admitted under the immigration laws to the United States in any fiscal year . . . to 3 per centum of the number of foreign-born persons of such nationality resident in the United States as determined by the United States census of 1910."

This fixed the total annual immigration at 357,803 and that from Europe at 353,747, approximately one-third of the number of European immigrants during the years 1913 and 1914. The proportion or quota for Great Britain and Ireland under this law was 77,342, for Germany 68,059, for Italy 42,057, for Poland 25,827, for Russia 34,284 and for Sweden 20,042. Certain categories of persons were excluded from the quota arrangements.

This Act not only limited the aggregate numbers of immigrants. It was also selective in character, in that its effect was to reduce the proportion of immigrants from southern and eastern Europe to less than one-half of the total, viz., 198,000 from northern and western Europe and 158,000 from southern and eastern Europe.

The object of the law was, however, partially defeated by increased immigration from Canada and Mexico, which were not included within the scope of the quota provisions, and from which aliens could enter provided they had been resident in a country on the American continent for one year (subsequently amended to five years). In consequence of the increase in immigration from Canada and Mexico the total immigration during the three years 1922–4 during which the law was in operation was actually on the up-grade, as will be seen from the following figures:—

Immigration Into the United States, 1920–4

Fiscal year	Oversea	Continental	Total
1920	287,615	142,386	430,001
1921	702,153	103,075	805,228
1922	243,195	66,361	309,556
1923	343,140	180,779	522,919
1924	416,870	290,026	706,896
Total	1,992,973	782,627	2,774,600

Clandestine immigration by land and sea added to these totals.

The Act of 1921 was only a temporary measure in order to allow time for framing a more permanent policy of restriction. This was embodied in the Immigration Act of 1924 (the "Johnson Act").
